ammonium thiosulfate are used for removing AgBr (fixing) in photography, although the ammonium salt has the advantage of shorter fixing and washing times. Silver thiosulfates may be used as flower preservatives and to inhibit ripening of fruit (it is believed that the thiosulfate disrupts the ethylene action that causes the onset of ripening). Sodium thiosulfate is also used to destroy excess chlorine in the bleaching industry, where it behaves as a moderate reducing agent (equation 30). The structure of the $[SeSO_3]^{2-}$ anion was recently determined with a central sulfur atom bound to the three oxygens and a selenium with a S-Se distance of 217 pm[61] Gold and silver thiosulfates are well-established materials for the treatment of arthritis, although the mechanism of action is not well understood.[62]

$$S_2O_3^{2-} + 4Cl_2 + 5H_2O \longrightarrow 2HSO_4^- + 8H^+ + 8Cl^- \quad (30)$$

3.6.4 Other Oxoacids

There are a range of S–O acids that contain S–S bonds, reflecting in part the variety of oxidation states available to sulfur.

Dithionic acid, $H_2S_2O_6$, can be obtained in quite concentrated aqueous solutions (equation 31) from barium dithionate. The metal dithionates are usually obtained by oxidizing the corresponding sulfite or metathesis.

$$BaS_2O_6 + H_2SO_4 \longrightarrow H_2S_2O_6 + BaSO_4 \quad (31)$$

Sodium dithionite, $Na_2S_2O_4$, is well known and used as a reducing agent. Like dithionate, it may be obtained from the sulfite, although commercially dithionites are usually prepared from SO_2 (equations 32 and 33). Dithionous acid is unknown.

$$Zn + 2SO_2 \longrightarrow ZnS_2O_4 \quad (32)$$

$$HCOONa + 2SO_2 + NaOH \longrightarrow Na_2S_2O_4 + CO_2 + H_2O \quad (33)$$

Although the dithionate anion usually adopts a staggered conformation, the dithionite anion has an eclipsed structure; they have quite different S–S bond lengths (215 vs. 239 pm).

Dithionite solutions display EPR signals, suggesting the presence of a monomer (radical) $\rightleftharpoons$ dimer equilibrium in solution. Dithionites are strong reducing agents and find applications in dyeing/printing, and in the precipitation of metals. In addition, sodium dithionite is used in the preparation of $HOCH_2SO_2Na$ (sodium hydroxymethanesulfinate), which is also used on a large scale in printing.

Apart from the well-known S–O anions mentioned above, there is a developing chemistry of the salts of the so-called polythionic acids, $H_2S_nO_6$. Some structures and synthetic routes to these species are shown in Figure 29 and 30. This is a complex, but fascinating, area that illustrates the difficulty of characterizing main group species. The original observations of the reactivity of SO_2 solutions with H_2S were made by Dalton, and systematically studied by Wackenroder in the 1840s, but it is only in relatively recent times that the structures of the various species have been elucidated. Further work is also now elucidating the synthetic routes and structures of complex mixed S/Se oxyanions such as $[Se(S_2O_3)_2]^{2-}$.[63]

There has recently been a report on the synthesis of the $[S_3O]^{2-}$ anion, obtained in the complex $[Pt(PPh3)_2(S_3O)]$ as a bidentate *S*,*S* complex – this complex may be important in the catalytic transformation of H_2S to sulfur.[64]

$$MnO_2 + 2SO_2 \longrightarrow MnS_2O_6$$
$$2KHSO_3 + SCl_2 \longrightarrow K_2S_3O_6 + 2HCl$$
$$2H_2SO_3 + S_2Cl_2 \longrightarrow H_2S_4O_6 + 2HCl$$
$$2S_2O_3^{2-} + I_2 \longrightarrow S_4O_6^{2-} + 2I^-$$
$$2H_2S_2O_3 + SCl_2 \longrightarrow H_2S_5O_6 + 2HCl$$
$$2H_2S_2O_3 + S_2Cl_2 \longrightarrow H_2S_6O_6 + 2HCl$$

Figure 29 Preparative routes to polythionic acids

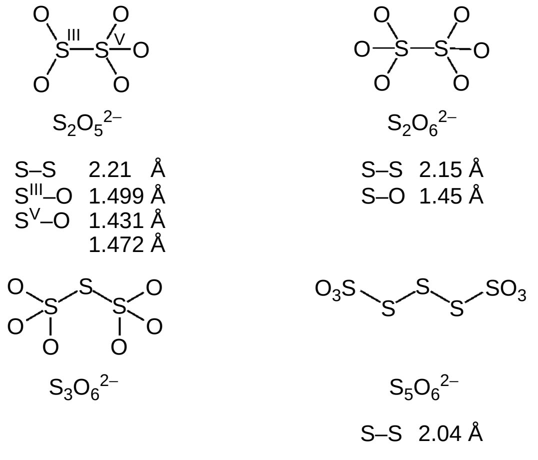

Figure 30 Structures of polythionic acids

4 SULFANES

4.1 Historical

The existence of the sulfanes has been recognized since the eighteenth century, both H_2S and 'persulfide of hydrogen' being studied; by the mid-nineteenth century, Thenard had shown that crude polysulfane solution was a mixture of variable composition.[65] In the early 1900s, significant progress was made with the separation, by vacuum distillation, of H_2S_2 and H_2S_3. Since 1940, very substantial progress has been made by Feher and coworkers, who have developed systematic preparative routes to a range of sulfanes and thoroughly characterized the compounds by a variety of physical techniques, including Raman spectroscopy. Notwithstanding these achievements, the polysulfanes remain a difficult group of compounds to prepare and separate pure and currently there is more work on polysulfides and metal complexes containing S_x^{2-} ligands than on the free acids.

4.2 Preparation

H_2S occurs in Nature, in small concentrations as a result of reduction of sulfate or sulfur-containing proteins by microorganisms. It is most prevalent in crude oil and natural gas, where the H_2S content can be as high as 10%.

Hydrogen sulfide is usually prepared by the acid hydrolysis of sulfides (e.g. using iron(II) sulfide and hydrochloric acid in the Kipps apparatus),[65] although industrially it is prepared by the reaction of hydrogen with molten sulfur at 350 °C in the presence of a catalyst. The higher sulfanes are not thermodynamically stable and are obtained by one of four routes.

Aqueous polysulfide solutions give, upon acidification, a crude oil that, from Raman spectroscopy,[66] contains a range of polysulfanes (H_2S_x, $x = 2$–6); $x = 2$ and 3 species are obtained from this oil by careful distillation/cracking of the mixture.[67] The products can then be purified further by fractional distillation.

Closely related to the above method is the formation of $x = 2$–5 species by the acidification of K_2S_x with formic acid under anhydrous conditions.[68] This nonaqueous method has the advantage of avoiding some of the side reactions associated with the aqueous route.

Crude polysulfanes with $x = 7$–12 can be obtained in up to 50% yield at the cathode by reduction of SO_2/H_2SO_4 solutions. The initial reaction product at the cathode is dithionous acid $H_2S_2O_4$, which decomposes in strong acid to give sulfurous acid and sulfane. Persulfate is obtained at the anode.

For sulfanes with $x > 6$, vacuum distillation is not practical and systematic condensation reactions at −50 °C developed by Feher and coworkers are used.[69] The most general form of the reaction is equation (34).

$$aH_2S_n + bS_mX_2 \longrightarrow (a - b)H_2S_x + 2bHX \quad (34)$$

(where $x = (na + mb)/|(a - b)|$; $n = 1, 2, 3 \ldots$; $m = 0, 1, 2, 3 \ldots$; X = Cl, Br). When $a > b$ the reaction is used for the preparation of sulfanes, but when $b > a$ halosulfanes may be prepared, while if $a = b$, sulfur is formed. In a typical reaction, chain lengthening to give higher sulfanes can occur with a sequence illustrated in equation (35).

$$\begin{aligned} 2H_2S_2 + S_2Cl_2 &\longrightarrow H_2S_6 + 2HCl \\ 2H_2S_6 + S_2Cl_2 &\longrightarrow H_2S_{14} + 2HCl \end{aligned} \tag{35}$$

Assuming that the rates of reaction are comparable, it is possible to predict quite easily the relative proportions of different chain length sulfanes that will be obtained for any particular a/b ratio; and thus it is possible to prepare individual compounds in quite high purity.

4.3 Physical Properties and Molecular Structures

The physical properties of the polysulfanes are well defined (Table 11). Measurements of viscosity, molar volume, and density are convincing proof that the polysulfanes are a genuine homologous series. The molar volumes and densities increase in a simple additive way. The viscosities have been correlated with the square of the molecular weight, increasing with increasing molecular weight, although they do show a greater than predicted increase in mixtures of different chain lengths.

H_2S is bent in the gas, liquid, and solid state with H–S–H being 90° in the gas phase and 92.2° in the liquid phase; and H–S is 135 pm. The electronic spectra of sulfanes indicate some delocalization of electron density, probably by use of 3d orbitals; as chain length increases, the compounds exhibit deeper colors. In common with the homocyclic sulfur rings discussed in Section 2, Raman spectroscopy has proved to be extremely useful in the study of polysulfanes. Spectra have been reported for $x = 2-8$, and they are quite characteristic of chain length. The spectrum of H_2S_2 suggests that this compound has a structure similar to that of H_2O_2. The higher sulfanes exhibit hindered rotation about S–S bonds, and this leads to complex structures. Insight into the structures of polysulfanes can be gained by examination of the structures of the polysulfide anions.

Table 11 Physical properties of the sulfanes[a]

Sulfane	d^{20}	V	η^{20}	R
H_2S_2	1.344	49.6	1.631	17.7
H_2S_3	1.491	65.9	1.729	26.2
H_2S_4	1.582	82.3	1.791	34.9
H_2S_5	1.644	98.7	1.836	43.6
H_2S_6	1.688	115.2	1.867	52.2
H_2S_7	1.721	131.6	1.893	60.9
H_2S_8	1.747	148.0	1.912	69.5

[a] d^{20} = density (20 °C); V = molar volume; η = refractive index; R = molar refraction.

4.4 Reactions

Hydrogen sulfide is a weak acid ($pK_a = 6.88$), whereas the other sulfanes are considerably stronger, with pK_a decreasing as the chain length increases (for $x = 2$, 3, 4, 5 the first acid dissociation constants are 5.0, 4.2, 3.8 and 3.2, respectively). In neutral aqueous solution, the sulfanes decompose with formation of sulfur and H_2S, while they are stable under anhydrous conditions, in acid or in alkali (as the corresponding polysulfide anion). Reactions of H_2S are summarized in Figure 30. Commercially, the most important reactions are the formation of NaSH, Na_2S, and of organic sulfur compounds. HDS is used in the preparation of heavy water (equation 36).

$$HDS(g) + H_2O(l) \rightleftharpoons H_2S(g) + HDO(l) \tag{36}$$

In general, the sulfanes have a less well-developed chemistry, partly because of the difficulty in isolating them pure, although they have been used for the synthesis of some organosulfur compounds (*see* ***Sulfur: Organic Polysulfanes***).

4.5 Polysulfides

4.5.1 *Free Anions*

Simple sulfides are discussed elsewhere. However, the chemistry of polysulfides relates to that of the sulfanes, and some discussion is provided here.

In principle, deprotonation of any of the sulfanes gives polysulfide anions S_x^{2-}. In practice, this route is not employed and rather fewer anions are known compared with the sulfanes. It was established last century that sulfur dissolves in basic media to give intensely colored (often blue) solutions.[70] The well-known polysulfide solution $[NH_4]_2S_x$, which contains mostly $x = 4$ and 5, is obtained by bubbling H_2S through a suspension of sulfur in ammonium hydroxide. It is accepted nowadays that the blue coloration of many of these solutions is a consequence of the $S_3^{-\bullet}$ radical. This species has characteristic EPR, visible, and Raman spectra that have enabled its detection in a variety of solutions including liquid ammonia,[71] DMF, and HMPA. $S_2^{2-\bullet}$ can be introduced as an impurity into alkali metal halides. In lapis lazuli (lazurite that is made synthetically as ultramarine blue: $Na_8[A1_6Si_6O_{24}]S_n$, $n = 2-4$), the blue color is due to the presence of $S_3^{-\bullet}$ radicals, which has also been identified by *Resonance Raman Spectroscopy*.[72]

There is a range of polysulfide dianions S_x^{2-} that can be obtained by reaction of sulfur with simple sulfides, by high-temperature reaction of an alkali metal with sulfur, or by reaction of alkali metals with sulfur in liquid ammonia. Often, once formed, the anions are in equilibrium in solution, but individual anions can be complexed successfully. Structures of the free polysulfide anions are shown in Figure 31.

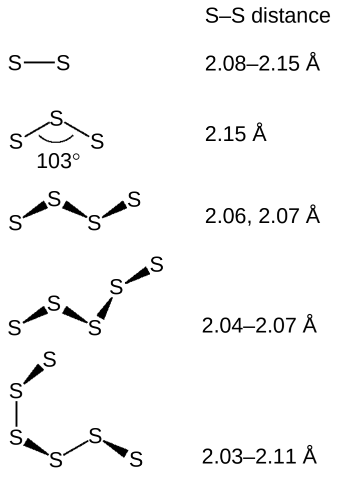

Figure 31 Structures of S_x^{2-} anions

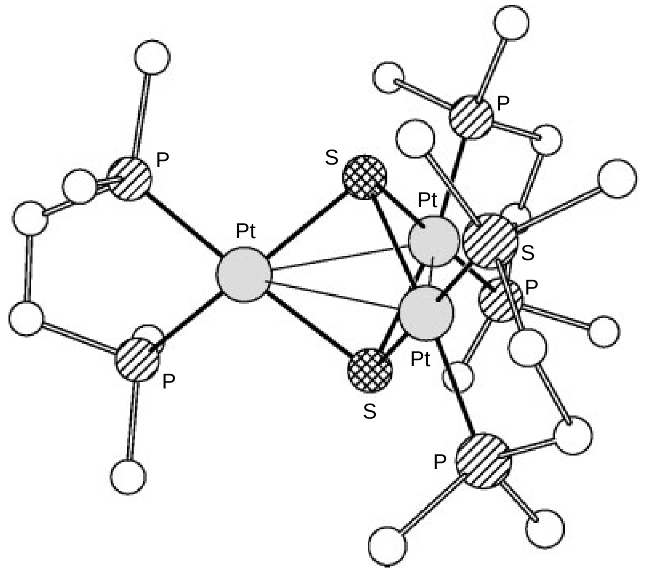

Figure 32 The X-ray crystal structure[78] of $[Pt_3(dppe)_3S_2]^{2+}$

4.5.2 *Metal Polysulfides*

This area continues to provide many new compounds and structures, reflecting the versatility and thermodynamic stability of polysulfide anions. Most of the compounds are described under the appropriate metal elsewhere in the Encyclopedia, some of the most elegant recent developments have been with other p-block elements such as tellurium, bismuth, and antimony.[73]

Preparation and Structure. Many minerals exist as sulfides, and these have been outlined in Section 2.1.1. The alkali and alkali earth metals form simple ionic sulfides that are water soluble. Many sulfides, polysulfides, and their complexes are known and there have been a number of reviews illustrating their structures,[73] catalytic uses,[74] and biological significance.[75] Excellent reviews illustrate the complexity of this area for the chemistry of Cr, Mo, and W sulfides.[76] Many of the sulfides exist in different phases depending upon the conditions used in their synthesis and they may be interconverted by annealing, etc. MoS_2 is used as a high-temperature lubricant.

The coordination chemistry of S_x^{2-} is very diverse.[73,74] The monosulfide dianion has important coordination chemistry in biological systems (e.g. *see* ***Iron–Sulfur Proteins***). There has recently been a report of the crystal structure of the $[Pt_3(dppe)_3S_2]^{2+}$ dication, which contains two face capping S^{2-} anions (Figure 32).[77] The disulfide anion S_2^{2-} can coordinate edge-on (*see Side-on Coordination*), or bridge two or more central metal atoms The most common are illustrated in Figure 33. *End-On Coordination* of S_2^{2-} is not well established although, there has been a recent example with Cu(I)[78] As can be seen, a wide range of coordination types is known. An interesting example illustrating the types of structural motifs that are possible is the reaction of $[Mo_2S_{12}]^{2-}$ with PhS^-, which gives $[Mo_2S_{10}]^{2-}$ (equation 37). The

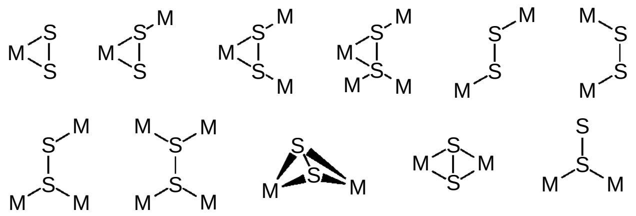

Figure 33 Coordination modes of S_2^{2-}

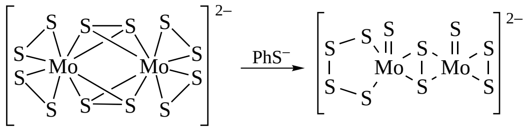
starting dianion actually exists in two isomeric forms ($[Mo_2(S_2)_4(\mu\text{-}S_2)_2]^{2-}$ and $[(MoS)_2(S_4)_2(\mu\text{-}S_2)]^{2-}$); the latter form is desulfurated to give a species containing bridging and nonbridging coordination of the S_2^{2-} ligand.[79]



(37)

Dibenzyl trisulfide provides[80] a useful source of sulfur for the preparation of sulfide anions via oxidative replacement of RS^- ligands (equation 38). $[Fe_2(\mu\text{-}S_2)(S_5)_2]^{2-}$ contains two FeS_5 rings bridged by two S^{2-} anions.

$$[Fe(SPh)_4]^{2-} + xs\ Bz_2S_3 \longrightarrow [Fe_2(\mu\text{-}S)_2(S_5)_2]^{2-} \qquad (38)$$

Another, quite general route[81] is to prepare a sulfide in situ by reduction of sulfur using superhydride (equation 39).

$$2LiBHEt_3 + \frac{5}{8}S_8 \longrightarrow Li_2S_2 + H_2 + 2BEt_3$$

$$Cp_2TiCl_2 + Li_2S_2 \longrightarrow Cp_2TiS_5 + 2LiCl \qquad (39)$$

Interestingly, although the TiS_5 ring is quite stable for Cp_2TiS_5, there are significant steric effects upon substituting the Cp rings. Thus for C_5Me_5, monomeric $(C_5Me_5)_2TiS_3$ is known,[82] but for C_5H_4Me the dimeric $[(C_5H_4Me)_2TiS_3]_2$, containing bridging $S_3{}^{2-}$ ligands, is observed.[83]

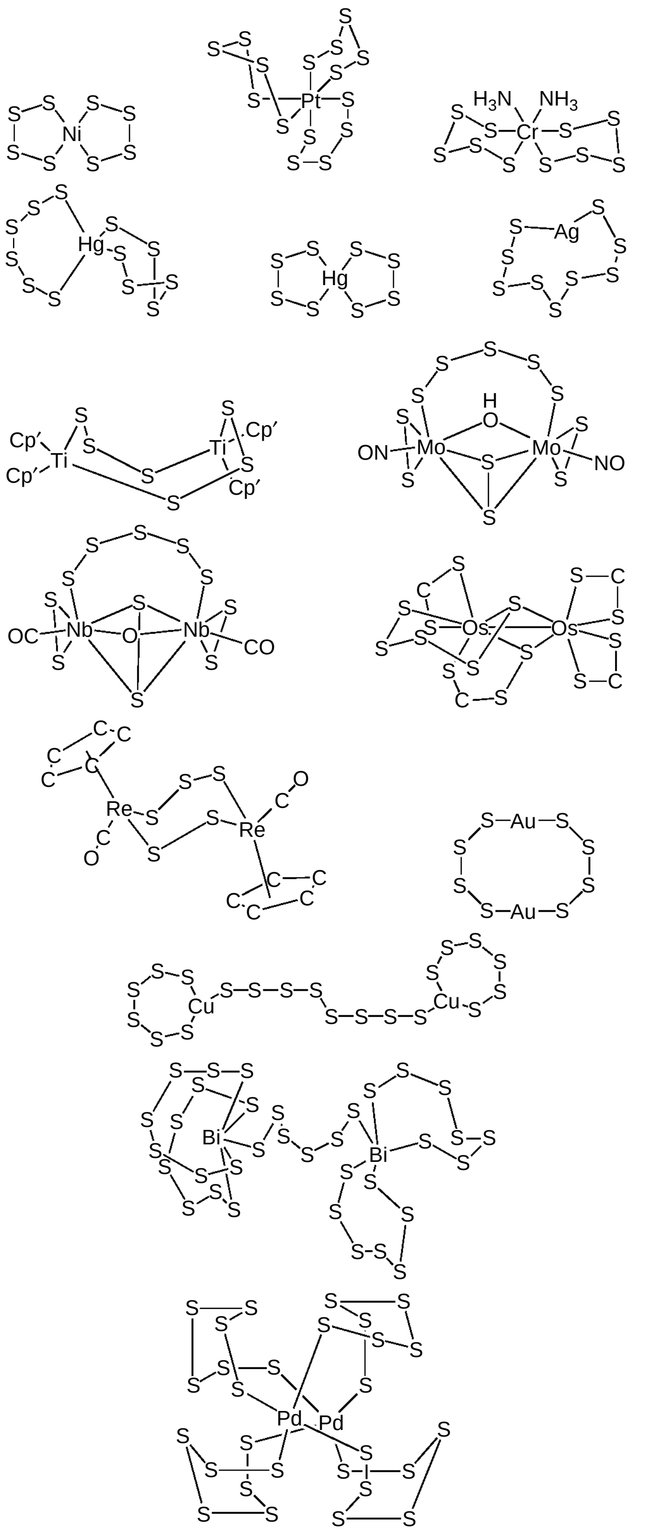


Figure 34 Examples of metal–polysulfide coordination modes

Larger $S_x{}^{2-}$ ligands are known (Figure 34); the commonest sulfido complexes consist of MS_4 and MS_5 units, which probably reflects the stability of the anions in solution and even more so as coordinated ligands in MS_4 and MS_5 rings, although $S_4{}^{2-}$ can also behave as a bridging ligand. Larger MS_x rings have been characterized (e.g. $AuS_9{}^-$), as have larger anions. Perhaps the most well-known polysulfide complex is Cp_2TiS_5, which has already been mentioned above; some of its reactions are illustrated in Figure 5.

Oxidative Addition reactions may also be employed. For example, reaction of $M(PPh_3)_4$ with sulfur (M = Pd, Pt) gives $M(PPh_3)_2S_4$.[84] Sulfur may be reacted without oxidation of the metal centre, for example with Cp_2TiMe_2 or $Cp_2Ti(SH)_2$ to give Cp_2TiS_5,[85] or with oxosulfur or sulfur anions such as $MoOS_3{}^{2-}$, $WS_4{}^{2-}$, and so on.[86] The majority of the homoleptic complexes have been obtained from reactions of $S_x{}^{2-}$ solutions (water, ethanol, MeCN, or DMF) and some examples are included in Figure 35.

One interesting recent report illustrates the subtlety of this area.[87,88] Na_2E_4 (prepared by stirring the appropriate quantities of sodium and elemental S/Se/Te together in liquid ammonia) was stirred together with $M(CO)_6$ (M = Mo, W) in DMF. The contrasting reactivity of S and Se versus Te is immediately apparent from equations (40) and (41).

$$M(CO)_6 + S_4{}^{2-} \longrightarrow MS_4{}^{2-} \qquad (40)$$

$$M(CO)_6 + Te_4{}^{2-} \longrightarrow [(CO)_4MTe_4]^{2-} \qquad (41)$$

Molten salt routes have been employed[89,90] for the synthesis of a range of materials, with particular emphasis being directed towards obtaining systems with 'extended' structures. These reactions can be performed at surprisingly low temperatures (for example, M_2S_4 (M = Na, K) have melting points of ca. 160 °C), although most of the media have quite a wide liquid range (up to 600 °C), which offers the scope for great flexibility in the reaction conditions. Typically, a reaction medium (and reactant) is obtained by adding sulfur to a metal sulfide M_2S; another metal, metal sulfide, or halide is then added and the whole is ground together, sealed in a suitable vessel (usually made of quartz), heated to the desired temperature (for several hours or even days), and

$$2FeCl_2 + 12S + 6Na \xrightarrow{\text{DMF}} Na_2[Fe_2S_{12}] + 4NaCl$$

$$Cp_2MoCl_2 + Na_2S_2 \longrightarrow Cp_2Mo(S_2) + 2NaCl$$

$$MoO_4{}^{2-} + S_n{}^{2-} \longrightarrow [Mo_3S(S_2)_6]^{2-} + [Mo_2(S_2)_6]^{2-}$$

$$[NH_4]_2S_x + Cp_2TiCl_2 \longrightarrow Cp_2TiS_5$$

$$[NH_4]_2S_x + K_2PtCl_6 \longrightarrow [NH_4]_2[Pt(S_5)_3]$$

Figure 35 Preparation of metal polysulfide complexes from polysulfide solutions

slowly cooled. The products are usually obtained by removing unwanted, soluble M_2S_x. For example, transparent orange crystals of K_4TaS_{11} were obtained by reaction of K_2S, Ta, and S (3:2:5 ratio) at 800 °C.[89] Reaction of copper in molten K_2S_x (1:3 ratio) depends on the temperature employed. At high temperatures (350 °C), CuS is obtained; at 215 °C, α-K[Cu_4S_3] is the product; while at 250 °C, β-K[Cu_4S_3] is formed.[90] The molten salt route has been applied particularly to the formation of low-dimensional polychalcogenides rather than 'molecular' species. Especially interesting are the layer compounds (e.g. $[CuS_4]_n{}^{n-}$) that are emerging.

The structural chemistry associated with polysulfide molecules and materials reflects the stereochemical freedom of the sulfur atom; as mentioned above, disulfide ligands can coordinate in a number of ways. Similarly, larger rings may adopt a variety of geometries (from X-ray studies) and the evidence that is available suggests that many of the rings are fluxional in solution. Muller has classified and discussed some aspects of this problem for molecular species, but the rationalization of the structures adopted in solid-state materials is not yet complete.[73]

Reactions of Sulfido Complexes. Some reactions of polysulfide complexes have been studied. For example, $[Pt(S_5)_3]^{2-}$ reacts with CN^- with reduction[91] and loss of one ligand to give $[Pt(S_5)_2]^{2-}$, and with PPh_3 to give[92] $SPPh_3$ and $Pt(PPh_3)_2S_4$. We have already mentioned the oxidation of S_2 ligands for the formation of S_2O and S_2O_2 complexes, and illustrated the reactions of Cp_2TiS_5. Other important reactions include thermal decompositions (a) of $Cs_2[Mo_2(S_2)_6]\cdot nH_2O$ with elimination of S_2, which was identified by matrix-isolation spectroscopy,[93] and (b) of $[NH_4]_2[Mo_3S(S_2)_6]\cdot nH_2O$, which gives MoS_2 as the final product.[94] The reactions of polysulfide complexes with activated acetylenes (e.g. dimethyl acetylenedicarboxylate) proceed with insertion. Thus $(MeCp_2Ti)_2(S_2)_2$ gives $MeCp_2TiS_2(CCO_2Me)_2$ containing a TiS_2C_2 ring;[95] some molybdenum complexes behave in a similar fashion.[96]

The use of polysulfide complexes in catalysis has been discussed. Two major classes of reactions are apparent: (1) hydrogen activation and (2) electron transfers. For example, $[CpMo(S)(SH)]_2$ catalyzes the conversion of nitrobenzene to aniline at room temperature,[97] while $(CpMo(S))_2S_2CH_2$ catalyzes a number of reactions such as the conversion of bromoethylbenzene to ethylbenzene[98] and the reduction of acetyl chloride, as well as the reduction of alkynes to the corresponding *cis*-alkenes.[99] Electron transfer reactions (*see* ***Electron Transfer in Coordination Compounds***) have been studied because of their relevance to biological processes (in, for example, ferrodoxins), and these cluster compounds are dealt with in ***Iron–Sulfur Proteins***. Other studies include the use of metal polysulfide complexes as catalysts for the photolytic reduction of water by THF[100] and copper compounds for the hydration of acetylene to acetaldehyde.[101]

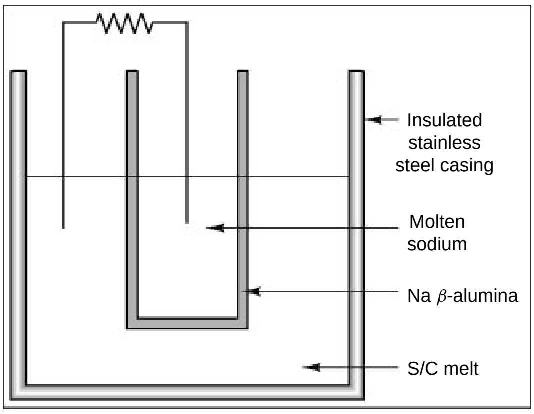

Figure 36 The sodium–sulfur battery

The Sodium Sulfur Battery. Lightweight, high-capacity batteries based upon alkali metals and sulfur have been the subject of much study, and are now commercialized. In contrast to conventional (lead–sulfuric acid) batteries, they consist of a solid electrolyte that separates the two liquid electrodes (molten sulfur is the anode and molten sodium the cathode) (Figure 36). The Na/S system can store up to five times the energy of an equivalent weight conventional battery but is more expensive to produce; it operates at ca. 300 °C and so must be well insulated to maintain the molten electrodes when not in use. In operation the sodium is oxidized to Na^+ and the sulfur reduced to polysulfide anions during the discharge of the battery, resulting in the formation of Na_2S_x, which is readily converted back into Na and S if the polarity of the cell is reversed. Typical systems suitable for road vehicles are expected to contain up to 1000 small cells, capable of providing 50 kWh at 100 V and fully rechargeable up to 1500 times. The chemistry associated with this type of electrochemical cell has been extensively studied.[102,103]

5 SULFUR HALIDES

As might be expected, there is a vast range of compounds containing sulfur–halogen bonds (Figure 37), and they play an important role in synthetic sulfur chemistry. For convenience, they are divided by oxidation state. The sulfur oxyhalides are also dealt with in this section.

5.1 Sulfur(VI)

5.1.1 *Sulfur Hexafluorides and Derivatives*

Apart from sulfur hexafluoride (and sulfuryl halides), the S^{VI} oxidation state is maintained[104,105] for species SF_5R and SF_4R_2. All of these compounds are octahedral and the latter species may adopt cis or trans configurations.

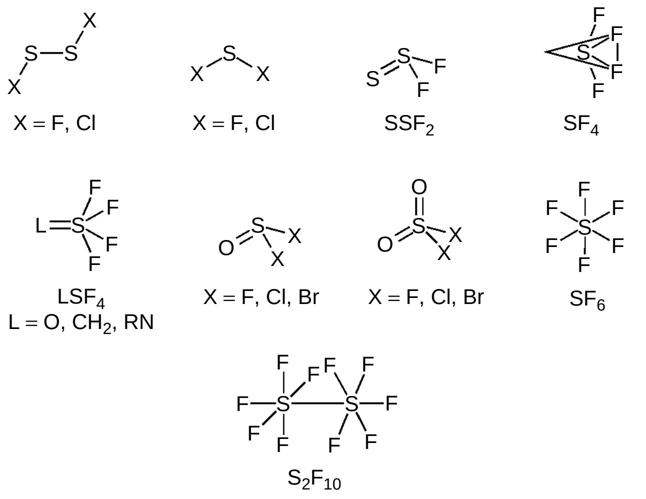

Figure 37 Structures of sulfur halides and oxohalides

Sulfur hexafluoride was first isolated and characterized in 1900; obtained by burning sulfur in a fluorine atmosphere, it is a colorless generally unreactive gas. This lack of reactivity has been put to use, with SF_6 being employed in tracer studies on flue gases from power stations, and as an insulating gas in transformers. Some reactions are possible, however. For example, treatment of SF_6 with SO_3 gives sulfuryl fluoride.[106] In general, however, SF_6 is not an especially useful starting material.

Disulfur decafluoride can be prepared in a similar fashion to SF_6, provided the reaction conditions are adjusted and carefully controlled, although a more convenient laboratory scale reaction is the photochemical reaction of SF_5Cl with H_2 (equation 42).[107]

$$SF_5Cl + H_2 \longrightarrow S_2F_{10} + 2HCl \qquad (42)$$

S_2F_{10} is a colorless liquid (bp 30 °C) that is extremely toxic and much more reactive than SF_6. Structurally, it should be noted that the two SF_5 groups are staggered with respect to each other (Figure 37). It disproportionates on heating to give SF_4 and SF_6. It is, as expected, a powerful oxidizing agent. Under carefully controlled conditions it reacts with ammonia to give NSF_3. With chlorine or bromine it forms SF_5X, and with SO_2, F_5SOSO_2F is formed (Figure 38).[108]

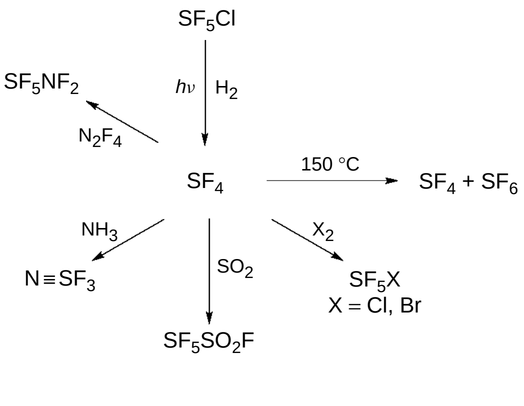

Figure 38 Reactions of S_2F_{10}

There are a number of SF_5L and SF_4L_2 species (Table 12). Perfluoroalkyl compounds are formed by oxidative fluorination of thiols.[109] ^{19}F NMR provides a simple and quick method for establishing the stereochemistry in the bis compounds; there does not appear to be any fluxionality.

SF_5Cl and SF_5Br are usually prepared by oxidation of SF_4 (equations 43 and 44).[110,111]

$$SF_4 + ClF \longrightarrow SF_5Cl \qquad (43)$$

$$SF_4 + Cl_2 + CsF \longrightarrow SF_5Cl + CsCl \qquad (44)$$

Both compounds are more reactive than SF_6 or S_2F_{10}. For example, they are hydrolyzed by aqueous alkali, and the bromide will even react with water. The increase in reactivity is probably a consequence of the dipolar S–X bond [X(δ+)] with initial attack being at X. This view is supported by the higher reactivity of the bromide versus the chloride. Some examples of SF_5L compounds prepared from SF_5X are given in Table 12. With organic alkenes, SF_5Cl reacts both photochemically and thermally.[112] It is a common feature of the chemistry of SF_5X to proceed via $SF_5\bullet$ radicals and a

5.1.2 *Sulfur Oxyfluorides and Oxychlorides*

SOF_4 is obtained by fluorination of thionyl fluoride (equation 46) or by the oxidation of SF_4.[113] It has a trigonal-bipyramidal structure with the S=O in the equatorial plane.[114]

$$SOF_2 + F_2 \longrightarrow SOF_4 \tag{46}$$

It is easily hydrolyzed by water to sulfuryl fluoride and reacts with ammonia to give $NH{=}SOF_2$. With F_2/AgF_2, SF_5OF is obtained.

SF_5OF and the related compound bis(pentafluorosulfur) peroxide undergo facile decomposition to give radicals (equation 47) and are very powerful oxidizing agents. The radicals have been used in reactions with, for example, N_2F_4 to give SF_5ONF_2. With benzene, $PhOSF_5$ is obtained; the OSF_5 activates the ring to electrophilic substitution at the *para* position in a similar manner to fluorine.

$$F_5SOOSF_5 = SF_5O{\bullet} \tag{47}$$

The sulfuryl halides are usually prepared by reaction of X_2 with SO_2. SO_2F_2 and SO_2Cl_2 are both tetrahedral in geometry; SO_2Br_2 is not well characterized and is probably unstable at room temperature. The S–X and S=O bonds are shorter than in the simple halides (SF_6 and S_2Cl_2) and the S=O is also shorter in SO_2F_2 than in SO_3 or SO_2Cl_2.

Sulfuryl fluoride is not especially reactive, whereas sulfuryl chloride is extensively used in industry.[8] It readily dissociates into SO_2 and chlorine, and is widely used for chlorination (particularly selective side-chain chlorination of aromatics) and sulfochlorination (introduction of SO_2Cl) in organic chemical manufacture for dyes, disinfectants, herbicides, and so on.

5.2 Sulfur(IV)

5.2.1 *Halides*

Only SF_4 is stable at room temperature, although $RSCl_3$ compounds are known. SF_4 may be prepared on a laboratory scale by reaction of sulfur dichloride with sodium fluoride in an aprotic solvent such as acetonitrile (equation 48).[115]

$$3SCl_2 + 4NaF \longrightarrow S_2Cl_2 + SF_4 + 4NaCl \tag{48}$$

It is a colorless gas that condenses to give an associated liquid. Spectroscopic studies (IR/Raman, microwave, NMR)[116,117] suggest that the structure is based upon a trigonal bipyramid with one of the equatorial sites occupied by a lone pair. Its ^{19}F NMR spectrum consists of a singlet at room temperature and two triplets at $-98\,°C$.[116]

SF_4 is rapidly hydrolyzed by water to give thionyl fluoride and hydrofluoric acid and so great care must be exercised when using it as a reagent. It can be used (Figure 39) as a powerful fluorinating agent (equations 49 and 50).

$$I_2O_5 + 5SF_4 \longrightarrow 2IF_5 + 5SOF_2 \tag{49}$$

$$CsF + W(CO)_6 + xs\ SF_4 \longrightarrow CsWF_6 \tag{50}$$

SF_4 forms adducts with main group inorganic fluorides, and these have been variously described as simple Lewis acid–base systems (with SF_4 behaving as the base) or as ionic systems such as $[SF_3]^+\ [BF_4]^-$. The reactions of SF_4 with organic molecules have been widely studied. The most important reaction is the conversion of a carbonyl group to a difluoride (equation 51).

$$R_2CO + SF_4 \longrightarrow R_2CF_2 + SOF_2 \tag{51}$$

As expected, it undergoes oxidative addition with fluorine or ClF. With fluorinated peroxides $FSO_2OOSO_2F_2$, the SF_4 inserts into the O–O bond to give $SF_4(OSF_5)_2$.

As mentioned above, SCl_4 is unstable at room temperature. Sulfur dichloride reacts with liquid chlorine at $-75\,°C$ to give a white solid that has the empirical formula SCl_4, but decomposes above $-30\,°C$. By analogy with PCl_5, it is postulated that the structure is $[SCl_3]Cl$.

Organic sulfur trihalides (RSX_3, X = Cl, F) are known.[118] The arylsulfur trifluorides can be obtained by oxidation of the disulfide with silver difluoride but this reaction fails for alkyl compounds. Fluoroalkenes provide a valuable source of compounds according to equation (52), which is catalyzed by cesium fluoride.

$$CF_3CFCF_2 + SF_4 \longrightarrow (CF_3)_2CFSF_3 \tag{52}$$

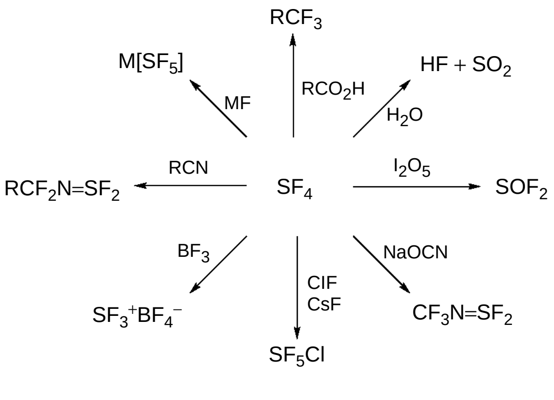

Figure 39 Reactions of SF_4

The trichloro compounds, like SCl_4, are less thermally stable than their fluoro analogs. Generally they are prepared by reaction of the appropriate sulfenyl chloride with chlorine (equation 53).

$$RSCl + Cl_2 \longrightarrow RSCl_3 \quad (53)$$

5.2.2 *Thionyl Halides*

The known thionyl halides include SOX_2 (X = F, Cl, and Br; Table 13) as well as the mixed compound SOFCl. They are pyramidal in geometry, with the S=O bond being shorter in the fluoride than the chloride or bromide.[119] Thionyl chloride is prepared industrially by reacting sulfur dioxide or trioxide with sulfur dichloride or sulfur monochloride, or by the reaction of phosphorus trichloride with sulfuryl chloride (equations 54–57).

$$SO_3 + 2SCl_2 + Cl_2 \longrightarrow 3SOCl_2 \quad (54)$$

$$2SO_2 + S_2Cl_2 + 3Cl_2 \longrightarrow 4SOCl_2 \quad (55)$$

$$SO_3 + S_2Cl_2 + 2Cl_2 \longrightarrow 3SOCl_2 \quad (56)$$

$$SO_2Cl_2 + PCl_3 \longrightarrow SOCl_2 + POCl_3 \quad (57)$$

The other thionyl halides are obtained by treatment of thionyl chloride with appropriate halide exchange reagents (e.g. SbF_3, NaF, KBr).

The thionyl halides hydrolyze in water to give sulfur dioxide and HX. A common inorganic application of this reaction is for the preparation of anhydrous metal chlorides (although it can lead to difficulties for some metal chlorides). Industrially, thionyl chloride is used for the preparation of anhydrous metal halides and oxyhalides as well as in organic transformations, where it converts hydroxyl groups to chlorides. Over 50 000 tonnes a year are manufactured.

SOF_2 has not been studied as extensively as $SOCl_2$. It is used in reaction with $Me_2SnS_2N_2$ to give the five-membered heterocycle $(O)SS_2N_2$.

Iminosulfur difluorides, $RNSF_2$, are isoelectronic with SOF_2. They are obtained by the reaction of SF_4 with cyanates, nitriles, and amines (e.g. equations 58 and 59).

$$RNCO + SF_4 \longrightarrow RNSF_2 + COF_2 \quad (58)$$

$$RNH_2 + SF_4 \longrightarrow RNSF_2 + [RNH_3]F \quad (59)$$

Table 13 Properties of S^{IV} compounds

$(i\text{-}C_3F_7)_2SF_2$	<−78	111

Thiothionyl fluoride, $S{=}SF_2$ (an isomer of S_2F_2), is also known, although it is not especially stable;[120] it is often obtained mixed with disulfur difluoride, but may be obtained directly by reaction of NF_3 with sulfur or by the fluorination of S_2Cl_2 with KF in SO_2.

5.3 Sulfur(II)/(I)

The only established example of a sulfur(II) halide is SCl_2; we shall include the S^I halides in this section (Table 14).

Disulfur difluoride is prepared by several routes, including the reaction of sulfur with silver fluoride. It is a colorless liquid (bp 15 °C). Disulfur dichloride is obtained by reaction of the elements and the bromide is prepared by reaction of S_2Cl_2 with HBr. Industrially, S_2Cl_2 is continuously manufactured by passing Cl_2 into liquid sulfur.[8] Sulfur dichloride is obtained by further chlorination of S_2Cl_2. Disulfur dihalides have structures similar to that of hydrogen peroxide, while SCl_2 has the expected bent geometry.

The sulfur chlorides are poisonous yellow/orange liquids; pure SCl_2 is difficult to obtain since it readily disproportionates to give S_2Cl_2. Both chlorides hydrolyze with water and burn in oxygen. Most of their reactions are described in other sections, since the sulfur chlorides are useful reagents. Industrially, disulfur dichloride and sulfur dichloride are used for the manufacture of thionyl chloride and SF_4, as a catalyst for the chlorination of acetic acid, and in rubber vulcanization. Perhaps the most notorious use of sulfur chlorides is in the preparation of the highly toxic 'mustard gases' (equation 60).[121]

$$C_2H_4 + SCl_2 \longrightarrow ClC_2H_4SCl \xrightarrow{C_2H_4} (ClC_2H_4)_2S \quad (60)$$

Sulfur dichloride reacts with Lewis acids with halide transfer (equation 61) and behaves as a typical acid chloride (equation 62).

$$SCl_2 + AlCl_3 \longrightarrow SCl^+AlCl_4^- \quad (61)$$

$$SCl_2 + Hg(SCN)_2 \longrightarrow S(CN)_2 + HgCl_2 \quad (62)$$

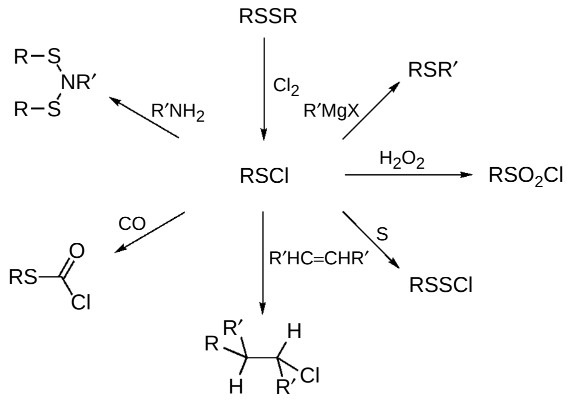

Figure 40 Reactions of RSCl

A large class of compounds derived from sulfur dichlorides are the sulfenyl chlorides, RSCl. They are most commonly obtained by chlorination of a disulfide (RSSR) using Cl_2 or SO_2Cl_2. They have a large organic chemistry that has been reviewed;[122,123] selected reactions are illustrated in Figure 40.

6 SULFUR–CARBON COMPOUNDS

6.1 Neutral Carbon–Sulfur Compounds

There is an extensive chemistry of carbon sulfides.[124–126] The simplest neutral carbon sulfide is CS, which is obtained by treating a stream of CS_2 with a silent discharge. It has been spectroscopically characterized by *Matrix Isolation*; it polymerizes at 50 K to give brown $(CS)_x$ and reacts with chalcogens to give CSE (E = S, Se, Te).[127] Although free CS is substantially less stable than CO, like carbon monoxide it does behave as a ligand and this aspect of its chemistry has been thoroughly reviewed.[128] Some examples of the preparation and structures of CS complexes are given in Figure 41. Carbon monosulfide complexes may be prepared by a variety of routes. Direct cocondensation reaction of carbon monosulfide with nickel atoms gives $Ni(CS)_4$, but is a unique route.[129] Reaction of metal chlorocarbenes with SH^- proceeds with elimination of HCl. Many CS compounds are formed from carbon disulfides.[130,131] The CS_2 is methylated and then acidified. Alternatively, a route that makes use of the thiophilicity of phosphines is the use of PPh_3/CS_2. When reacted with an appropriate metal complex the CS_2 complex is initially formed, and this rapidly loses $SPPh_3$ to give the carbon monosulfide.[132] CS may also behave as a bridging ligand in a similar fashion to carbon monoxide,[133] as well as bridging with donation from the sulfur atom.[134]

Carbon disulfide is prepared commercially by the reaction of charcoal with liquid sulfur at elevated temperatures,

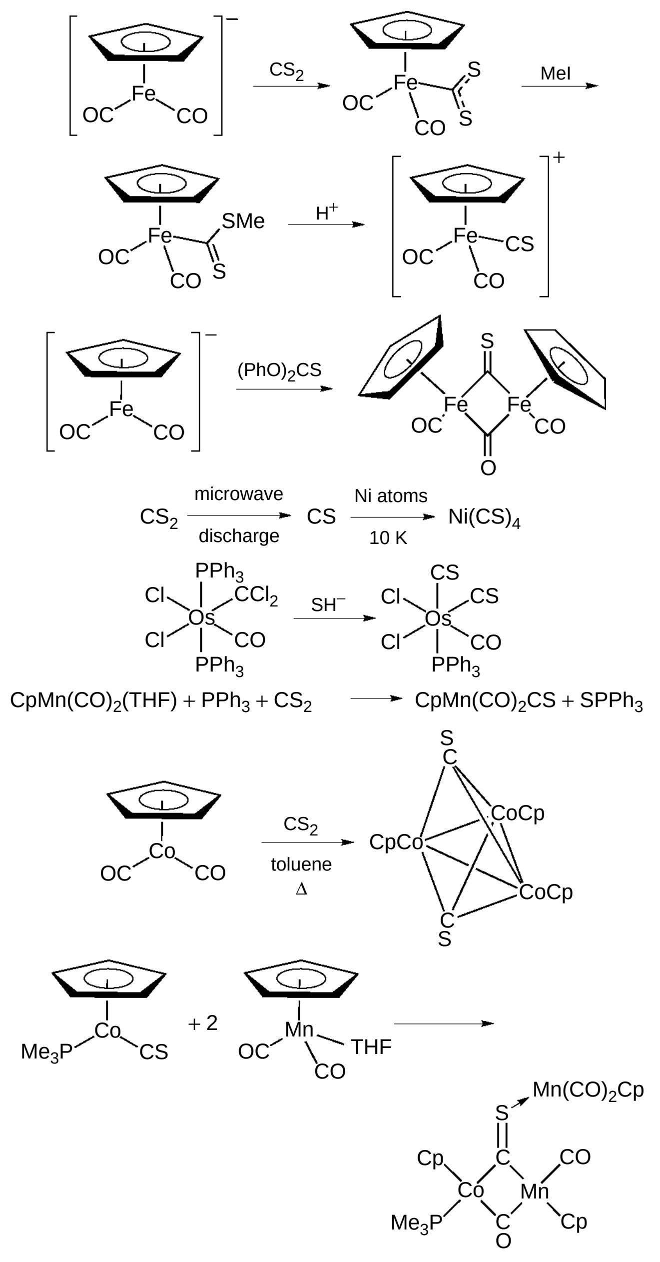

Figure 41 Complexes of carbon monosulfide

although the use of methane as a feedstock (equation 63) is gaining in importance.[8] It is a revolting smelling, volatile liquid that is easily ignited (flash point −30 °C).

$$CH_4 + \tfrac{1}{4}S_8 \longrightarrow CS_2 + 2H_2S \qquad (63)$$

Typical reactions of CS_2 are summarized in Figure 42. CS_2 forms a range of metal complexes,[135] making use of one, two, or all of its atoms (Figure 43). Commercially, the reaction with alcohol (cellulose) is used in the manufacture of viscose fiber; this use, together with the preparation of CCl_4, accounts for the majority of CS_2 manufacture, with lesser

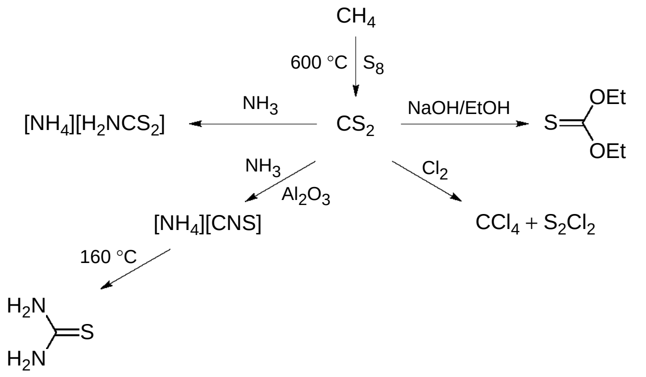

Figure 42 Reactions of carbon disulfide

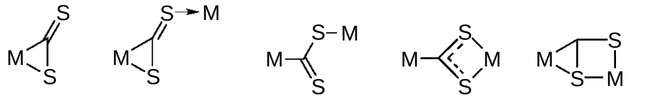

Figure 43 Coordination modes of CS_2

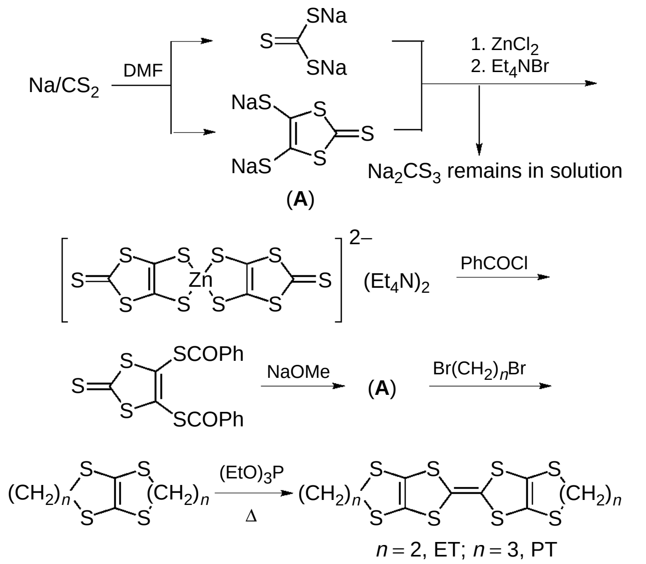

Figure 44 Preparation of ET

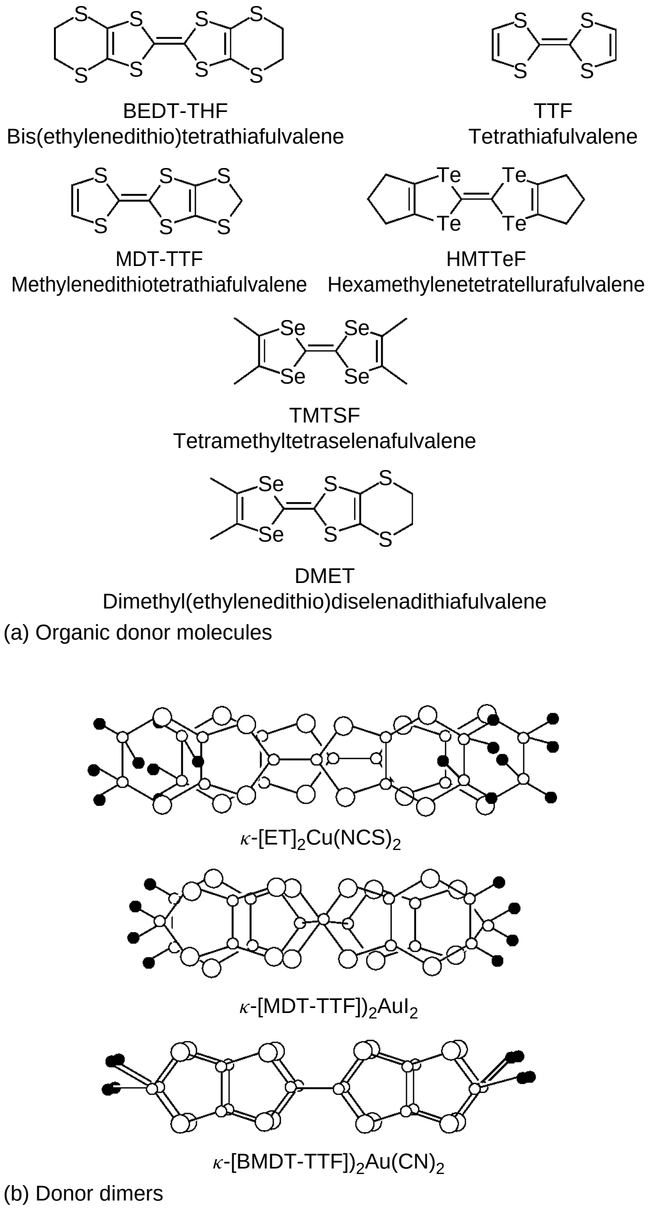

Figure 45 (a) Organosulfur compounds used in organic metals; (b) typical stacking motifs for organosulfur rings in organic metals

amounts being used in the manufacture of rubber and the pharmaceutical industry. The reaction of CS_2 with NaOH/R_2 NH to give dithiocarbamates has been studied in some detail, since these behave as ligands in a range of systems.[136] For a discussion of these related ligands, such as dithiolenes, *see* ***S-donor Ligands***.

Reduction of CS_2 gives[137] α-$C_3S_5^{2-}$, which is used in the preparation of bis(ethylene)dithiotetrathiafulvalene (ET) (Figure 44 and 45), which has itself been extensively studied as a constituent of organic metals.[137]

Higher binary C–S compounds are illustrated in Figure 46. The majority have been prepared from C–S anions, and the reactions used are described below. Quite recently C_2SO has been prepared in an argon matrix by irradiating (254 nm) a mixture of CS and CO at 10K[138]

6.2 Anionic Carbon Sulfides

Examples of anionic compounds are shown in Figure 46. $C_3S_3^{2-}$ is obtained by desilylation[139] of $C_3S(SC_2H_4SiMe_3)_2$; $C_4S_4^{2-}$ is obtained from squaric acid; and reduction of CS_2 gives α-$C_3S_5^{2-}$, which thermally rearranges to give the β

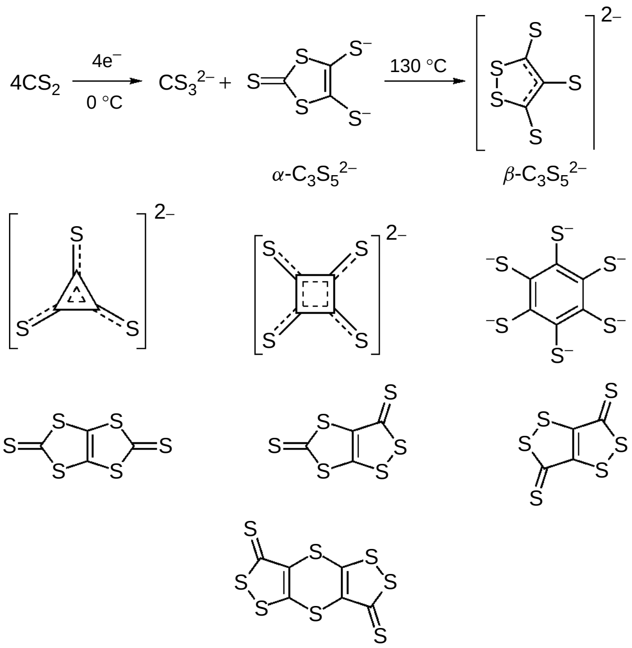

Figure 46 Binary carbon–sulfur compounds

isomer.[140] The $C_6S_6{}^{6-}$ anion is obtained[141] by reduction of $C_6(SCH_2Ph)_6$ with Na/NH_3(liq). The anions may be complexed with metals such as zinc or with the Cp_2Ti unit. The metal complexes can then be reacted with simple halides in an analogous fashion to the reactions of Cp_2TiS_5 (equation 64).

$$[Zn(C_3S_5)_2]^{2-} + 2S_2Cl_2 \longrightarrow ZnCl_4{}^{2-} + \tfrac{1}{2}C_6H_{12} + C_3S_8 \qquad (64)$$

Reactions of thionyl chloride and sulfuryl chloride with zinc complexes of α- and β-C_3S_5 have been used[142] for the preparation of C_6S_8, $C_6S_{10}\cdot 0.5CS_2$, and $(\beta\text{-}C_3S_5)_n$. Reaction of $C_6S_6{}^{6-}$ with thiophosgene gives C_9S_9. A second isomer of this empirical formula is also known.[143] A simple route to $[CS_3]^{2-}$ has been devised. Reaction of CS_2 in liquid ammonia followed by addition of $Pt(PR_3)_2Cl_2$ gives $Pt(PR_3)_2(CS_3)$ complexes in good yield.[144]

The chemistry of carbon sulfides is not especially well developed as yet, but some general trends in reactivity have been recognized.[126] (1) S–S bonds are usually able to be reductively cleaved to give anions; (2) S–S subunits will add to low-valent metals; (3) electrophilic alkenes and alkynes add across S–S bonds; (4) the sulfur atoms are most often nucleophilic.

Although binary carbon sulfides appear to be something of a curiosity at the moment, given their stability (especially compared to binary S–N compounds) and their usefulness in the synthesis of new organosulfur compounds and ligands that may be redox active, it is to be expected that their chemistry will develop rapidly over the next few years.

7 MAIN GROUP RINGS AND CAGES

7.1 Phosphorus–Sulfur Cages

There are believed to be 19 different binary phosphorus sulfides (including isomers) – the six well-established phosphorus sulfides[145] are shown in Figure 47, together with examples of mixed P–O–S cages. Closely related to these are mixed phosphorus–arsenic sulfides ($P_xAs_{4-x}S_3$) and phosphorus–sulfur selenides, $P_4S_xSe_{3-x}$. There have also been recent reports on the nmr characterization of two new binary phosphorus sulfides – both isomers of the previously elusive P_4S_6[146] the δ isomer contains a central P_4S_5 core with one terminal P=S bond while the ε isomer contains a central P_4S_4 core and two terminal P=S units. Structurally, all of the compounds can be derived from the P_4 tetrahedron by edge bridging or vertex addition of chalcogen atoms. In P_4S_4, the sulfur atoms are in a square plane with the phosphorus atoms in a P_4 tetrahedron above and below the plane. This viewpoint underlines the structural similarity of P_4S_4 with Se_4N_4 and S_4N_4. The structure of P_4S_5 is analogous to $S_4N_5{}^-$ but there is, as yet, no sulfur–nitrogen analog of P_4S_7. Though the gross geometries appear similar, there are significant differences in the bonding descriptions. All of the phosphorus sulfides may be adequately described by simple two-centre–two-electron bonds and there is no indication of additional cluster bonding. The situation for sulfur–nitrogen compounds is more complex and is discussed in ***Sulfur–Nitrogen Compounds***.

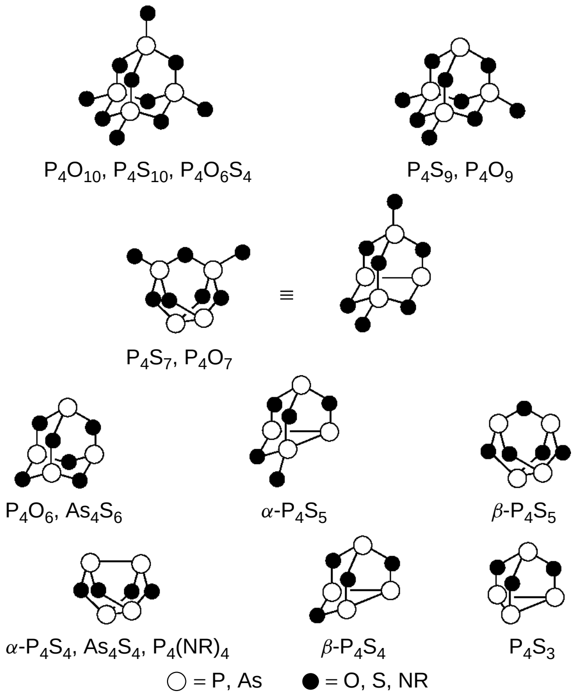

Figure 47 Phosphorus–sulfur and related cages

Originally, phosphorus–sulfides were prepared by direct combination of the elements and, for many compounds this is still a satisfactory procedure. P_4S_3, P_4S_7, and P_4S_{10} are made commercially by reaction of white phosphorus and sulfur at elevated temperatures (over 300 °C) under an inert atmosphere, with the products being distilled from the reactions. Convenient laboratory scale preparations use red phosphorus and sulfur, often in an inert solvent (e.g. xylene). There has recently been an nmr reinvestigation of the reaction of white phosphorus with sulfur that reveals that at 100 °C 12 of the known binary sulfides form[147] with the major product being P_4S_7. Combination of P_4S_{10} or P_4S_3 with the appropriate quantity of phosphorus or sulfur can be used to give P_4S_5, P_4S_7, and P_4S_9 (equation 65).[148]

$$P_4S_3 + \tfrac{1}{4}S_8 \longrightarrow P_4S_5 \qquad (65)$$

Some rather milder and more elegant strategies have been developed,[40] and these are useful for the thermally unstable compounds P_4S_5 and P_4S_4. Triphenylphosphine can be progressively used as a desulfurating agent and the tin reagent $(Me_3Sn)_2S$ is useful (equations 66 and 67).[149]

$$\begin{array}{c} P_4S_{10} + PPh_3 \longrightarrow P_4S_9 + SPPh_3 \\ \downarrow 2PPh_3 \\ \beta\text{-}P_4S_5 \longleftarrow P_4S_7 + 2SPPh_3 \end{array} \qquad (66)$$

$$\begin{array}{c} P_4S_3 + I_2 \longrightarrow \beta\text{-}P_4S_3I_2 \longrightarrow \alpha\text{-}P_4S_3I_2 \\ \downarrow (Me_3Sn)_2S \\ \alpha\text{-}P_4S_4 + 2Me_3SnI \end{array} \qquad (67)$$

With the exception of P_4S_3, the phosphorus sulfides are moisture sensitive and readily hydrolyzable. The relative stability is sometimes used in its purification; the impure material is suspended in boiling water, which hydrolyzes the other compounds present (equation 68).

$$P_4S_{10} + 16H_2O \longrightarrow 4H_3PO_4 + 10H_2S \qquad (68)$$

All of the phosphorus sulfides burn readily in air, and P_4S_3 is still used (in combination with $KClO_4$ and binders) in 'strike anywhere' matches.

We have already mentioned the reaction of iodine with P_4S_3; this compound and the others that contain P–P bonds (P_4S_5 and P_4S_7) also react with bromine (equation 69).[150] The first stage of the reaction may be an opening of the P–P bond.

$$P_4S_7 + 3Br_2 \longrightarrow P_2S_6Br_2 + P_2S_5Br_4 \qquad (69)$$

Reactions with chlorine completely destroy the cages; P_4S_{10} gives S_2Cl_2, SCl_2, and PCl_5. P_4S_{10} reacts with anisole to give 'Lawesson's reagent', which is extensively used as a reagent for the conversion of C=O into C=S. Interestingly, a *cis* analog of Lawesson's reagent has recently been reported from the reaction of P_4S_{10} with bromonaphthalene (Figure 48).[151] This compound has been studied extensively in recent times both as a source of sulfur in thionation reactions and because it represents a useful entry into disubstituted naphthalenes. Reactions with alcohols lead to mono- and dialkoxy acids (equation 70).

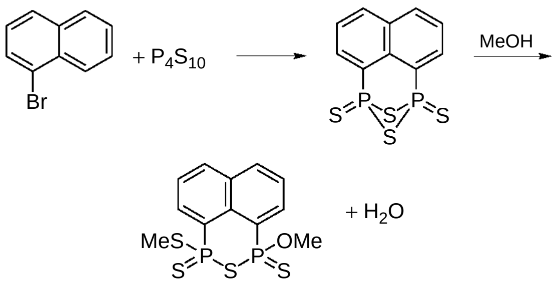

Figure 48 Organophosphorus–sulfur compounds

$$P_4S_{10} + 8ROH \longrightarrow 4(RO)_2PS(SH) + 2H_2S \qquad (70)$$

The dithiophosphoric acids are very important commercially for the preparation of pesticides such as malathion and in the manufacture of engine oil additives such as zinc dialkyldithiophosphates (ZDDPs). The structure of basic ZDDP was finally determined to be similar to beryllium acetate with a central Zn_4O core bridged along each edge by the dialkyldithiophosphate ligand[152] The coordination chemistry of dithio- and (more recently) monothiophosphoric acid derivatives has been studied as a consequence of the commercial importance of ZDDPs. The monothio derivatives can behave as bridging ligands with the hard oxygens bonding to hard metals such as zinc, and the soft sulfur atoms coordinating softer metals such as platinum (Figure 49).[153]

Reaction of P_4S_{10} with KCN/H_2S yields the trithiometaphosphate anion PS_3^-, which has been stabilized using the bulky cation Ph_4As^+ to stop dimerization to $P_2S_6^{2-}$. The latter can be prepared directly by heating together an alkali metal with the appropriate quantities of phosphorus and sulfur.

Treatment of P_4S_{10} with NaN_3 gives $P(N_3)_2S_2^-$; this reacts with additional P_4S_{10} to give $[P_4S_9N]^-$ in which an N^- has replaced a bridging sulfur atom.

7.2 Phosphorus–Sulfur Ligands

A number of metal complexes in which P_4S_3 acts as a donor ligand through its apical phosphorus have been prepared (equations 71 and 72).

$$Ni(\eta^3\text{-}C_3H_5)_2 + 4P_4S_3 \longrightarrow Ni(P_4S_3)_4 \qquad (71)$$

$$Mo(CO)_6 + P_4S_3 \longrightarrow Mo(CO)_5(P_4S_3) \qquad (72)$$

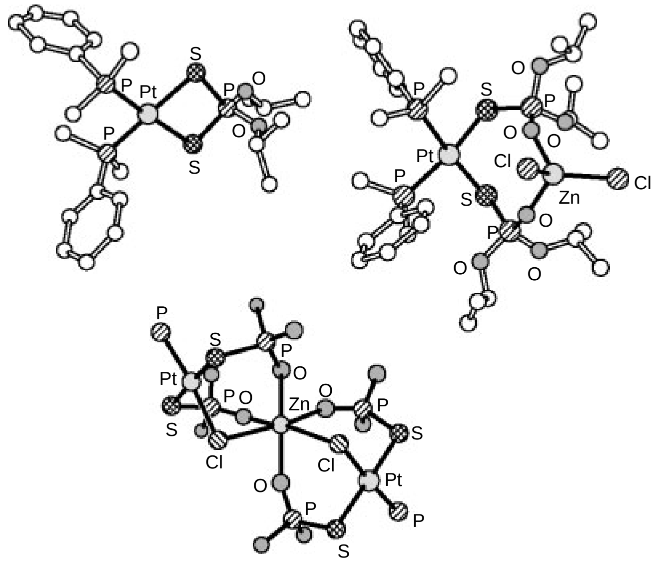

Figure 49 Mononuclear dithiophosphate and dinuclear and trinuclear complexes containing monothiophosphate ligands. In the trinuclear complex, the methyl substituents on phosphorus and the *i*-Pr groups on the oxygen atoms have been omitted for clarity

Insertion into the basal P–P bond is also possible. For example, in the oxidative addition reaction of P_4S_3 to Vaska's compound, *trans*-$Ir(CO)Cl(PPh_3)_2$ in benzene at 60 °C gives an octahedral Ir^{III} complex $[Ir(CO)Cl(P_4S_3)(PPh_3)]_2$ as a green air-stable solid. Related reactions have been described.[30,31] Metal centers can also be used to trap reactive arsenic–sulfur species (equation 73).

$$[(C_5Me_5)Co(CO)_2]_2 + As_4S_4 \xrightarrow[h\nu]{\text{THF}} [(C_5Me_5)_2Co_2(As_2S_3)] \quad (73)$$

7.3 Phosphorus–Sulfur Rings

The structural types observed for phosphorus–sulfur rings are rather more diverse than for the oxygen congeners. Figure 50 shows representative examples.

The most stable and well-known species are the four-membered rings RP(S)S$_2$P(S)R, in particular, Lawesson's reagent[154] (R = $MeOC_6H_4$), which is readily prepared from P_4S_{10} and is used in organic synthesis as a sulfurating agent (equation 74).

$$P_4S_{10} + 4PhOMe \longrightarrow 2[(MeOC_6H_4)PS_2]_2 + 2H_2S \quad (74)$$

Larger rings are known but only when large sterically demanding substituents (i.e. mesityl and 'supermesityl') are present (equations 75 and 76).[155,156]

$$(2,4,6\text{-}t\text{-}Bu_3C_6H_2)PCl_2 + Li_2S \longrightarrow [(2,4,6\text{-}t\text{-}Bu_3C_6H_2)PS]_3 + 2LiCl \quad (75)$$

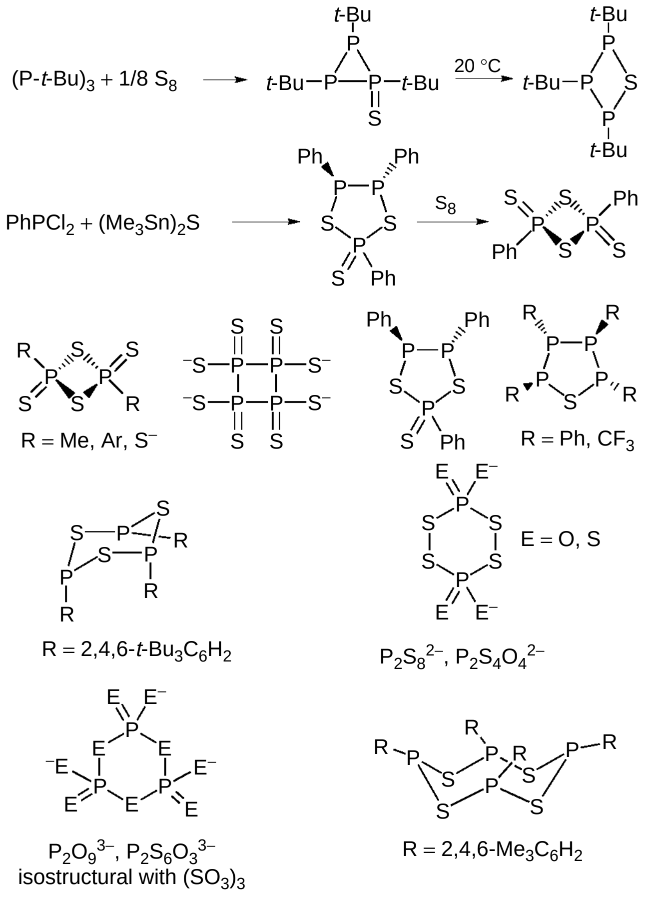

Figure 50 Phosphorus–sulfur rings

$$(2,4,6\text{-}Me_3C_6H_2)PCl_2 + (Me_3Si)_2S \longrightarrow [(2,4,6\text{-}Me_3C_6H_2)PS]_4 + 2Me_3SiCl \quad (76)$$

In comparison it is worth noting that use of a simple phenyl group allows formation of a five-membered ring with adjacent PPh groups and an exocyclic sulfur.[157] This five-membered ring readily reacts with sulfur to give $(PhPS_2)_2$.

The six-membered $(RPS)_3$ has a chair cyclohexane conformation, while $(RPS)_4$ has a crown (S_8) structure, which is as predicted from simple electron counting, since CH_2, RP, and S are isoelectronic. Although the six-membered ring is thermally stable, the eight-membered ring compound (which has smaller substituents on phosphorus) forms $(RPS_2)_2$ on standing in toluene solution.

7.4 Other Nonmetal Sulfides

Sulfur–nitrogen rings and cages are discussed in ***Sulfur–Nitrogen Compounds***. There are several boron–sulfur and silicon–sulfur rings[5] and examples are given in Figure 51.

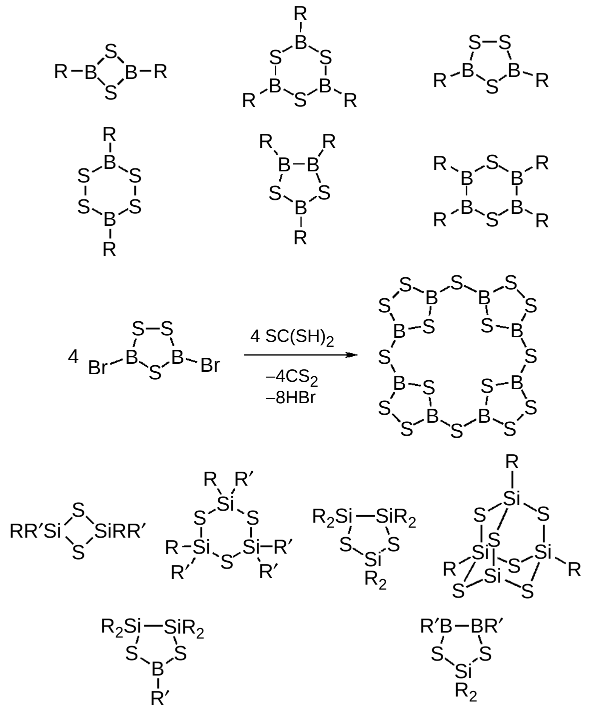

Figure 51 Examples of boron–sulfur and silicon–sulfur rings

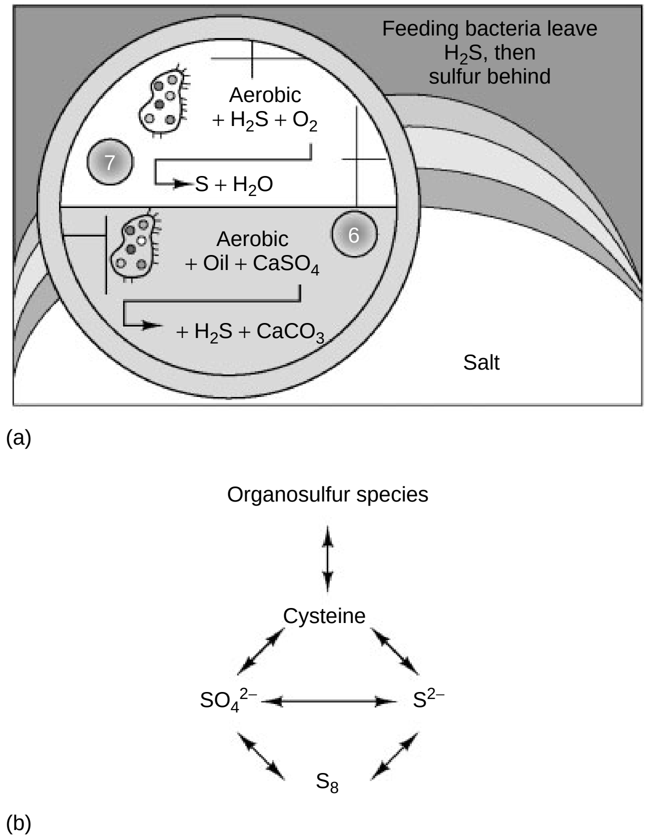

Figure 52 (a) Formation of sulfur in the cap rocks of lime. (b) The biological sulfur cycle

8 INORGANIC BIOLOGICAL SULFUR CHEMISTRY

Sulfur compounds are widespread in Nature in living organisms and this is also reflected in the geochemistry of sulfur. A constituent of amino acids (cysteine, methionine) and of cofactors such as biotin, thiamine, and coenzyme A, sulfur is essential for the maintenance of cells. Inorganic sulfur compounds, in the Earth's crust, the sea, and the atmosphere are converted by plants and microorganisms into organosulfur compounds, while the demands of animals and humans for sulfur is much lower and is usually met by the oxidation of amino acids.

Nature provides inorganic sulfur in a variety of forms. In seawater, the average concentration of sulfate is ca. $0.03\,mol\,L^{-1}$, although the concentrations in fresh water are much more variable and depend on local conditions. Freshwater may also contain sulfides. Soil samples can contain both of these sources of sulfur along with sulfate esters. Geological sulfur consists largely of sulfides and sulfates, although free sulfur is common. Figure 52 illustrates the cycle for the formation of sulfur in the salt domes of limes. Atmospheric SO_2 may be used by higher plants either directly, or after absorption through the soil. This process must account for the observation that, in some crops, the sulfur concentration is higher than is achievable based on the sulfur content of the soil alone.

The most important biological sulfur transformations[158] are illustrated in Figure 52(b). In general, plants and microorganisms convert inorganic sulfur into sulfur-containing organic molecules (sometimes described as 'reduced' sulfur), which then provide essential nutrition for animals. There are some exceptions to this generalization, most notably ruminants and birds (probably via symbiosis with microorganisms in their digestive system). The ability of plants to utilize inorganic sulfur is very markedly affected by the activities of the microflora in the local environment. In addition to the transformations in Figure 52, there is a range of metal–sulfur (e.g. iron–sulfur) proteins that are very important; examples of these are shown in Figure 53; more discussion of this aspect is provided in ***Iron–Sulfur Proteins***.

The key intermediates in the metabolism of inorganic sulfur are two sulfate containing nucleotides, adenylyl sulfate (APS), and 3′-phosphoadenylyl sulfate (PAPS, Figure 54). PAPS is biosynthesized from ATP by the enzymes ATP-sulfurylase and APS-kinase, and is a source of the sulfuryl group for a number of functions; the transfer usually being catalyzed by the sulfotransferases. Typical cycles are illustrated in Figure 54. PAPS is involved in the transport of sulfur for assimilatory and dissimilatory sulfate reduction (i.e. small-scale reduction to give sulfur-containing organic cell

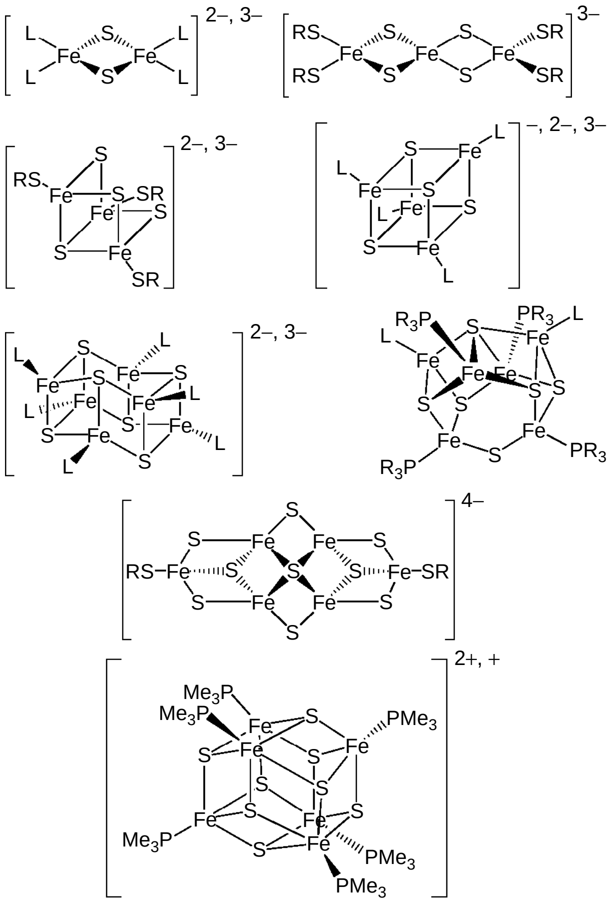

Figure 53 Examples of biologically important M–S clusters

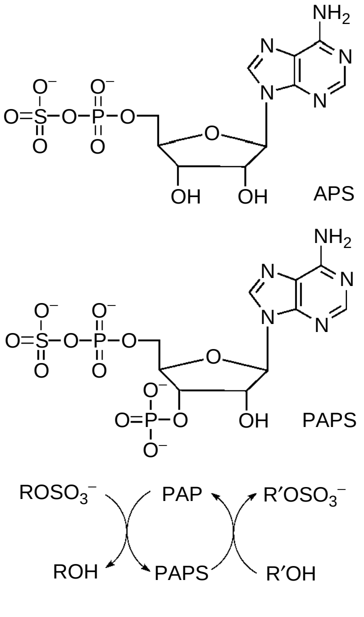

Figure 54 Adenylyl sulfate (APS) and 3′-phosphoadenylsulfate (PAPS) and a typical sulfur transfer cycle for PAPS

constituents and large-scale transformations to give sulfides as part of energy-yielding transformations, respectively). A detailed discussion of the biological processes involving sulfur is available.[158]

9 ANALYSIS OF INORGANIC SULFUR COMPOUNDS

Qualitative methods for the identification are given in Table 15.[159] Quantitative methods are well documented.[158,159] Sulfur compounds are readily studied by vibrational spectroscopy, both IR and Raman. The oxides and oxyanions have characteristic spectra[160] in the IR while the sulfanes and *cyclo*-sulfur compounds give strong Raman spectra as a result of their high polarizability. The only potentially useful NMR nucleus is ^{33}S, which is quadrupolar and low in abundance (Table 2). In general, measurements of ^{33}S NMR

$SO_4{}^{2-}$	$BaCl_2 \rightarrow BaSO_4(\downarrow)$
	$AgNO_3 \rightarrow AgSO_4$ (sol. in H_2O)
$S_2O_4{}^{2-}$	$KI \rightarrow I_2$
	$AgNO_3 \rightarrow Ag_2O_2$
$S_2O_3{}^{2-}$	$+HCl \rightarrow S(\downarrow) + SO_3{}^{2-}$
	$AgNO_3 \rightarrow Na_3[Ag(S_2O_3)_2] \rightarrow\rightarrow Ag_2S$
	$[Ni(en)](NO_3)_2 \rightarrow [Ni(en)_3]S_2O_3(\downarrow)$ violet

Table 16 Typical ^{33}S NMR data

Species	$\delta(^{33}S)$ (ppm)	$\Delta W_i/2$ (Hz)	Solvent
Na_2SO_4	0	6.5	D_2O
$Na_2S_2O_3$	33.5	60	D_2O
CS_2	−332	320	Neat
SO_2	707	375	Neat
OCS	−260	594	Neat
$SOCl_2$	224	600	Neat
SO_2Cl_2	−45	600	Neat
SO_2F_2	−41	–	Neat
$SO_2(NH_2)_2$	−15.3	256	D_2O
SF_6	−176	Multiplet	Neat
H_2S	−503	–	Neat
$[WS_4]^{2-}$	159	13	H_2O
$[WS_3O]^{2-}$	57	140	H_2O
$[WS_2O_2]^{2-}$	−56	220	H_2O
$[WSO_3]^{2-}$	−166	300	H_2O
Na_2S	34	60	H_2O
ZnS	−100	53	Solid

spectra are achieved most readily with high-field solid-state machines that are capable of very rapid pulsing at high powers and of implementing sequences such as RIDES (to reduce ringing in the probe). Quite variable line widths, which can be related to the symmetry of the substituents about the nucleus, are observed. Notwithstanding the difficulties, ^{33}S NMR has become increasing widely used in recent years;[161–164] solid-state ^{33}S NMR has even been reported.[165] Although the lines can be very broad, the chemical shift range is still useful. Some examples of δ values and line widths are given in Table 16.

Glossary

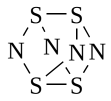
π-Electron-rich compound: a compound in which the number of π-electrons exceeds the number of atoms
Heterocyclothiazene: an unsaturated sulfur–nitrogen ring system containing another element
Thiazene: a compound containing an unsaturated sulfur–nitrogen bond

Abbreviations

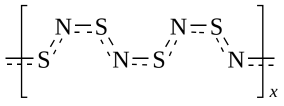
DFT = density functional theory; HMQC = heteronuclear multiple quantum coherence; SOMO = singly occupied molecular orbital; PES = photoelectron spectroscopy; CI = configuration interaction; LUMO = lowest unoccupied molecular orbital; HOMO = highest occupied molecular orbital; TLC = thin layer chromatography.

1 INTRODUCTION

Sulfur–nitrogen (S–N) compounds have a long history. The first example, S_4N_4, was discovered in 1835, but the intriguing cage structure (**1**) of this inorganic heterocycle was not established until 1963.[1] The related polymer, $(SN)_x$ (**2**), was first obtained in 1910 and its metallic character was noted. However, it was the discovery in 1975 that $(SN)_x$ is a superconductor at 0.26 K that excited considerable interest in S–N chemistry.[2]



(**1**)



(**2**)

Three years earlier, in 1972, Banister had proposed that planar S–N heterocycles belong to a class of 'electron-rich aromatics', which conform to the Hückel $(4n + 2)$ π-electron rule.[3] These two aspects of S–N chemistry have attracted the attention of both synthetic chemists and theoreticians. Since the 1970s, the field has reached maturity. Many new S–N compounds with unusual structures and properties have been characterized, and theoretical studies have provided reasonable rationalizations of the structure–reactivity relationships of these fascinating compounds.[4,5] The versatile behavior of S–N compounds as ligands in transition metal complexes has also been established.[6,7] Recent studies have focused on the magnetic and conducting properties of materials derived from C–S–N radicals.[8,9]

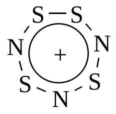
A book by Heal, published in 1980, is the only text devoted to inorganic S–N chemistry.[10] A more recent monograph contains substantial coverage of S–N compounds.[11] Specialized reviews of specific aspects of S–N chemistry are referred to in the appropriate sections of this article.

2 STRUCTURE AND BONDING

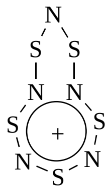
Banister's proposal that *planar* S–N ring systems obey the Hückel $(4n + 2)\pi$-electron rule was based on the reasonable assumption that each sulfur contributes two electrons and each nitrogen one electron to the π system.[3] The heterocycles S_2N_2 (6π) (**3**), $S_4N_3^+$ (10π) (**4**), and $S_5N_5^+$ (14π) (**5**) were cited as examples to support this suggestion. These ring systems are referred to as π-electron-rich since the number of π-electrons exceeds the number of atomic centers in the ring.[12] However, this simple counting procedure belies the fact that the surplus of electrons is accommodated in π^* (or $n\pi$) orbitals. Consequently, the π-bond orders in S–N heterocycles are significantly lower than those in the corresponding aromatic hydrocarbons. The electronic structures of planar S–N rings have been discussed at the simple and extended Hückel levels[13,14] and for ab initio molecular orbital calculations[5] (*see* ***Molecular Orbital Theory***). These calculations provide a detailed description of

the frontier orbitals of S–N heterocycles, which is essential for understanding their reactivity patterns and the nature of electronic transitions.

(3)

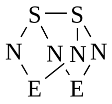


(4)

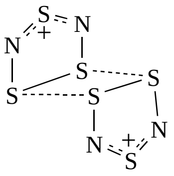


(5)

A characteristic feature of eight-membered (or larger) S–N heterocycles is the formation of folded structures with a transannular S–S interaction. The classic example is S_4N_4 (**1**) and the same structural feature is evident in the related ring systems $E_2N_4S_2$ (**6**) where E = PR_2 or $CNMe_2$. The S–S distance of ca. 250–260 pm in these compounds is substantially longer than the normal S–S single-bond length of 205 pm, indicating an unusual type of bonding. Molecular orbital calculations reveal that the folded structures result from an *intramolecular* $\pi^*-\pi^*$ interaction, as shown in Figure 1.[7] A similar type of bonding is found in S_8^{2+} (*see* ***Sulfur: Inorganic Chemistry***). *Intermolecular* $\pi^*-\pi^*$ bonding is also a significant feature of S–N compounds, as exemplified by the dimer $S_6N_4^{2+}$ (**7**), where two $S_3N_2^+$ rings (a 7π-electron system) are connected by weak S–S interactions [d(S–S) = 300–310 pm].[14]



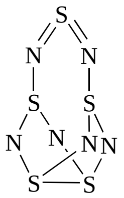
(**6**)



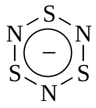
(**7**)

3 THERMAL STABILITY

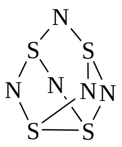
Electron-rich S–N heterocycles are thermodynamically unstable with respect to the loss of N_2 and there is often a low kinetic barrier to decomposition. Consequently, caution must be exercised to avoid explosions when handling certain S–N compounds, for example, S_2N_2 (**3**), S_4N_4 (**1**), S_5N_6 (**8**), and alkali metal salts of the anions $S_3N_3^-$ (**9**) and $S_4N_5^-$ (**10**). These compounds may explode when subjected to mechanical or thermal stress, for example, on contact with a metal spatula or upon gentle heating.



(**8**)



(**9**)



(**10**)

Under suitably controlled conditions, thermal decomposition may be used to prepare certain S–N compounds. For example, S_2N_2 is obtained by the mild thermolysis of a variety of S–N heterocycles (see Section 5.1.3); and heating solutions of $S_3N_3^-$ salts in boiling acetonitrile produces the acyclic $SSNSS^-$ anion (see Section 5.3.4). Bond enthalpies for S–N compounds can be estimated from S–N bond lengths.[15]

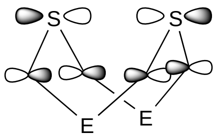


Figure 1 The $\pi^*-\pi^*$ interaction in $E_2N_4S_2$ (E = $CNMe_2$, PR_2)

4 PHYSICAL METHODS

4.1 X-Ray Crystallography

The structures of many S–N compounds are often unpredictable. Furthermore, the reactions of these compounds frequently result in substantial reorganization of their structural frameworks, for example, ring contraction or expansion and the formation of acyclic products from ring systems (or vice versa), to give products with unexpected structures.

Spectroscopic methods are usually not sufficient to provide decisive structural information. Consequently, the ability to establish atomic arrangements rapidly by X-ray crystallography has been of paramount importance in the development of S–N chemistry (*see* ***Diffraction Methods in Inorganic Chemistry***). X-Ray crystallography also provides the details of intermolecular interactions in the solid state, which are important for understanding the physical properties, for example, conductivity and magnetic behavior of S–N compounds with extended structures.

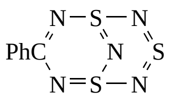
4.2 $^{14}N/^{15}N$ NMR Spectroscopy

Although NMR spectroscopy played a minor role in the early development of S–N chemistry, the availability of high-field instruments with Fourier transform capabilities has facilitated nitrogen NMR investigations. Nitrogen has

two nuclei, ^{14}N ($I = 1$, 99.6%) and ^{15}N ($I = 1/2$, 0.4%) that are amenable to NMR studies. The advantages of ^{15}N NMR are narrow, well-resolved lines and the potential ability to observe spin–spin coupling patterns. The disadvantages include lengthy acquisition times due to long spin-lattice relaxation times and the necessity to prepare isotopically enriched materials in order to observe the effects of spin–spin coupling.[16] On the other hand, the ^{14}N nucleus gives rise to relatively broad lines, poorer resolution, and loss of coupling information. To offset these disadvantages, very short delays between pulses are possible in view of the short spin-lattice relaxation times and good signal-to-noise ratios can be achieved in relatively short acquisition times when the appropriate experimental conditions are used.[17]

Some important examples of the application of ^{14}N NMR spectroscopy in S–N chemistry include (a) investigations of the $(NSCl)_3 \rightleftharpoons 3NSCl$ equilibrium in solution[18] and (b) identification of the S–N species present in solutions of sulfur in liquid ammonia.[19] The half-width of ^{14}N NMR resonances is dependent on the symmetry of the atomic environment as well as other factors, such as solvent viscosity. The values may vary from ca. 10 Hz for solutions of $NS_2^+ AsF_6^-$ in liquid SO_2 to >1000 Hz in metal–S–N complexes. However, the chemical shift range for S–N compounds is ca. 800 ppm, so that useful information may frequently be obtained despite the broad lines.[17] Liquid SO_2 is a particularly good solvent for ^{14}N NMR studies of cationic S–N species,[18] while liquid ammonia is well suited to investigations of S–N anions.[17,19]

^{15}N NMR spectroscopy has been applied to the identification of complex mixtures of S–N rings and cages formed from the air oxidation of $S_3{}^{15}N_3^-$ in acetonitrile[20] and to investigations of the dynamic behavior of the bicyclic compound $PhCN_5S_3$ (**11**), which undergoes 1,3-nitrogen shifts.[21]



(**11**)

In S–N compounds containing ^1H directly bonded to nitrogen, reverse 2D $^1H\{^{15}N\}$ NMR spectroscopy can be applied to give ^{15}N chemical shifts and coupling constants involving ^{15}N nuclei using natural-abundance ^{15}N molecules.[22]

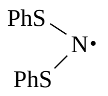
The only sulfur isotope with a nuclear spin is ^{33}S, which is quadrupolar ($I = 3/2$) and of low natural abundance (0.76%). Consequently, ^{33}S NMR spectroscopy has found very limited applications in S–N chemistry.

4.3 ESR Spectroscopy[23]

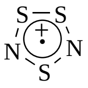
Many radicals containing the S–N linkage are persistent for more than several hours at room temperature. The majority of these radicals have semioccupied orbitals to which the sulfur and nitrogen p orbitals make a dominant contribution. In cyclic species, the unpaired electron often occupies a delocalized π-orbital, which may contribute to the stability of the species. ESR spectroscopy is an excellent technique for the characterization of S–N radicals and, in conjunction with MO calculations, provides unique information about their electronic structures.

The ^{14}N nucleus ($I = 1$, 99.6%) has a moderately large magnetic moment and hyperfine splittings from this nucleus are a distinctive feature of the ESR spectra. For example, the thermally unstable $S_4N_4^{-\bullet}$ radical anion has been identified by its characteristic nine-line ESR spectrum. For ^{33}S ($I = 3/2$, 0.76%), isotopic labeling is usually necessary to obtain information on electron spin density at sulfur.

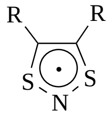
The first radical containing S–N linkages, PhSNSPh (**12**), was produced in 1925. It was 50 years later when the ESR spectra of (**12**) and related radicals were reported.[24] Some of the more important S–N radicals include the 7π-electron system $S_3N_2^+$ (**13**) and the isoelectronic neutral radicals (**14**) and (**15**).



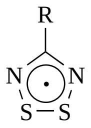
(**12**)



(**13**)



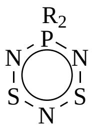
(**14**)



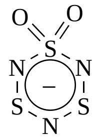
(**15**)

4.4 UV–Visible and Magnetic Circular Dichroism Spectroscopy

Electron-rich S–N heterocycles usually exhibit intense colors ranging from yellow to orange and red to blue. The colors are due to low-energy ($\pi^* \rightarrow \pi^*$ or $n \rightarrow \pi^*$) transitions.[4] For example, the 8π-electron heterocycles $R_2PN_3S_2$ (**16**) and $S_3N_3O_2^-$ (**17**) both have intense purple colors due to a visible absorption band at 550–560 nm attributed to the HOMO(π^*)–LUMO(π^*) transition.



(**16**)



(**17**)

The experimental values of these excitation energies (from electronic spectra) have been correlated with those calculated by the transition-state method with considerable success.

Assignments of the UV–visible absorption bands to the appropriate electronic transitions can usually be made by comparing the calculated transition moments for the various alternatives. The technique of Magnetic Circular Dichroism (MCD) spectroscopy has also been applied to a variety of S–N ring systems in conjunction with π-electron calculations.[25] The MCD spectra can be interpreted in terms of $\pi^* \rightarrow \pi^*$ excitations and, in some cases, reveal transitions that are obscured in the electronic absorption spectra.

4.5 IR and Raman Spectroscopy

Several planar S–N heterocycles have been the subject of a complete vibrational analysis. For example, the IR and Raman spectra of S_2N_2, $S_3N_3^-$, and $S_4N_4^{2+}$ have been interpreted on the basis of D_{2h}, D_{3h}, and D_{4h} geometries, respectively.

The IR and Raman spectra of $S_4^{14}N_4$ and $S_4^{15}N_4$ have been assigned in accordance with the D_{2d} structure (**1**).[26] The method of ^{15}N enrichment has also been used to distinguish S–N from S–S vibrations in, for example, the $SSNSS^-$ and $SNSS^-$ anions.[20] The S–S vibration appears as a strong band in the Raman spectrum and this technique can be used to detect transannular (π^*–π^*) S–S interactions in bicyclic or cage S–N molecules or ions. The strong Raman-active S–S vibrations occur at frequencies in the range 185–270 cm^{-1} for S–S bond lengths of 240–270 pm.

The vibrational assignments for S_7NH and $S_4N_4H_4$ have been assigned with the aid of both ^{15}N and ^2H labeling, and the force constants for these molecules were determined.[27] Matrix isolation techniques combined with ^{15}N and ^{34}S labeling have provided the IR spectra of the unstable species NS, N_2S, and NS_2.[28]

4.6 Mass Spectrometry

Low ionizing potentials or soft ionization methods are necessary to observe the parent ions in the mass spectra of many S–N compounds because of their facile thermal decomposition. Indeed, mass spectrometry has been used to investigate the thermal breakdown of S_4N_4 (**1**) in connection with the mechanism of the formation of the polymer $(SN)_x$ (**2**).[29] On the basis of appearance and potential of various S_xN_y fragments, two important steps were identified: (a) the fragmentation of S_4N_4 to S_2N_2 and (b) the transformation of cyclic S_2N_2 to an open form, $(SN)_2$. The $S_3N_3^{\bullet}$ radical has been identified by MS (in conjunction with PES) as the major product of the vaporization of the $(SN)_x$ polymer.[30]

4.7 Electrochemical Studies[31]

Electrochemical studies provide important information about the redox states of S–N compounds that are potential neutral radical conductors, for example, $[RCN_2S_2]^{\bullet}$ (**15**) (see Section 8.1.1).[31] Electron-rich S–N heterocycles are good electron acceptors since the lowest unoccupied molecular orbitals (LUMOs) are low lying relative to those in aromatic hydrocarbons or cyclophosphazenes (*see* ***Phosphorus–Nitrogen Compounds***). Since the LUMOs are π^*-orbitals antibonding with respect to S–N linkages, the addition of electrons promotes ring opening to give either chains or ring-contracted products. For example, the electrochemical reduction of S_4N_4 at −0.93 V (vs. Ag/0.1 M $AgClO_4$) produces the anion radical $S_4N_4^-$, which decomposes above 0 °C to give the six-membered ring $S_3N_3^-$ (**9**).[32]

Electrochemical methods may also be used to promote the polymerization of S–N rings. Thus, the electrochemical reduction of salts of the $S_5N_5^+$ cation (**5**) in SO_2 or CH_2Cl_2 at low temperatures produces microcrystalline $(SN)_x$.[33]

4.8 Photoelectron Spectroscopy (*See Photoelectron Spectroscopy of Transition Metal Systems*)

Photoelectron spectra supply information about the energy of either inner-core (X-ray PES) or valence-level (UV-PES) electrons. The data obtained provide experimental support for MO calculations of electronic energy levels and atomic charges in various molecules. UV-PE spectra are most readily obtained for reasonably volatile compounds, and studies of S–N heterocycles have included S_2N_2 (**3**), S_4N_2 (**18**), S_4N_4 (**1**), and 1,5-$R_2C_2N_4S_2$ (**6**; E = CR).[4] The UV-PE spectrum of S_2N_2 shows that the two upper π-levels (π_S and π_N) are nearly degenerate. They are primarily nonbonding orbitals located on the sulfur atoms and nitrogen atoms, respectively, with π_S being of slightly higher energy than π_N. The UV-PE spectra of S_4N_4, S_4N_2, and 1,5-*t*-$Bu_2C_2N_4S_2$ provide ionization potentials that are in good agreement with calculated values.[4]

UV-PES studies of 1,2,4,6-thiatriazinyl $[R_2C_2N_3S]^{\bullet}$ and 1,2,3,5-dithidiazolyl $[RCN_2S_2]^{\bullet}$ (**15**) radicals have also provided ionization potentials that are in good agreement with modified neglect of differential overlap (MNDO) calculations.[34]

5 BINARY SULFUR–NITROGEN COMPOUNDS

5.1 Neutral Molecules

Sulfur analogues of the well-known nitrogen oxides NO and NO_2 (*see* ***Nitrogen: Inorganic Chemistry***) are thermally unstable and the most common binary sulfur nitride is the tetramer S_4N_4 (**1**). This reflects the tendency of multiply bonded species containing heavier main group elements to oligomerize in the absence of steric protection (*see* ***Electronic Structure of Main-group Compounds***).

5.1.1 *Thiazyl Monomer (Sulfur Nitride), NS*[35]

Thiazyl monomer is a radical with one unpaired electron. In contrast to nitric oxide, it polymerizes so readily that it cannot be isolated as a monomeric solid or liquid and has only a transient existence in the gas phase. Thiazyl monomer may be generated in a number of ways, including the volatilization of $(SN)_x$ (**2**) or pyrolysis of S_4N_4 (**1**) over quartz wool above 300 °C. The emission spectrum and ESR spectrum have been reported. The bond length is calculated to be 149.7 pm from its spectroscopic moment of inertia. This indicates a bond order of between two and three. The dissociation energy of this strong sulfur–nitrogen bond is estimated to be 463 kJ mol^{-1} from spectroscopic data. Nevertheless, like other sulfur nitrides, NS is endothermic and unstable with respect to its elements. Thiazyl monomer exhibits an IR band at 1209 cm^{-1}.[28] The experimental dipole moment is 1.83 ± 0.03 D and the ionization potential is 9.85 eV.

Thiazyl monomer can be stabilized by coordination to a metal, and many thionitrosyl complexes with Cr, Mo, Re, Ru, Os, Co, Rh, Ir, and Pt are known.[6,7,35] Comparison of the spectroscopic properties and the electronic structures of M–NS and M–NO complexes indicates that NS is a better σ-donor and π-acceptor ligand than NO. Oxygen transfer from an NO_2 to an NS ligand on the same metal center occurs in ruthenium porphyrin complexes.[36]

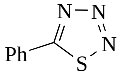
Several routes are available for the preparation of thionitrosyl–metal complexes. These include (a) reaction of nitride complexes with sulfur or sulfur halides, (b) reaction of $(NSCl)_3$ with transition metal complexes, and (c) reaction of NS^+ salts with metal complexes. The first organometallic thionitrosyl complex was prepared by method (b) (equation 1).

$$\mathrm{Na[CpCr(CO)_3]} + \frac{1}{3}\mathrm{(NSCl)_3} \xrightarrow{\text{THF}} \mathrm{CpCr(CO)_2(NS)} + \mathrm{CO} + \mathrm{NaCl} \quad (1)$$

Two bonding modes, linear and bent, have been established for metal–thionitrosyl complexes. The characteristic stretching vibration for linear M–NS complexes occurs in the range 1150–1370 cm^{-1}, while that for terminal bent complexes appears at lower frequencies.

5.1.2 *Dinitrogen Sulfide, N_2S*[37]

A variety of acyclic and cyclic S–N compounds decompose at moderate temperatures (100–150 °C) with the formal loss of a symmetrical NSN fragment, but this molecule has never been detected. Ab initio calculations indicate that linear NNS is the lowest energy of N_2S species. The molecule, N_2S, can be generated by flash vacuum pyrolysis of 5-phenyl-1,2,3,4-thiatriazole (equation 2).



$$\xrightarrow{\Delta} \mathrm{PhCN} + \mathrm{N_2S} \quad (2)$$

Unlike N_2O, which is a stable unreactive molecule, N_2S is only stable up to 160 K. The IR spectrum is dominated by a very strong band at 2040 cm^{-1} [υ(NN)].[28] The gaseous N_2S molecule has been detected by high-resolution mass spectrometry. The first ionization potential has been determined by PES to be 10.6 eV. These data indicate that N_2S resembles diazomethane, CH_2N_2 rather than N_2O. It decomposes to give N_2 and diatomic sulfur, S_2, and, hence, elemental sulfur, rather than monoatomic sulfur. The bond lengths of linear and cyclic N_2S have been determined by calculations.[38]

5.1.3 *Disulfur Dinitride, S_2N_2*[39]

S_2N_2 (**3**) forms large colorless crystals with an iodine-like smell. It detonates with friction or on heating above 30 °C, but can be sublimed at 10^{-2} Torr at 20 °C. It has a square planar structure with S–N bond distances of 165.4 ppm and bond angles of $90.0 \pm 0.4°$. It is prepared by the thermolysis of other cyclic S–N compounds, for example, S_4N_4 (over silver wool at 220 °C), $S_4N_3{}^+Cl^-$, or $Ph_3AsNS_3N_3$ at ca. 130 °C. S_2N_2 is a six II-electron system, but four of these electrons occupy non-bonding orbitals.[40] It exhibits significant diradical character.[41]

S_2N_2 dimerizes rapidly to S_4N_4 in the presence of nucleophiles and this process can be understood in terms of the frontier orbital interactions between the singly occupied molecular orbital (SOMO) of an $S_2N_2{}^{-\bullet}$ radical anion and the LUMO of an S_2N_2 molecule.[5] The polymerization of crystalline S_2N_2 is a nondiffusive process that produces a mixture of monoclinic (90%) and orthorhombic (10%) $(SN)_x$.[42]

S_2N_2 forms both mono- and diadducts, $S_2N_2{\cdot}L$ and $S_2N_2{\cdot}L_2$, with Lewis acids such as BCl_3 or $SbCl_5$, and with a variety of transition metal halides.[43] The S_2N_2 ligand is attached to the Lewis acid through nitrogen in these complexes and coordination has very little effect on the geometry of the four-membered ring. The formation of π-complexes, for example, $(\eta^4\text{-}S_2N_2)M(CO)_3$ (M = Cr, Mo, W), in which S_2N_2 acts as a 6π-electron ligand, has been proposed,[44] but only N-bonded adducts are observed.

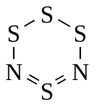
5.1.4 *Trisulfur Trinitride, S_3N_3*[30]

The $S_3N_3^{\bullet}$ radical has been characterized by photoelectron and quadrupole mass spectroscopy as the major product from the vaporization of $(SN)_x$. In the condensed state, it reforms the polymer and other colored materials. Ab initio CI calculations indicate a planar geometry with close to D_{3h} symmetry for the $S_3N_3^{\bullet}$ radical.

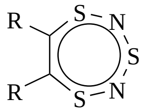
5.1.5 *Tetrasulfur Dinitride, S_4N_2*[39]

S_4N_2 forms dark-red needles (mp 23 °C) upon recrystallization from diethyl ether. It sublimes readily at room temperature, but must be stored at −20 °C to avoid decomposition. Several methods are available for the preparation of S_4N_2. The decomposition of $Hg(S_7N)_2$ at room temperature gives the best yield (65%), while the reaction of S_2Cl_2 with aqueous ammonia is quick and cheap.

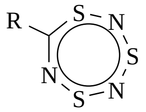
The S_4N_2 molecule consists of a six-membered ring in a half-chair conformation (**18**). There are long S–N bonds (168 pm) connecting the –SSS–and –N=S=N– units, which have S–N distances of 156 pm.[45] Few chemical reactions of S_4N_2 have been studied owing to its thermal instability.



(**18**)



(**19**)

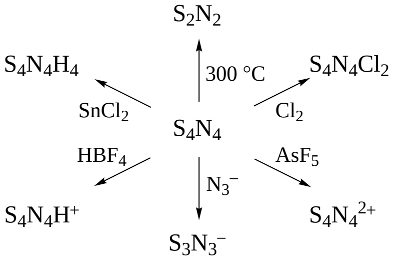


(**20**)

5.1.6 *Tetrasulfur Tetranitride, S_4N_4*[5,39]

Tetrasulfur tetranitride is orange–yellow at room temperature, but becomes almost colorless at −190 °C. In CS_2 solution, it is readily recognized by two strong, characteristic bands at 705 and 938 cm^{-1} in the IR spectrum. The standard synthesis of S_4N_4 involves the treatment of S_2Cl_2 with chlorine, followed by ammonia gas in carbon tetrachloride at 20–50 °C. Alternatively, S_4N_4 can be prepared by the reaction of $[(Me_3Si)_2N]_2S$ with an equimolar mixture of SCl_2 and SO_2Cl_2.[46] Crystalline S_4N_4 may explode when subjected to heat or friction.

Tetrasulfur tetranitride (**1**) adopts a cage structure with equal S–N bond lengths (162 pm) and two weak transannular S–S interactions of ca. 260 pm at room temperature. Although S_4N_4 is thermochromic (*see Thermochromism*), there is no significant difference between the value of the S–S distance and that found at 120 K. Rietveld analysis indicates that S_4N_4 undergoes a transition to a new orthorhombic phase at 397 K.[47] Theoretical and experimental charge densities reveal intermolecular attractions in S_4N_4 that correspond to molecular recognition in the solid state.[48] The unusual structure of S_4N_4, in which the sulfur atoms are three coordinate and the nitrogen atoms are two coordinate, is the inverse of that found for α-P_4S_4 and As_4S_4, where the more electronegative atoms occupy the lowest coordination sites. A planar (D_{4h}) S_4N_4 molecule would be a 12π-electron system with an open-shell configuration, unstable with respect to the Jahn–Teller distortion. Correlation of the molecular orbitals of the hypothetical planar molecule with those of the experimental (D_{2d}) conformation shows that the orbital degeneracy of the ground state is lost in the latter, and four of the previously π^* electrons are accommodated in S–S σ-bonds.[49]



Scheme 1 Some reactions of S_4N_4

The S_4N_4 molecule exhibits a very versatile chemical behavior and is a source of many other S–N heterocycles, as shown in Scheme 1.[4] The synthesis of other S–N rings from S_4N_4 can be classified as follows: reactions with (a) halogens or other oxidizing agents, (b) nucleophiles or reducing agents, and (c) metal halides or organometallic reagents. The eight-membered ring is retained in 1,5-$S_4N_4Cl_2$ and $S_4N_4^{2+}$, the initial products of chlorination or oxidation of S_4N_4, respectively. Further chlorination or oxidation results in ring contraction to give $(NSCl)_3$ or the $S_6N_4^{2+}$ cation (**7**). The reaction of S_4N_4 with nucleophiles also leads to ring contraction. For example, the degradation of S_4N_4 by anionic nucleophiles produces $S_3N_3^-$ (**9**), while Ph_3EN–S_3N_3 (E = P, As) is obtained from S_4N_4 and triphenylphosphine or -arsine. N-Bonded adducts of the type $S_4N_4{\cdot}L$, where the eight-membered ring is flattened into a puckered boat with no cross-ring interactions, are formed with a variety of Lewis or Brønsted acids and some transition metal halides, for example, $FeCl_3$ and VCl_5. However, the reactions of S_4N_4 with metal halides or organometallic reagents more often give rise to cyclometallathiazenes in which the metal becomes part of the S–N ring (see Section 8.5).

The reactions of S_4N_4 with alkynes have also been investigated in considerable detail.[50] These reactions produce 1,3,5,2,4-trithiadiazepines (**19**) and 1,3,5,2,4,6-trithiatriazepines (**20**), both of which are planar, 10π-electron seven-membered rings, in addition to 1,2,5-thiadiazoles, which are the major products (see Section 8.1).

5.1.7 *Pentasulfur Hexanitride, S_5N_6*[39]

Pentasulfur hexanitride is an explosive, air-sensitive, orange solid, which is best prepared from $S_4N_4Cl_2$ (equation 3).[51] The structure of S_5N_6 (**8**) resembles a basket in which a –N=S=N–unit bridges two sulfur atoms of an S_4N_4 cradle via S–N single bonds. It decomposes in warm solvents to give S_4N_4. Because of its hazardous nature, very few reactions of S_5N_6 have been reported. An exception is the reaction with $[Ph_4P]_2[Pd_2Cl_6]$ to give $[Ph_4P]_2[Pd_2Cl_4(S_2N_3)]$, which contains a chelating $S_2N_3^-$ ligand.[52]

$$S_4N_4Cl_2 + Me_3SiNSNSiMe_3 \longrightarrow S_5N_6 + 2Me_3SiCl \qquad (3)$$

5.2 Sulfur–Nitrogen Cations

Investigations of binary S–N cations have played an important role in the development of S–N chemistry. The cyclic cations, $S_2N_3^+$, $S_3N_2^{2+}$, $S_4N_3^+$, $S_4N_4^{2+}$, and $S_5N_5^+$, are of interest in the context of Banister's proposal that planar S–N rings obey the Hückel $(4n + 2)\pi$-electron rule.[3] The simple cations, NS^+ and NS_2^+, are useful reagents for the synthesis of other S–N compounds.

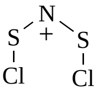
5.2.1 The Thiazyl Cation, SN$^+$[35]

Thiazyl salts were first prepared in 1971 by the reaction of NSF with AsF_5 or SbF_5.[53] They are more conveniently prepared from $(NSCl)_3$ by reacting with (a) $AgAsF_6$ in liquid SO_2 (equation 4) or (b) $AlCl_3$ in CH_2Cl_2 under the influence of heat or ultrasound.

$$(NSCl)_3 + 3AgAsF_6 \xrightarrow{SO_2} 3[NS][AsF_6] + 3AgCl \qquad (4)$$

The S–N bond length in thiazyl salts is about 1.42 Å and the vibrational frequency [ν(S–N)] occurs at 1437 cm^{-1} in $[NS][AsF_6]$. The NS^+ cation exhibits an ^{14}N NMR resonance at ca. 200 ppm, and this technique is useful for monitoring reactions of NS^+.[18]

The thiazyl cation is used for the preparation of other S–N compounds (see Scheme 2). For example, the insertion reactions with S_4N_4 and SCl_2 produce the $S_5N_5^+$ (**5**) and $ClSNSCl^+$ (**21**) cations respectively. Insertion of thiazyl cations into the metal–halogen bond of $Re(CO)_5X$ (X = Cl, Br) provides a route to thiazyl halide complexes.

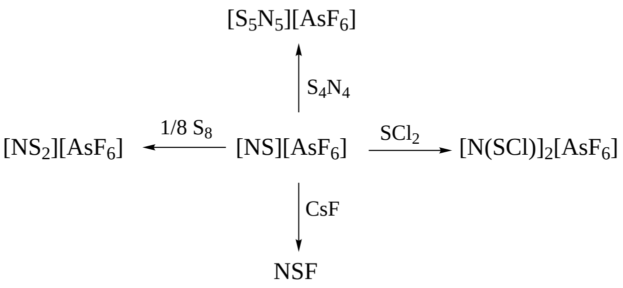


(**21**)

5.2.2 The Dithianitronium Cation, S$_2$N$^+$[54]

The S_2N^+ cation was first obtained in 1978 by the oxidation of S_7NH with $SbCl_5$.[55] Another route to S_2N^+ salts involves the reaction of AsF_5 with a mixture of S_4N_4 and sulfur in appropriate proportions. More conveniently, the reaction of in-situ–generated NS^+ salts with sulfur (see Scheme 2) or the reduction of the $ClSNSCl^+$ cation (**21**) with anhydrous tin(II) chloride in SO_2 or CH_2Cl_2 can be used to prepare NS_2^+ salts (equation 5).[56]

$$[N(SCl)_2][AlCl_4] + SnCl_2 \longrightarrow [SNS][AlCl_4] + SnCl_4 \qquad (5)$$



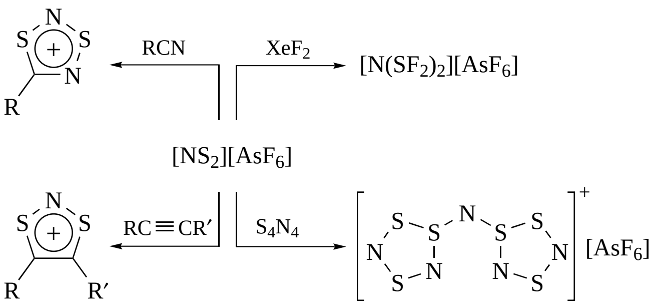
Scheme 2 Some reactions of $[NS][AsF_6]$

The SNS^+ cation is a linear species isoelectronic with CS_2. The S–N bond distances are 146–147 pm. The NS_2^+ cation exhibits a very narrow ^{14}N NMR resonance at −91 ppm ($\nu 1/2 = 8$ Hz) in SO_2 and this technique is useful for monitoring reactions of the cation.[18]

The NS_2^+ cation is an important reagent in S–N chemistry, especially in thermally allowed cycloaddition reactions with organic nitriles and alkynes that give quantitative yields of heterocyclic cations (see Scheme 3).[54] The dominant orbital interaction in these cycloadditions is between the LUMO of S_2N^+ and the HOMO of the alkyne or nitrile (see Figure 2). Cycloaddition reactions also occur with alkenes, and colored charge-transfer complexes are formed with arenes.

5.2.3 The Dithiatriazyl Cation S$_2$N$_3$$^+$[57]

The cyclic $S_2N_3^+$ cation (**22**), a 6π-electron system, is the only example of a nitrogen-rich, binary S–N cation. The



Scheme 3 Some reactions of $[NS_2][AsF_6]$

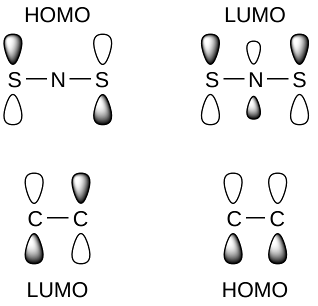


Figure 2 Frontier orbital interactions in the cycloaddition reaction of NS_2^+ with alkynes

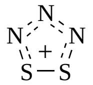
thermally stable salt $[S_2N_3]_2[Hg_2Cl_6]$ is obtained from the reaction of $(NSCl)_3$ with $HgCl_2$ in CH_2Cl_2. The bond lengths in the five-membered ring indicate a delocalized π-bonding that is attenuated across the S–S bond.[57]



(**22**)

5.2.4 *The Thiodithiazyl Cations, $S_3N_2^{n+}$ (n = 1, 2), and Dimer, $S_6N_4^{2+}$*[39]

Although the $S_3N_2^{+\bullet}$ radical cation (**13**) has been well characterized in solution by its characteristic five-line (1:2:3:2:1) ESR signal ($g = 2.01$; $a_N = 3.15$ G),[23] this S–N heterocycle is usually found in the solid state as the dimeric cation $S_6N_4^{2+}$ (**7**), in which two 7π-electron $S_3N_2^+$ rings are associated via weak intermolecular S–S interactions [d(S–S) = 300–310 pm].

The 6π-electron $S_3N_2^{2+}$ dication has been prepared as the AsF_6^- salt by the cycloaddition of NS^+ and NS_2^+ cations in SO_2 (equation 6) and structurally characterized.[58] It decomposes in solution to NS^+ and NS_2^+, with a calculated barrier to dissociation of 5.6 kJ mol^{-1}.[59]

$$[NS][AsF_6] + [NS_2][AsF_6] \rightleftharpoons [S_3N_2][AsF_6]_2 \qquad (6)$$

5.2.5 *The Cyclotrithiazyl Cation, $S_3N_3^+$*

The $S_3N_3^+$ cation is an interesting example of an antiaromatic 8π-electron system. Ab initio CI calculations indicate that a triplet cation, with a planar ring, is more stable than the singlet cation.[30] The $S_3N_3^+$ cation has been obtained as the norbornene adduct,[60] but salts of the free cation have not been isolated.

5.2.6 *The Thiotrithiazyl Cation, $S_4N_3^+$*[39]

The thiotrithiazyl cation in $[S_4N_3]Cl$ was one of the earliest S–N heterocycles to be prepared and structurally characterized. It is obtained as a reasonably air-stable, yellow solid by the reaction of S_4N_4 or $[S_3N_2Cl]Cl$ with S_2Cl_2 in CCl_4 (equation 7).

$$3[S_3N_2Cl]Cl + S_2Cl_2 \longrightarrow 2[S_4N_3]Cl + 3SCl_2 \qquad (7)$$

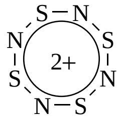
The $S_4N_3^+$ cation (**4**) is a planar seven-membered ring with approximately equal S–N bond lengths and an S–S bond. This cation is a 10π-electron system. The ^{15}N NMR spectrum shows the expected doublet–triplet pattern. The seven-membered ring fragments upon heating at ca. 250 °C give S_2N_2 and, hence, the polymer $(SN)_x$. The reduction of $[S_4N_3]Cl$ with metals such as iron or mercury gives S_4N_4.

5.2.7 *The Cyclotetrathiazyl Dication, $S_4N_4^{2+}$*[39]

The $S_4N_4^{2+}$ cation was first reported in 1977.[61] It is prepared by the oxidation of S_4N_4 with an excess of a Lewis acid, such as $SbCl_5$ or AsF_5, or with $S_2O_6F_2$ (equation 8).

$$S_4N_4 + S_2O_6F_2 \longrightarrow [S_4N_4][FSO_3]_2 \qquad (8)$$

The $S_4N_4^{2+}$ cation (**23**) is a planar eight-membered ring with equal S–N bond lengths (D_{4h}) of ca. 155 pm. It is a fully delocalized 10π-electron system with a strong π-network.



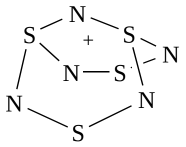
(**23**)

5.2.8 *The Tetrasulfur Pentanitride Cation, $S_4N_5^+$*[39]

The bicyclic $[S_4N_5]Cl$ is a yellow–orange, hygroscopic solid which decomposes violently on heating. It is readily prepared from $(NSCl)_3$ (equation 9).[62] The treatment of $[S_4N_5]Cl$ with AgF_2, $SbCl_5$, or $AgAsF_6$ gives $[S_4N_5]F$, $[S_4N_5][SbCl_6]$, or $[S_4N_5][AsF_6]$, respectively.

$$(NSCl)_3 + Me_3SiNSNSiMe_3 \longrightarrow [S_4N_5]Cl + 2Me_3SiCl \qquad (9)$$

$[S_4N_5]Cl$ has a polymeric, predominantly ionic structure in which $S_4N_5^+$ cations (**24**) are bridged by Cl^- ions with d(S–Cl) = 281 pm. The unbridged S–S distance is 401 pm (cf. 271 pm in the corresponding anion $S_4N_5^-$) (**10**). A number of covalent derivatives of the S_4N_5 cage have been prepared by the reaction of $[S_4N_5]Cl$ with various silylated reagents.



(**24**)

5.2.9 *The Cyclopentathiazyl Cation, $S_5N_5^+$*[39]

The first $S_5N_5^+$ salt was reported in 1969.[63] These salts are moisture sensitive, but they dissolve without decomposition in $SOCl_2$ or formic acid. The $S_5N_5^+$ cation is formed by the reaction of S_4N_4 with the NS^+ cation (see Scheme 2).

The $S_5N_5^+$ cation is a 14π-electron system. With the exception of $[S_5N_5]Cl$, which is red, salts of $S_5N_5^+$ are yellow. The planar, 10-membered ring usually has an azulene shape (**5**), with alternating sulfur and nitrogen atoms.[33]

5.3 Sulfur–Nitrogen Anions

Sulfur and nitrogen represent a versatile combination in the formulation of binary anions with cyclic, cage, or catenated structures, none of which have counterparts among the known N–O anions. In addition, several S–N anions are known only in complexes with transition metals (see Section 8.5).

5.3.1 *The Sulfur Diimide Dianion,* SN_2^{2-} [64]

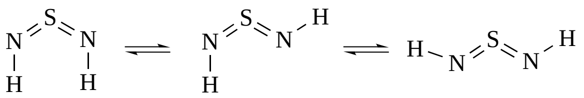
The pale yellow salt, $K_2[SN_2]$, is prepared from bis(trimethylsilyl)sulfur diimide in boiling dimethoxyethane (equation 10). It reacts explosively with water. The dilithium salt, $Li_2[SN_2]$, is generated from $Me_3SnNSNSnMe_3$ and MeLi in the same solvent.[65] The SN_2^{2-} ion is also formed upon exhaustive electrochemical reduction of S_4N_4.

$$Me_3SiNSNSiMe_3 + 2KO\text{-}t\text{-}Bu \longrightarrow K_2[SN_2] + 2Me_3SiO\text{-}t\text{-}Bu \quad (10)$$

The SN_2^{2-} ion is isoelectronic with the thionylimide anion, NSO^-, and with sulfur dioxide, SO_2. The frequencies of the three fundamental vibrations are 1198, 1001, and 528 cm^{-1}. The salt $K_2[SN_2]$ is an important reagent for the preparation of other sulfur diimide derivatives when $Me_3SiNSNSiMe_3$ is not sufficiently reactive.[64] For example, both acyclic and cyclic arsenic(III) compounds, t-$Bu_2AsNSNAs$-t-Bu_2 and t-$BuAs(NSN)_2As$-t-Bu, have been obtained in this way.

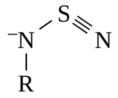
Protonation of the anion SN_2^{2-} by acetic acid in diethyl ether produces the thermally unstable sulfur dimide $S(NH)_2$. Like all symmetrical sulfur diimides, the parent compound $S(NH)_2$ can exist as three isomers (see Scheme 4). Ab initio MO calculations indicate that the (cis, cis) configuration is somewhat more stable than the (cis, trans) isomer, while the (trans, trans) isomer is expected to possess considerably higher energy.

Salts of the sulfur diimide anions $RNSN^-$ (**25**; R = aryl, t-Bu, $SiMe_3$) are prepared by Si–N cleavage of $RNSNSiMe_3$ with $[(Me_2N)_3S][Me_3SiF_2]$.[66] The anions (**25**) adopt cis configurations with short terminal S–N bond lengths (144–149 pm), indicative of a thiazylamide anion. Anions of the type (**25**) exhibit well-separated ^{14}N NMR chemical shifts.[67]



(cis, cis) (cis, trans) (trans,trans)

Scheme 4 Isomers of sulfur diimide, HNSNH



(**25**)

5.3.2 *The* $[S(Nt\text{–}Bu)_x]^{2-}$ *Ions* ($x = 3,4$)[68]

The dimer $[Li_2S(Nt\text{-}Bu)_3]_2$, prepared from t-BuNSNt-Bu and LiNHt-Bu in toluene (equation 11), has a hexagonal, prismatic structure.[68] It is readily oxidized to the deep blue radical $\{Li_3[S(Nt\text{-}Bu)_3]_2\}$.[69] The pyramidal $[S(Nt\text{-}Bu)_3]^{2-}$ anion is isoelectronic with sulfite, SO_3^{2-}. Oxidation with halogens provides easy access to $[S(Nt\text{-}Bu)]_3$, which is isoelectronic with SO_3. The tetrakisimidosulfate dianion $S(Nt\text{-}Bu)_4^{2-}$ can be prepared from $S(Nt\text{-}Bu)_3$ using methodology similar to that shown in equation (11).[70]

$$2S(Nt\text{-}Bu)_2 + 4LiNHt\text{-}Bu \longrightarrow [Li_2S(Nt\text{-}Bu)_3]_2 + 2H_2Nt\text{-}Bu \quad (11)$$

5.3.3 *The* $SSNS^-$ *Ion*[20]

The orange–red S_3N^- ion (λ_{max} 465 nm) is obtained by the addition of triphenylphosphine to a solution of a S_4N^- salt in acetonitrile. It can be isolated as a salt in combination with large counterions, for example, Ph_4As^+ or $N(PPh_3)_2^+$, but it is unstable with respect to the formation of the blue S_4N^- ion in solution or in the solid state under the influence of heat or pressure.[71]

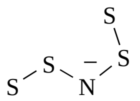
Although the structure of the S_3N^- ion has not been established by X-ray crystallography, the vibrational spectra of 30% ^{15}N-enriched S_3N^- suggest an unbranched ($SNSS^-$) arrangement of atoms in contrast to the branched structure (D_{3h}) of the isoelectronic CS_3^{2-} ion and the isovalent NO_3^- ion. Many metal complexes are known where the S_3N^- ion is chelated to the metal by two sulfur atoms (see Section 8.5).[6,7]

5.3.4 *The* $SSNSS^-$ *Ion*[20]

The dark blue S_4N^- ion (λ_{max} 580 nm) was first obtained in 1972 by the decomposition of $[n\text{-}Bu_4N][S_7N]$, produced by deprotonation of S_7NH with n-Bu_4NOH in diethyl ether at $-78\,°C$.[20] It is more conveniently prepared by the thermolysis of salts of the $S_3N_3^-$ ion with large cations in boiling acetonitrile.[72] The S_4N^- ion is also formed in (a) the reaction of S_2Cl_2 with ammonia in polar solvents (the preparation of cyclic sulfur imides) (see Section 10), (b) solutions of sulfur in liquid ammonia, and (c) the reaction of sulfur with sodium azide in $(Me_2N)_3PO$.[20]

The S_4N^- ion (**26**) is a planar (E,Z) chain with nitrogen as the central atom and short, terminal S–S bonds [d(S–S) ~190 pm], which give rise to strong bands at ca. 565 and 590 cm^{-1} in the Raman spectrum. The S_4N^- ion is an 8π-electron system and the intense visible absorption band near

580 nm has been assigned to a π^*(HOMO) → π^*(LUMO) transition.[72]



(**26**)

5.3.5 *The $S_2N_2H^-$ Ion*

The $S_2N_2H^-$ ion has been characterized by ^{14}N and ^{15}N NMR spectroscopy.[19] It is formed in liquid ammonia by treatment of $S_4N_4H_4$ with 2 mol. equiv. of potassium amide or by the reaction of the S_3N^- ion with potassium amide. Although it has not been isolated as a salt, the $S_2N_2H^-$ ion is well known in complexes with metals, for example, Ni, Pd, Pt, where it acts as a bidentate (S,N) ligand (see Section 8.5).[6,7]

5.3.6 *The Trisulfur Trinitride Ion, $S_3N_3^-$*[20]

The yellow $S_3N_3^-$ ion is formed, together with the $S_4N_5^-$ ion, from the reaction of S_4N_4 with a variety of nucleophilic reagents, for example, ionic azides, organolithium reagents, or secondary amines. The best preparation involves the reaction of S_4N_4 with an azide of a large cation, for example, $(Ph_3P)_2N^+$. The large cation is necessary to stabilize the anion; alkali metal salts of $S_3N_3^-$ are explosive. Two $S_3N_3^-$ salts with interesting solid-state structures are $[PhCN_2S_2][S_3N_3]$,[73] prepared from $[PhCN_2S_2]_2$ and $[S_5N_5]Cl$, and $[Cp_2Co][S_3N_3]$,[74] obtained by the reduction of S_4N_4 with cobaltocene (*see* ***Cobalt: Organometallic Chemistry***).

The $S_3N_3^-$ ion (**9**) is an essentially planar, six-membered ring with bond angles at nitrogen of ca. 123° and at sulfur of ca. 117° and almost equal S–N bond lengths.[75] The vibrational spectra of most alkali metal salts are consistent with D_{3h} symmetry for the anion. The $S_3N_3^-$ ion is an important example of a 10π-electron system. Although the π-orbital pattern is similar to that of benzene, the occupancy of the π-orbitals is very different (Figure 3). The presence of four electrons in the degenerate antibonding (π^*) orbitals dramatically weakens the S–N framework. The thermolysis of yellow solutions of $S_3N_3^-$ in boiling acetonitrile produces the deep blue S_4N^- ion. The yellow color (λ_{max} 360 nm) of $S_3N_3^-$ is assigned to a π^*(HOMO) → π^*(LUMO) transition and this assignment is confirmed by the MCD spectrum.

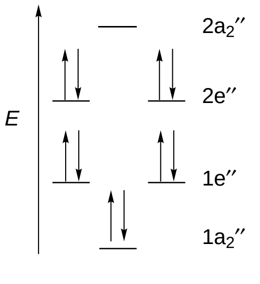


Figure 3 π-Energy levels of $S_3N_3^-$

5.3.7 *The Tetrasulfur Pentanitride Ion, $S_4N_5^-$*[20]

The yellow $S_4N_5^-$ ion was first reported in 1975 from the methanolysis of sulfur dimides (equation 12).[76] It can also be prepared by the treatment of S_4N_4 with certain nucleophiles, for example, secondary amines or azides of small alkali metals.[20]

$$t\text{-BuN=S=NSiMe}_3 \xrightarrow{\text{MeOH}} \text{NH}_4^+\text{S}_4\text{N}_5^- \qquad (12)$$

The structure of $S_4N_5^-$ (**10**) is closely related to that of S_4N_4. In $S_4N_5^-$, five of the six edges of the S_4 tetrahedron are bridged by nitrogen atoms. The S–S distance for the sixth edge is ca. 270 pm.

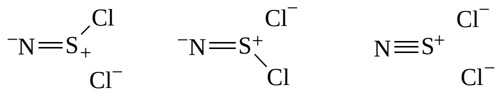
Alkali metal salts of $S_4N_5^-$ are explosive when subjected to heat or mechanical shock, but salts with large counterions, for example, Ph_4As^+ or $(Ph_3P)_2N^+$, are safe to handle in the solid state. The carefully controlled thermolysis of solutions of $S_4N_5^-$ salts in boiling acetonitrile generates $S_3N_3^-$ (**9**) and, subsequently, the S_4N^- ion (**26**). The reaction of $S_4N_5^-$ with bromine or iodine produces pentasulfur hexanitride S_5N_6 (**8**), whereas oxidation with chlorine yields $[S_4N_5]Cl$.

6 SULFUR–NITROGEN HALIDES

6.1 Thiazyl Halides, NSX (X = F, Cl, Br)

Thiazyl fluoride is a moisture-sensitive, thermally unstable gas.[77] It is conveniently generated by decomposition of $FC(O)NSF_2$ or $Hg(NSF_2)_2$. It may also be obtained from $[NS][AsF_6]$ and CsF or from $(NSCl)_3$ and KF in tetramethylene sulfone at 80 °C. The microwave spectrum of NSF indicates a bent structure. Thiazyl fluoride can be stabilized by coordination to a transition metal and such complexes, for example, $[M(NSF)_6][AsF_6]$ (M = Co, Ni), are conveniently prepared in liquid SO_2.[6,7]

Monomeric NSCl is formed as a greenish yellow gas by heating the cyclic trimer $(NSCl)_3$ under vacuum or in an inert gas stream. It trimerizes in the condensed state. The monomer NSCl may also be generated in solutions of $(NSCl)_3$ in liquid SO_2 at room temperature or in CCl_4 at 70 °C.[18] Numerous metal–NSCl complexes are known.[78] Typically, the preparation of these complexes involves the reaction of a high oxidation–state metal chloride with $(NSCl)_3$ in $POCl_3$ or CCl_4 (equation 13). Spectroscopic and X-ray structural data



Scheme 5 Resonance structures of $NSCl_2^-$

indicate M=N=S–bonding in these complexes.

$$2MCl_6 + \frac{2}{3}(NSCl)_3 \xrightarrow[M = Mo \text{ or } W]{} [MCl_4(NSCl)]_2 + 2Cl_2 \quad (13)$$

Monomeric NSBr is generated in the gas phase by pyrolysis of $[S_4N_3]Br$. It has been characterized by its IR spectrum.

6.2 Thiazyl Halides, NSX_2^- (X = Cl, F)[79]

The $NSCl_2^-$ anion, isoelectronic with $OSCl_2$, is prepared by the addition of $[Ph_4P]Cl$ or $[Me_4N]Cl$ to a solution of $(NSCl)_3$ in CH_2Cl_2.[79] The $NSCl_2^-$ anion in the $[(Ph_3PN)_2SCl]^+$ salt has a slightly distorted C_s structure with a very short S–N bond (144 pm) and two loosely bound chlorine atoms [d(S–Cl) = 242 pm]. The structure is best described by three resonance forms (see Scheme 5).

6.3 Thiazyl Trifluoride, NSF_3[77]

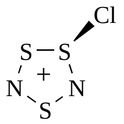
Thiazyl trifluoride, a colorless gas with a pungent odor, is obtained by fluorination of NSF or $FC(O)NSF_2$ with AgF_2. On the basis of spectroscopic data, NSF_3 has a distorted tetrahedral structure. A number of transition metal complexes of NSF_3, for example, $[M(NSF_3)_4][AsF_6]_2$ (M = Mn, Fe, Co, Ni or Cu), are known.[6] The S–N bond distance in these complexes (136–137 pm) is extremely short. The thiazyl difluoride complex $[Ir(CO)ClF(NSF_2)(PPh_3)_2]$ is prepared by oxidative addition of NSF_3 to $[Ir(CO)Cl(PPh_3)_2]$.[80]

6.4 Thiodithiazyl Dichloride, $[S_3N_2Cl]Cl$[39]

Thiodithiazyl dichloride is a rust-colored, moisture-sensitive solid, which is conveniently prepared by heating S_2Cl_2 with dry, finely ground ammonium chloride (equation 14).

$$4S_2Cl_2 + 2NH_4Cl \longrightarrow [S_3N_2Cl]Cl + 8HCl + \frac{5}{8}S_8 \quad (14)$$

$[S_3N_2Cl]Cl$ reacts readily with chloride ion acceptors, for example, $AlCl_3$ and $FeCl_3$, to give salts of the $S_3N_2Cl^+$ cation, which consists of a slightly puckered five-membered ring (**27**). $[S_3N_2Cl]Cl$ is a useful source of the sulfur–nitrogen oxides, S_3N_2O and $S_4N_4O_2$, by reactions with anhydrous formic acid and $SO_2(NH_2)_2$ respectively. Gentle heating of $[S_3N_2Cl]Cl$ under vacuum gives the dark green dimer $(S_3N_2Cl)_2$, which contains the $S_6N_4^{2+}$ cation (**7**).



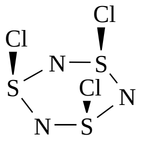
(**27**)

6.5 Cyclotrithiazyl Halides, $S_3N_3X_3$[39]

The trimer $(NSCl)_3$ is obtained as pale yellow, moisture-sensitive crystals by the chlorination of $[S_3N_2Cl]Cl$ (equation 15).

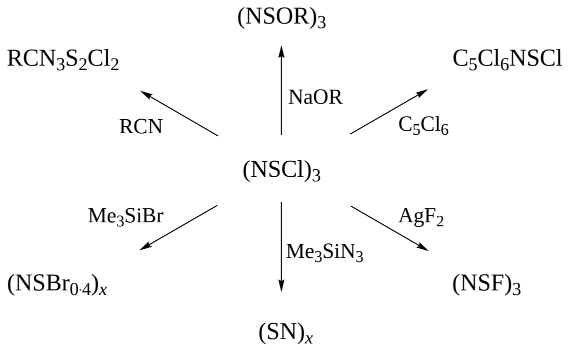
$$3S_3N_2Cl_2 + 3SO_2Cl_2 \longrightarrow 2S_3N_3Cl_3 + 3SCl_2 + 3SO_2 \quad (15)$$

The six-membered ring in $(NSCl)_3$ adopts a chair conformation with all three chlorine atoms in axial positions (**28**). This arrangement is stabilized by the anomeric effect (delocalization of the nitrogen lone pair into an S–Cl σ^* orbital).[81]



(**28**)

The cyclic trimer is an important reagent in S–N chemistry as a source of both cyclic and acyclic compounds (see Scheme 6).[4,39] In part, the synthetic utility of $(NSCl)_3$ stems from the ease with which it dissociates into monomeric NSCl in solution. Thus, the trimer provides a facile source of the NS^+ cation (see Section 5.2.1). Monomeric NSCl, generated from $(NSCl)_3$, undergoes a [2 + 4] cycloaddition reaction



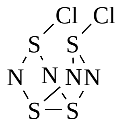
Scheme 6 Some reactions of $(NSCl)_3$

with hexafluorobutadiene to give a six-membered ring, but it reacts as a nitrene with fluorinated alkenes to give *N*-(chlorosulfenyl)aziridines.[82] The reactions of $(NSCl)_3$ with sodium alkoxides to give $(NSOR)_3$[83] or with AgF_2 to produce $(NSF)_3$ are two examples of transformations which occur with retention of the six-membered ring. Cyclotrithiazyl chloride is also a useful reagent in organic chemistry, for example, in the synthesis of 1,2,5-thiadiazoles and isothiazoles.[84,85]

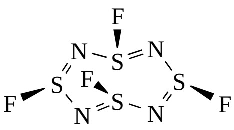
The structure of $(NSF)_3$ is similar to that of the corresponding chloride (**28**).[77] The six-membered ring is retained in the formation of $[N_3S_3F_2][MF_6]$ from $(NSF)_3$ and MF_5 (M = As, Sb).

6.6 1,5-Dihalocyclotetrathiazenes, $S_4N_4X_2$[39]

The oxidative addition of one mole of X_2 (X = Cl, F) to S_4N_4 under mild conditions produces 1,5-$S_4N_4X_2$ as moisture-sensitive, thermally unstable compounds. The structure of 1,5-$S_4N_4Cl_2$ (**29**) consists of a folded eight-membered ring [d(S–S) = ca. 245 pm] with the exocyclic substituents in *exo, endo* positions. The halogen atoms in $S_4N_4Cl_2$ can be replaced by dialkylamino groups by using trimethylsilyl reagents.



(**29**)



(**30**)

6.7 Tetrafluorocyclotetrathiazene, $S_4N_4F_4$[77]

The fluorination of S_4N_4 with an excess of AgF_2 in CCl_4 under reflux gives $S_4N_4F_4$. The heterocyclic ring of $S_4N_4F_4$ (**30**) is boat-shaped with alternate long (166 pm) and short (154 pm) S–N bonds as a result of Jahn–Teller distortion.[86] The fluorine substituents occupy alternate axial and equatorial positions. The structure of $S_4N_4[ON(CF_3)_2]_4$ is similar to that of (**30**). The tetramer $(NSF)_4$ dissociates into a NSF monomer when heated under vacuum at 300 °C. Treatment of $S_4N_4F_4$ with AsF_5 results in ring contraction to give $[S_3N_3F_2][AsF_6]$.

7 SULFUR–NITROGEN OXIDES[39]

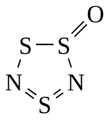
7.1 Neutral Molecules

7.1.1 *Thiodithiazyl Oxide, S_3N_2O*

The sulfur–nitrogen oxide S_3N_2O is a red liquid. It was first prepared in 1975 by the reaction of $(Me_2SnS_2N_2)_2$ with SOF_2, but it is more conveniently prepared from $[S_3N_2Cl]Cl$ (equation 16).[87]

$$[S_3N_2Cl]Cl + HCO_2H \longrightarrow S_3N_2O + 2HCl + CO \qquad (16)$$

The ^{15}N NMR spectrum of S_3N_2O exhibits two resonances consistent with the five-membered ring structure (**31**). Lewis acids such as $SnCl_4$ form 2:1 adducts with S_3N_2O, in which the ligands are coordinated to tin in a cis configuration through their oxygen atoms.



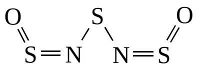
(**31**)

7.1.2 *Trisulfur Dinitrogen Dioxide, $S_3N_2O_2$*[88]

Trisulfur dinitrogen dioxide or bis(sulfinylimino) sulfide, $S(NSO)_2$, is a yellow, moisture-sensitive solid that has been known since 1953. It is conveniently prepared in high yields by the procedure described in equation (17).

$$2Me_3SiNSO + SCl_2 \longrightarrow S(NSO)_2 + 2Me_3SiCl \qquad (17)$$

$S(NSO)_2$ is a planar acyclic molecule with C_{2v} symmetry (**32**). The stability of the observed molecular conformation can be attributed to an electrostatic interaction between the negatively charged oxygen centers and the positively charged central sulfur atom. The central S–N distances are ca. 165 pm, while the S–N distances in the NSO group are ca. 153 pm.



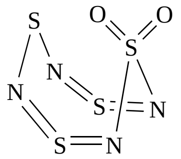
(**32**)

Complexes of $S(NSO)_2$ with silver(I) and zinc(II) where the ligand bonds to the metal through either oxygen or nitrogen atoms have been structurally characterized.

7.1.3 *Cyclotetrathiazene Dioxide, $S_4N_4O_2$*[39]

The dioxide $S_4N_4O_2$ is obtained as orange–yellow needles by the condensation of $[S_3N_2Cl]Cl$ with sulfamide $SO_2(NH_2)_2$. The S–N bond lengths in $S_4N_4O_2$ (**33**) indicate a structure in which two –N=S=N– units bridge a sulfur atom and a SO_2 group to form a boat-shaped eight-membered ring.[87] Sodium methoxide attacks $S_4N_4O_2$ at the sulfur atom opposite the SO_2 group to give $S_4N_4O_2(OMe)^-$, an eight-membered ring with a transannular S–S interaction. Other nucleophiles promote ring

contraction. For example, the reaction of $S_4N_4O_2$ with azide ion in acetonitrile produces the purple $S_3N_3O_2{}^-$ ion (**17**).



(**33**)

7.2 Anions

7.2.1 The Thionyl Imide Ion, NSO^-

Thionyl imide, HNSO, is a thermally unstable gas, which polymerizes rapidly.[10] It can be prepared by the reaction of thionyl chloride with ammonia in the gas phase. It has a planar, cis structure according to IR and microwave spectra. Some transition metal complexes of thionyl imide, for example, $[M(CO)_5(HNSO)][AsF_6]$ (M = Mn, Re), are known.[7]

Potassium thionyl imide, K[NSO], is readily prepared from Me_3SiNSO and potassium *t*-butoxide in THF. Sodium, rubidium, and cesium salts are synthesized in a similar manner.[89] The more soluble $(Me_2N)_3S^+$ salt has also been prepared (equation 18).[90]

$$[(Me_2N)_3S][Me_3SiF_2] + Me_3SiNSO \longrightarrow [(Me_2N)_3S][NSO] + 2Me_3SiF \quad (18)$$

These salts can be used for the synthesis of both transition metal and main group element thionyl imides by metathetical reactions, for example, $Cp_2Ti(NSO)_2$ and $Ph_{3-x}As(NSO)_x$ ($x = 1, 2$), respectively.[64] The M–NSO group invariably adopts a cis geometry in these derivatives. A characteristic reaction of thionyl imides is the thermal or base-promoted elimination of SO_2 to give the corresponding sulfur dimide.[64]

7.2.2 The Thionitrite and Perthionitrite Anions, SNO^-, and $SSNO^-$[91]

The red $SSNO^-$ ion is produced by the reaction of an ionic nitrite with elemental sulfur or a polysulfide in acetone. It has been isolated as the $N(PPh_3)_2{}^+$ salt and shown to have a planar cis structure (**34**) with a short S–S bond distance (199 pm).[91] The $SSNO^-$ ion is probably involved as an intermediate in the gunpowder reaction, which entails the reaction of potassium nitrite (produced by reduction of potassium nitrate with charcoal) and sulfur.[92] The treatment of $SSNO^-$ with triphenylphosphine produces the thionitrite ion SNO^-, which has a bent structure with a bond angle of ca. 120° at nitrogen.[91] Ab initio MO calculations, including a correlation energy correction, indicate that the SNO^- ion is less stable than the isomer NSO^- by at least 38 kJ mol^{-1}.[93]

Organic derivatives RSNO (*S*-nitrosothiols), which have important roles in NO transport and regulation in biological systems,[94] have been characterized by X-ray crystallography, ^{15}N NMR, and IR spectra. Both syn and anti forms are present in solution. The barriers to rotation about the S–N bond are 11–12 kcal mol^{-1} and the S–N bond dissociation energies are estimated to be 20–30 kcal mol^{-1}.[95–98]

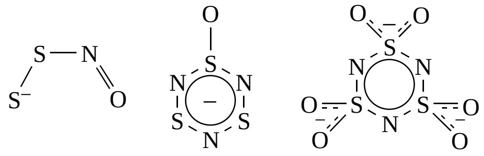
7.2.3 The $SO_xN_3{}^-$ (x = 2,3) Anions[99]

Yellow $(SO_2)_2N_3{}^-$ salts, obtained from SO_2 solutions of CsN_3 or $[Me_4N]N_3$, lose SO_2 to give the corresponding $SO_2N_3{}^-$ salts. The $SO_3N_3{}^-$ ion is prepared by the reaction of $CsSO_3Cl$ with trimethylsilyl azide (see equation 19). The S–N bond in $SO_2N_3{}^-$ is much weaker than that in $SO_3N_3{}^-$.

$$CsSO_3Cl + Me_3SiN_3 \longrightarrow CsSO_3N_3 + Me_3SiCl \quad (19)$$

7.2.4 The $S_3N_3O_x{}^-$ Ions (x = 1,2,4)[39]

The controlled oxidation of solutions of $S_3N_3{}^-$ in acetonitrile produces the red $S_3N_3O^-$ (**35**) and purple $S_3N_3O_2{}^-$ (**17**) ions.[20] The latter may also be obtained from $S_4N_4O_2$ (**33**) and azide ion. The yellow anion $S_3N_3O_4{}^-$ is produced as the $S_6N_4{}^{2+}$ salt, together with $S_3N_2O_5$, from the treatment of $S_4N_4O_2$ with SO_3.



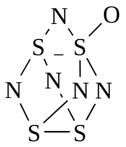
(**34**) (**35**) (**36**)

7.2.5 The $S_3N_3O_6{}^{3-}$ Anion

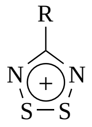
The $S_3N_3O_6{}^{3-}$ anion (**36**) in the ammonium salt has a chair conformation with approximately equal S–O bond lengths.[100]

7.2.6 The $S_4N_5O_x{}^-$ Ions (x = 1,2)

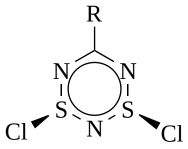
The yellow $S_4N_5O^-$ anion (**37**) is obtained as the water-soluble $NH_4{}^+$ salt from the reaction of $SOCl_2$ with liquid ammonia.[101] The oxygen atom in $S_4N_5O^-$ is attached to a sulfur atom that is connected to three nitrogen atoms. The $S_4N_5O_2{}^-$ ion has been prepared from $S_3N_3O_2{}^-$ (**17**) by oxidative addition with $PhICl_2$, followed by treatment with $Me_3SiNSNSiMe_3$.[5]



(**37**)



(**38**)



(**39**)

8 HETEROCYCLOTHIAZENES

Heterocyclothiazenes are S–N ring systems containing one (or more) other element(s). In view of the isolobal correspondence (*see Isolobal Analogy*) between S^+ and the groups RC or R_2P^V as substituents in an S–N ring, it is not surprising that C–N–S and P–N–S heterocycles have been the subject of recent investigations.[5] The replacement of one or more S^+ substituents in a binary S–N cation by RC or R_2P^V groups confers greater stability on the ring system, and in the case of the RC group, provides a link between these inorganic heterocycles and the benzenoid compounds. The introduction of R_2P^V groups supplies an informative, structural probe via ^{31}P NMR spectroscopy and generates heterocycles that are hybrids of π-electron-rich (S–N) and π-electron-precise ring systems (cyclophosphazenes, *see* ***Phosphorus–Nitrogen Compounds***).

8.1 Carbon–Sulfur–Nitrogen Rings

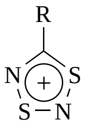
Activity in this area of S–N chemistry has been stimulated by the theoretical prediction that polymers of the type $(RCNSN)_x$ will have conducting properties similar to those of $(SN)_x$.[102] Consequently, there have been extensive investigations of C–S–N heterocycles as potential precursors for such polymers.[5,50] In addition, a new area of radical chemistry based on $RCN_2S_2^{\bullet}$ (dithiadiazolyl) systems has emerged.[103] These heterocycles and their selenium analogs exhibit considerable potential for the development of one-dimensional metals.

8.1.1 Five-Membered Rings[103]

The first examples of the 1,2,3,5-dithiadiazolium cation (**38**) were obtained in 1977 from the treatment of organic nitriles with $(NSCl)_3$. This reaction has subsequently been shown to proceed by the intermediate formation of *S,S′*-dichlorodithiatriazines (**39**).[104] Another route to (**38**) involves the cyclocondensation of trisilylated amidines with sulfur dichloride (equation 20). This method is readily extended to the synthesis of multidithiadiazolium cations, for example, 1,3,5-$C_6H_3(CNSSN)_3^{2+}$.[103]

$$RC(NSiMe_3)[N(SiMe_3)_2] + 2SCl_2 \longrightarrow [RCN_2S_2]Cl + 3Me_3SiCl \qquad (20)$$

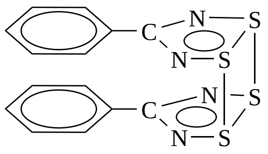
The isomeric 1,3,2,4-dithiadiazolium cation (**40**) is prepared by the $(4+2)\pi$ cycloaddition of the NS_2^+ cation to the C–N triple bond of organic nitriles (see Figure 2).[54] The NS_2^+ cation also reacts with polycyano compounds, for example, dicyano- and tricyanobenzenes, to give the corresponding bis- and tris(dithiadiazolium) cations.



(**40**)

The color of salts containing the cations (**38**) or (**40**) depends markedly on the anion. Weak donor (hard) anions, for example, AsF_6^-, give yellow (**38**) or colorless (**40**) salts, whereas softer anions, for example, Br^- or I^-, bestow darker (burgundy or black) colors.

The $RCN_2S_2^+$ ring is a 6π-electron system, which is readily reduced to the corresponding 7π-electron radical $RCN_2S_2^{\bullet}$ (**15**). The structures of (**15**) are highly dependent on the nature of R. By changing R, it is possible to produce a monomer, a variety of cis, trans, and staggered dimers, or polymeric structures.[103] Thus when R = Ph, the rings are associated by two S–S interactions in a cis configuration (**41**), whereas both the Me_2N and CF_3 derivatives involve only one S–S interaction and the CN_2S_2 rings are twisted at ca. 90° to one another. Interestingly, the bulky *t*-Bu group prevents dimerization and *t*-BuCNSSN˙ is a paramagnetic liquid at room temperature. The related dithiazole (**14**; R = CF_3) is also a paramagnetic liquid that vaporizes to give a blue gas.

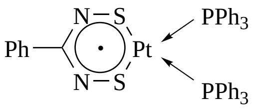


(**41**)

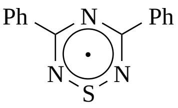
Dithiadiazolyl radicals are of interest in the design of molecular conductors. Multifunctional radicals, for example, 1,3,5-$C_6H_3(CN_2S_2)_3$, have been prepared.[103,105] Iodine doping increases the conductivity of these radical systems.[106] Materials with unique magnetic properties are produced by introducing substituents that inhibit the dimerization process.[9]

1,3,2,4-Dithiadiazoles are unstable with respect to isomerization to the 1,2,3,5-isomers, but several such structures have been isolated. An interesting example is the biradical p-$C_6H_4(CNSNS)_2$, which has a polymeric structure.[103] The isomerization is a photochemically symmetry-allowed process which is thermally symmetry forbidden. It can readily be monitored by ESR spectroscopy because the 1,3,2,4-dithiadiazoles exhibit a 1:1:1 triplet, whereas the 1,2,3,5-isomers give a 1:2:3:2:1 quintet. A bimolecular head-to-tail rearrangement has been proposed to account for this isomerization.[107]

The dimer $[PhCNSSN]_2$ (**41**) reacts with a variety of zerovalent metal complexes via ligand replacement and cleavage of the S–S bond.[108] For example, reaction with $Pt(PPh_3)_3$ produces the chelated complex (**42**).



(**42**)

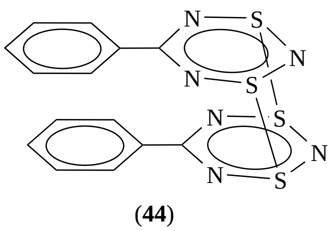


(**43**)

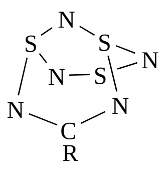
8.1.2 *Six-Membered Rings*

The thiatriazinyl system (**43**), prepared by the reduction of the corresponding S-chloro derivative, is also a 7π-electron radical. In the solid state, it exists as a cofacial dimer with an S–S distance of ca. 2.67 Å.[109] In solution, the ESR spectrum of (**43**) gives a seven-line pattern with equal hyperfine coupling constants to all three nitrogen atoms.

The dithiatriazine ring, prepared by the reduction of the corresponding S,S'-dichloro derivative, also exists as a cofacial dimer (**44**) in the solid state with an S–S separation of 253 pm.[110] MNDO calculations for the 8π-electron monomer (**44**; R = H) reveal a triplet ground state and the S–S bonds arise from intermolecular π^*–π^* interactions. The dimer (**44**) can also be prepared by reaction of the dithiadiazolyl dimer (**41**) with excited nitrogen atoms generated in a low-pressure direct current discharge.[103] Monomeric dithiatriazines can be stabilized by the formation of 1,3(S,S') adducts with electron-rich alkenes, for example, norbornadiene. The regiochemistry and kinetic control of these cycloadditions is governed by the interaction of the alkene HOMO with the LUMO of the dithiatriazine.[5]



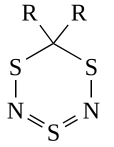
(**44**)



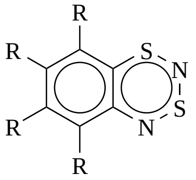
(**45**)

Bicyclic derivatives of the type RCS_3N_5 (**45**) may be prepared from S,S'-dichlorodithiatriazines (**39**) and $Me_3SiNSNSiMe_3$. ^{15}N NMR studies have demonstrated that (**45**; R = Ph) is a fluxional molecule that undergoes a series of degenerate 1,3-nitrogen shifts.[21]

1,3,5,2,4-Trithiadiazines (**46**), first obtained from S_4N_4 and diazoalkanes, are conveniently synthesized from 1,1-bis(sulfenyl chlorides) and $Me_3SiNSNSiMe_3$.[111] The 9π-electron radical $HCS_3N_2^{\bullet}$, isoelectronic with $S_3N_3^{\bullet}$, is formed on treatment of (**46**; R = H) with benzoyl peroxide.



(**46**)



(**47**)

The antiaromatic 12π-electron benzodithiadiazine (**47**; R = H), an inorganic naphthalene analogue, is obtained as a volatile deep blue solid by the reaction of $PhNSNSiMe_3$ with SCl_2, followed by an intramolecular condensation of HCl.[5] The tetrafluoro derivative (**47**; R = F) is prepared by treatment of $C_6F_5SNSNSiMe_3$ with CsF in acetonitrile. In contrast to (**47**; R = H), which has an essentially planar structure in the solid state, the dithiadiazine ring in the tetrafluoro derivative is somewhat twisted. In the gas phase, electron diffraction studies show that (**47**) (R = F) is planar, whereas (**47**) (R = H) is nonplanar.[112,113]

8.1.3 *Seven-Membered Rings*

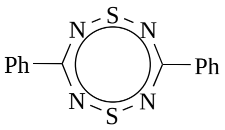
The seven-membered rings (**19**), a 1,3,5,2,4-trithiadiazepine, and (**20**), a 1,3,5,2,4,6-trithiatriazepine, are 10π-electron systems isoelectronic with $S_4N_3^+$.[50] 1,3,5,2,4-benzotrithiadiazepine is formed in 50% yield as bright yellow crystals by the reaction of benzo-1,2-bis(sulfenyl chloride) with $Me_3SiNSNSiMe_3$. The tetrafluoro analogue has been prepared by a similar procedure.[114] The isomeric 1,2,4,3,5-benzotrithiadiazepine is obtained from the reaction of $PhNSNSiMe_3$ and S_2Cl_2 followed by intramolecular cyclization.[115] The parent trithiadiazepine, (**19**; R = H), is planar and the bond lengths indicate complete π-delocalization. It is inert to protic and Lewis acids and, as befits an aromatic structure, it does not undergo cycloaddition reactions. Trithiadiazepine undergoes standard electrophilic aromatic-substitution reactions at carbon. For example, the 6-bromo and 6,7-dibromo derivatives are obtained in high yields upon treatment with N-bromosuccinimide.

The parent trithiatriazepine, (**20**; R = H), is obtained as a colorless solid of high thermal stability by carefully heating the ester, (**20**; R = CO_2Me), with aqueous HCl followed by decarboxylation of the carboxylic acid so formed. The ester has a planar, aromatic structure.

8.1.4 *Eight-Membered Rings*

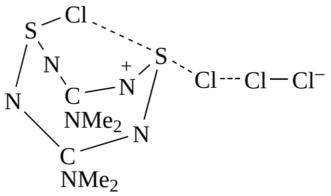
1,5-Dithiatetrazocines, $R_2C_2N_4S_2$, were first reported in 1981.[116] These eight-membered rings were prepared by the cyclocondensation of a benzamidine or dimethylguanidine with SCl_2 in the presence of a base. The yields are low and improved methods have been devised.[117] Cyclophanes containing one or two $C_2N_4S_2$ rings have also been synthesized.[118]

The structures of 1,5-dithiatetrazocines are remarkably dependent upon the nature of the group attached to carbon. With (**48**; R = Ph), the heterocyclic ring is planar and the bond lengths indicate a fully delocalized 10π-electron aromatic system (cf. $S_4N_4^{2+}$). By contrast, the bis(dimethylamino) derivative (**6**; E = Me_2NC) adopts a folded structure with d(S–S) = 243 pm. This folding is explained by the destabilizing influence of the π-donor Me_2N substituents on the HOMO of the $C_2N_4S_2$ ring and subsequent second-order Jahn–Teller distortion.[5] 1,5-Dithiatetrazocines with exocyclic N(Me)Bu groups exhibit both cis/trans and ring inversion isomerism on the NMR timescale.[119]



(**48**)

Consistent with its aromatic character, the planar ring (**48**) has high thermal stability and is chemically unreactive.[116] For example, it does not react with n-butyllithium or m-chloroperbenzoic acid and it exhibits no basic properties toward $HClO_4$. By contrast, the folded ring (**49**) is readily oxidized and provides an informative model for understanding the processes involved in the oxidation of heterocycles containing transannular S–S bonds, for example, S_4N_4.[5] Two types of stereochemistries are involved in these oxidation processes: reaction with Cl_2 or Br_2 produces an *exo–endo* geometry (as in **29**), whereas fluorination or reaction with $(CF_3)_2NO^\bullet$ results in an *exo–exo* substitution pattern. These substitution patterns are the result of polar and radical oxidation mechanisms, respectively. In electronic terms, they can be understood by viewing the S–S σ and σ^* orbitals of S_4N_4 to be isolobal with the π and π^* orbitals of an alkene. The polar oxidation route is thought to involve the attack of a halogen X_2 on the S–S σ-bonding orbital of S_4N_4. Subsequent uptake of X^- should then occur in a position trans to that of X^+.[5] The structural characterization of the asymmetrically bridged cation (**49**) provides support for the proposed polar oxidation mechanism. The addition of nucleophilic radicals, on the other hand, is considered to proceed by interaction of the SOMO of the radical with the S–S σ^*-LUMO.



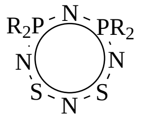
(**49**)

The folded ring system (**6**; E = Me_2NC) forms an $\eta^2 S,S'$ complex with platinum upon reaction with $Pt(PPh_3)_4$.[120]

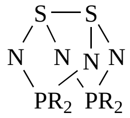
8.2 Phosphorus(V)–Sulfur–Nitrogen Rings[121]

Heterocycles of the type $R_2PS_2N_3$ (**16**) (cyclophosphadithiatriazines) are of interest as examples of 8π-electron systems. The first derivative (R = Me_3SiNH) was obtained in 1976 from the reaction of S_4N_4 with $(Me_3Si)_2NP(NSiMe_3)_2$.[122] The reaction of R_2PPR_2 (R = Me, Ph) or Ph_2PH with S_4N_4 in boiling toluene also provides a source of (**16**; R = Ph, Me), together with the eight-membered rings 1,3-$R_4P_2N_4S_2$ (**50**) and 1,5-$R_4P_2N_4S_2$ (**51**). The best route to (**16**; R = Ph) is shown in equation (21).

$$Ph_2P(NSiMe_3)(NHSiMe_3) + \tfrac{1}{2}S_4N_4 \xrightarrow[110\,°C]{\text{toluene}} Ph_2PS_2N_3 + (Me_3Si)_2NH \quad (21)$$



(**50**)

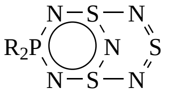


(**51**)

The compounds $R_2PS_2N_3$ are obtained as purple crystals (R = Me_3SiNH, Ph), or as a thermally unstable, purple oil (R = Me), which decomposes at room temperature to give 1,5-$Ph_4P_2N_4S_2$. The structure of (**16**; R = Ph) consists of a six-membered ring in which the phosphorus atom lies 26 pm out of the S_2N_3 plane.[123] The S–N bond lengths fall within a narrow range (156–158 pm). By contrast, the electron-donating Me_3SiNH group gives rise to localized π-bonding in the ring. Ab initio molecular orbital calculations confirm that the PS_2N_3 ring is an 8π-electron system. The purple color ($\lambda_{max} \sim 550$ nm) is attributed to the HOMO(π^*) → LUMO(π^*) transition.

The cyclophosphadithiatriazines (**16**) reversibly form white crystalline adducts with norbornadiene, where the alkene adds in a 1,3-fashion across the sulfur atoms to give the exo adduct.[123] This adduct formation provides a convenient way of characterizing the less-stable derivatives of (**16**; R = F, OPh, Me).

Bicyclic compounds of the type $R_2PS_3N_5$ (**52**) were first prepared by the reaction of PF_5 with $Me_3SiNSNSiMe_3$. They may also be obtained by the oxidative addition of Cl_2 to (**16**) followed by reaction of the *S*,*S*′-dichloro derivative with $Me_3SiNSNSiMe_3$.[39]

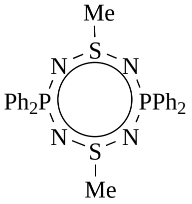


(**52**)

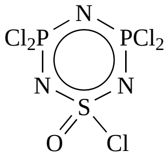
The diphosphadithiatetrazocines (**50**) and (**51**) contain one more R_2PN units in the ring than (**16**). The structure of the orange–red 1,3-isomer, (**50**; R = Ph), consists of an essentially planar S_2N_3 unit with phosphorus atoms located on opposite sides of the plane.[121] The isomer (**50**) forms a 1:1 adduct with norbornadiene via 1,3-addition across the sulfur atoms.

The 1,5-isomers (**51**) are colorless, air-stable solids. They are obtained by the cyclocondensation reaction of $R_2PN_2(SiMe_3)_3$ with sulfur dichloride or thionyl chloride. The structures of 1,5-$R_4P_2N_4S_2$ (R = alkyl, aryl) are folded eight-membered rings with a cross-ring S–S distance of ca. 250 pm. This structural feature is the result of an intramolecular $\pi^*-\pi^*$ interaction (Figure 1). It gives rise to anomalous ^{31}P NMR chemical shifts (110–140 ppm) (*see Intramolecular*) for the 1,5-isomers compared to other P–N–S rings or cyclophosphazenes. The dication $[Et_4P_2N_4S_2]^{2+}$ is planar.[124] Alkali metal derivatives of the dianion $[Ph_4P_2N_4S_2]^{2-}$ have been prepared, but not structurally characterized.[125] A methylene bridge can be inserted between the sulfur atoms of (**51**) by treatment of $Li_2[Ph_4P_2N_4S_2]$, generated from (**51**; R = Ph) and $Li[Et_3BH]$, with CH_2I_2.

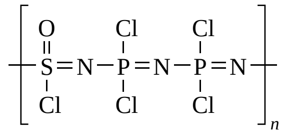
The 1,5-diphosphadithiatetrazocines (**51**) serve as excellent models for determining the identity of the initial products formed in the reactions of S–N compounds.[126] The NPR_2N units act as a brace as well as a source of structural information through ^{31}P NMR spectroscopy. Thus, in contrast to S_4N_4, the integrity of the eight-membered ring in (**51**) is retained in reactions with either electrophiles or nucleophiles. The oxidative addition of halogens occurs smoothly to give the *exo, endo* dihalogenated derivatives 1,5-$Ph_4P_2N_4S_2X_2$ (cf. **29**). Oxidative addition also occurs with platinum(0) or palladium(0) reagents to give η^2-S,S′ complexes that involve synergic metal–ligand bonding analogous to that found in the classic metal–alkene complexes (*see Dewar–Chatt–Duncanson Bonding Model*). The 1,5-diphosphadithiatetrazocines behave as weak Lewis bases in forming N-bonded adducts with protic or Lewis acids and with platinum(II). The cross-ring S–S bond is retained in these adducts. The reaction of (**51**; R = Ph) with organolithium reagents proceeds smoothly to the lithium derivatives $Li[Ph_4P_2N_4S_2R]$. The reaction of $Li[Ph_4P_2N_4S_2Me]$ with MeI gives the *S*,*S*′-dimethyl derivative (**53**).



(**53**)

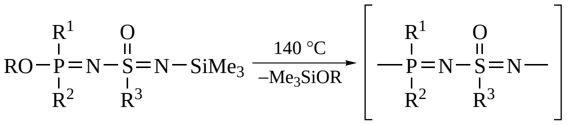


(**54**)



(**55**)

Six-membered rings containing two phosphorus atoms and one four-coordinate sulfur atom (**54**) have been known since 1972.[127] An ambient temperature reaction of (**54**) with $GaCl_3$ produces the high molecular weight poly(thionylphosphazene) (**55**) via ring-opening polymerization.[128] Subsequent reaction of (**55**) with *n*-$BuNH_2$ yields the hydrolytically stable polymer, $[NSO(NHBu)\{NP(NHBu)_2\}_2]_n$. Polymers with backbones of alternating S(O)=N and P=N units are prepared via a condensation route (equation 22).[129]

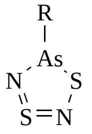


(22)

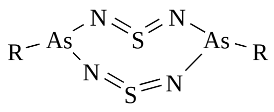
8.3 Phosphorus(III)–and Arsenic(III)–Sulfur–Nitrogen Compounds

The RP^{III} and RAs^{III} groups are isoelectronic with a sulfur atom as a substituent in an S–N ring. Thus, it is reasonable to expect that ring systems where sulfur atoms have been replaced by these groups will exist. The first examples $MeAsN_2S_2$ (**56**; R = Me) and $(MeAs)_2N_4S_2$ (**57**; R = Me) were reported in 1970.[130] The SN_2^{2-} anion has been used to prepare the acyclic arsenic(III) derivative *t*-$Bu_2AsNSNAs$-*t*-Bu_2, and the eight-membered ring (**57**; R = *t*-Bu) from *t*-Bu_2AsCl and *t*-$BuAsCl_2$ respectively.[64] The S–N bond lengths in the boat-shaped ring (**57**; R = *t*-Bu) are typical of a sulfur diimide. Phosphorus(III) derivatives of the type $R_2PNSNPR_2$ are only stable if R is a bulky group such as *t*-butyl or if the phosphorus atoms are coordinated to a transition metal. The eight-membered ring $(RP)_2N_4S_2$ has been obtained in transition metal complexes, for example (**58**), in which the $P_2^{III}N_4S_2$ is essentially planar with localized sulfur diimide bonding.[131] Six-membered rings of the type RPNSNSNH

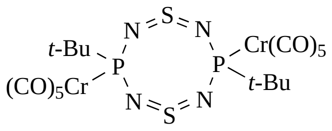
have also been structurally characterized in transition metal complexes, for example, (**59**).[64,126]



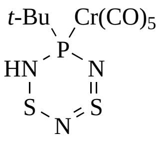
(**56**)



(**57**)



(**58**)



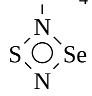
(**59**)

8.4 Sulfur–Nitrogen–Selenium Compounds

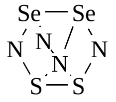
S–N compounds containing selenium provide an important bridge between binary S–N systems and their less-stable Se–N analogs (*see* ***Selenium: Inorganic Chemistry***). The compound $Se(NSO)_2$, prepared from a 1:1 mixture of Me_3SiNSO and selenium monochloride, is an important source of S–N–Se compounds.[132] For example, the reaction of $Se(NSO)_2$ with $TiCl_4$ produces the adduct $SeSN_2{\cdot}TiCl_4$ (**60**) and treatment with $POCl_3$ yields $SSe_2N_2Cl_2$. The acyclic reagent, $Me_3SiNSNSeNSNSiMe_3$, is prepared from $Me_3SiNSNSiMe_3$ and $SeCl_2$ (equation 23).[133] It can be used to prepare 1,5-$S_2Se_2N_4$ (**61**) (equation 24).

$$2Me_3SiNSNSiMe_3 + SeCl_2 \longrightarrow Me_3SiNSNSeNSNSiMe_3 + 2Me_3SiCl \quad (23)$$

$$Me_3SiNSNSeNSNSiMe_3 + SeCl_2 \longrightarrow 1{,}5\text{-}S_2Se_2N_4 + 2Me_3SiCl \quad (24)$$



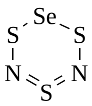
(**60**)



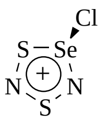
(**61**)

On the basis of vibrational and ^{77}Se NMR spectra, the hybrid sulfur/selenium nitride SeS_3N_2 has a cyclic structure in which the selenium atom is linked to two sulfur atoms (**62**).[134]

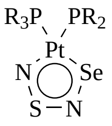
The five-membered ring $[S_2SeN_2Cl]^+$ (**63**) can be used to prepare platinum complexes of the $SSeN_2^{2-}$ anion (**64**) by treatment with *cis*-$PtCl_2(PR_3)_2$ in liquid ammonia.[6]



(**62**)



(**63**)



(**64**)

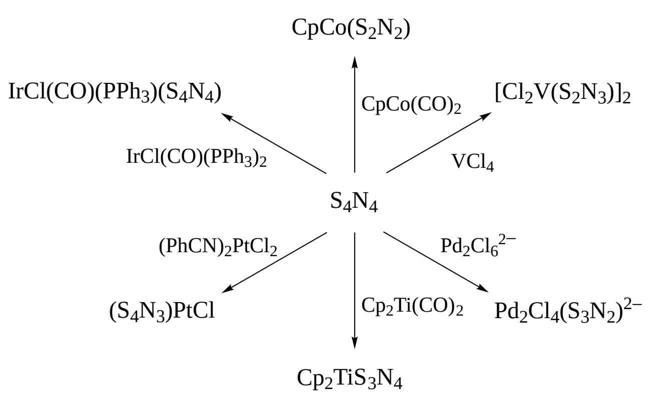
Salts of the sulfur–nitrogen–selenium cation radicals $[S_nSe_{3-n}N_2]^{+\bullet}$ ($n = 1,2$) have dimeric structures similar to that of $S_6N_4^{2+}$ (**7**).[135,136]

8.5 Cyclometallathiazenes[6,7]

A cyclometallathiazene is a ring system consisting of only sulfur, nitrogen, and one (or more) metal atoms. As indicated in Table 1, cyclometallathiazenes can formally be considered as complexes between cationic metal fragments and binary S–N anions where, with the exception of the $S_2N_2H^-$ and $S_4N_4^{2-}$ ions, both the sulfur and nitrogen atoms are two coordinate (*see* ***Mixed Donor Ligands***).

Since only two of these ions, S_3N^- and SN_2^{2-}, have been isolated as salts, the synthesis of cyclometallathiazenes usually employs S_4N_4 (**1**) as a source of the S–N fragment. Some representative examples are shown in Scheme 7.

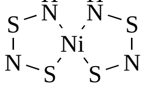
Complexes containing the $S_2N_2H^-$ ion comprise the best-characterized group of cyclometallathiazenes. The dark green nickel derivative $Ni(S_2N_2H)_2$ (**65**) is readily obtained in ca. 60% yields from the reaction of S_4N_4 with anhydrous $NiCl_2$ in methanol. The MS_2N_2H units in these complexes are planar. Compounds of the type $[Pt(S_2N_2H)(PR_3)_2]X$ are especially interesting since they form continuous stacking structures.[6] The NH groups in $M(S_2N_2H)$ complexes are readily deprotonated to give anions which can be converted to organic derivatives by treatment with organic halides.[7]



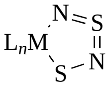
Scheme 7 Preparation of cyclometallathiazenes from S_4N_4

Table 1 Cyclometallathiazenes

Ring system	Corresponding S–N anion	Metal	Year of discovery (first X-ray structure)
	$S_2N_2^{2-}$	Co, Ir, Ni, Pd, Pt (Pb)	1982 (1982)
	$S_2N_2^{4-}$	Re	1984 (1984)
	$[S_2N_2H]^-$	Co, Ni, Pd, Pt	1953 (1958)
	S_3N^-	Co, Ni, Pd, Pt, Cu, Ag, Au	1958 (1966)
	$S_2N_3^-$	Pd	1992 (1992)
	$S_2N_3^{3-}$	V, Mo, W	1983 (1983)
	$S_3N_4^{2-}$	Ti	1983 (1983)
	$S_4N_3^-$	Pt	1981 (1981)
	SN_2^{2-}	Hg, Zr, Hf	1904 (1984)
	$S_3N_2^{2-}$	Pd	1966 (1982)
	$S_4N_4^{2-}$	Ir, Pt	1970 (1986)



(**65**)



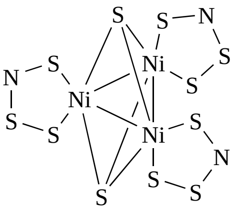
(**66**)

In addition to S_4N_4, a variety of S–N reagents, including $S_3N_3^-$, $S_4N_4H_4$/diazobicycloundecene, $[Me_2Sn(S_2N_2)]_2$, and solutions of $[S_4N_3]Cl$ in liquid ammonia, provide a source of $S_2N_2^{2-}$ for metal complexes. X-Ray structural data for MS_2N_2 complexes (**66**) indicate a localization of π-bonding within the NSN unit. The MS_2N_2 complexes are readily protonated at the nitrogen atom attached to the metal (equation 25).

$$Pt(S_2N_2)(PR_3)_2 + HBF_4 \longrightarrow [Pt(S_2N_2H)(PR_3)_2]BF_4 \quad (25)$$

The first metal complex of the S_3N^- anion, $Ni(S_3N)_2$, was obtained in 0.04% yield (9 mg) from $NiCl_2$ and S_4N_4 (10 g) in methanol and correctly identified.[137] Such complexes are now

obtained in acceptable yields via deprotonation of S_7NH in the presence of metal halides or by using the mercury complexes $Hg(S_7N)_2$ or $PhHg(S_7N)$ as a source of S_3N^-.[7] The formation of the trigonal bipyramidal anion $\{[Ni(S_3N)]_3S_2\}^-$ (**67**) by the former process is of particular interest.[138] In the $Cu(S_3N)(S_7N)^-$ anion, the S_7N ring is (partly) preserved and coordinated to copper through the nitrogen atom.[139]



(**67**)

Reaction of high-oxidation state early-transition metal halides with S_4N_4, $(NSCl)_3$, or $[S_3N_2Cl]Cl$ generates the MS_2N_3 ring, for example, $[VCl_2(S_2N_3)]_n$, which may be viewed as a complex of the $S_2N_3{}^{3-}$ trianion.[140] The thiazene segment of the ring in MS_2N_3 is usually planar but, in some cases, the metal is tilted out of this plane. Complexes of the monoanion $S_2N_3{}^-$ can be obtained by the reactions of $[PPh_4]_2[Pd_2Cl_6]$ with S_5N_6 or, preferably, $Me_3SiNSNSNSNSiMe_3$.[52] The electronic structures of cyclometallathiazenes have been investigated by Density Functional Theory (DFT) calculations.[141]

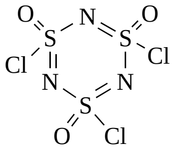
Coordination of the dianion, $S_4N_4{}^{2-}$, as a tridentate ligand has been established in a few cases.[6] The complexes $IrCl(CO)(S_4N_4)PPh_3$[142] and $PtCl_3(S_4N_4)^-$[143] contain this ligand *facially* bonded to the metal through one nitrogen and two sulfur atoms (see Table 1). By contrast, the same ligand adopts a *meridional* (S,S,N) geometry in the complex $PtCl_2(S_4N_4)(PMe_2Ph)$, which according to ^{15}N NMR investigations, is converted to a *facial* S,N,N isomer in boiling chloroform (*see* ***Coordination Numbers & Geometries***).[144]

9 SULFANURIC COMPOUNDS[39]

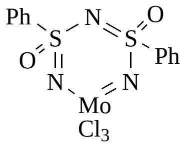
These compounds contain the characteristic group –N=S(O)X– (where X = Cl, F, alkyl, aryl, or R_2N). Unlike the isoelectronic cyclophosphazenes, only six-membered rings have been well characterized. The sulfanuric halides are colorless solids (X = Cl) or liquids (X = F), which are stable in dry air. Sulfanuric chloride is best prepared by treatment of $SOCl_2$ with sodium azide (equation 26). It may also be obtained as a mixture of α- and β-isomers in a two-stage reaction from H_2NSO_3H and PCl_5. The fluoride, $[NS(O)F]_3$, is formed as a mixture of isomers by the fluorination of $[NS(O)Cl]_3$ with SbF_3.

$$SOCl_2 + NaN_3 \xrightarrow[-35\,°C]{MeCN} \frac{1}{3}[NS(O)Cl]_3 + NaCl + N_2 \qquad (26)$$

The isomer α-$[NS(O)Cl]_3$ (**68**) is a six-membered ring in the chair form with equal S–N bond lengths of 157 pm. The three chlorine atoms are in axial positions on the same side of the ring. The β-isomer has one equatorial and two axial chlorine atoms.[145] The metal-containing sulfanuric ring system (**69**) has been prepared from $PhS(O)N(SiMe_3)_2$ and $ClNMoCl_4$.[146]



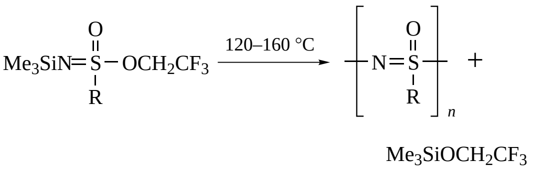
(**68**)



(**69**)

The fluoride $[NS(O)F]_3$ is more stable thermally and toward nucleophilic reagents than the corresponding chloride. For example, α-$[NS(O)Cl]_3$ is hydrolyzed by water to $NH(SO_2NH_2)_2$, whereas sulfanuric fluoride is unaffected by cold water. In warm water, however, hydrolysis occurs to give the $N_3S_3O_4F_2{}^-$ ion. All three fluorine atoms in $[NS(O)F]_3$ can be replaced by primary or secondary amines at 80–90 °C in the absence of a solvent.

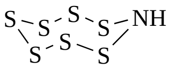
High molecular weight polymers containing repetitive [N=S(O)R] (R = Me, Ph) units have been characterized.[147] These polymers are produced by the condensation process shown in equation (27).



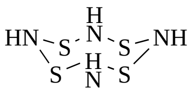
(27)

10 CYCLIC SULFUR IMIDES[10,39]

The best-known cyclic sulfur imides are saturated sulfur–nitrogen heterocycles, which are derived from *cyclo*-S_8 by the replacement of one or more sulfur atoms by an amido (NH) group. Derivatives containing adjacent NH groups are not found. Thus, the members of this series consist of S_7NH (**70**), three diimides 1,3-, 1,4- and 1,5-$S_6(NH)_2$, two triimides 1,3,5- and 1,3,6-$S_5(NH)_3$, and $S_4N_4H_4$ (**71**).



(**70**)



(**71**)

The standard preparation of cyclic sulfur imides, with the exception of $S_4N_4H_4$, involves the reaction of S_2Cl_2 with ammonia in DMF at ca. $-10\,°C$, followed by hydrolysis with cold dilute hydrochloric acid. This method gives mainly S_7NH, but the three diimide isomers and very small amounts of 1,3,6-$S_5(NH)_3$ can be separated by chromatography of CS_2 solutions on silica gel. The reaction of sodium azide with elemental sulfur in $(Me_2N)_3PO$ is an excellent source of S_7NH, and it has been used for making a ^{15}N-enriched product. Both these methods proceed via the formation of the deep blue S_4N^- ion for the synthesis of S_7NH.[39] The reduction of S_4N_4 by hydrazine in CCl_4 is the only useful route to 1,3,5-$S_5(NH)_3$. The tetraimide $S_4(NH)_4$ is best prepared from S_4N_4 by using methanolic $SnCl_2{\cdot}2H_2O$ as the reducing agent.

The cyclic sulfur imides form colorless, air-stable crystals, which undergo slow photochemical decomposition to give elemental sulfur. They all adopt the crown configuration of *cyclo*-S_8 with S–S bond lengths in the range 204–206 pm.[10] The S–N bond distances (166–168 pm) are significantly shorter than a S–N single bond and the geometry around the nitrogen atoms is almost planar, indicating three-center π-bonding in the –S–N(H)–S– units. Electron deformation density measurements of (**71**) indicate bent S–N bonds with endocyclic maxima.[148]

TLC (thin layer chromatography) gives a quick indication of the composition of a mixture of imides. IR spectroscopy provides a better method for the analysis of such mixtures. The IR spectra of CS_2 solutions exhibit bands in the S–N stretching region (775–840 cm^{-1}) that are characteristic of the individual imides. The characteristic ^1H and ^{15}N NMR chemical shifts of all the imides have been determined by the HMQC method.[149] The values of $^1J(^{15}N\text{–}^1H)$ fall within the narrow range 93–96 Hz, consistent with sp^2-hybridized nitrogen atoms.

The cyclic sulfur imides are weak Brønsted acids that are readily deprotonated by strong bases. In the case of S_7NH, deprotonation produces the thermally unstable, yellow S_7N^- ion, which decomposes to the deep blue S_4N^- ion (equation 28).[20] Some covalent derivatives of S_7N^- have been isolated.[10] The most important are the mercury(II) compounds, $PhHgS_7N$ and $Hg(S_7N)_2$.

$$S_7NH + Bu_4NOH \xrightarrow{-78\,°C} [Bu_4N][S_7N] \xrightarrow{>-50\,°C} [Bu_4N][S_4N] + \frac{3}{8}S_8 \qquad (28)$$

Both S_7NH and the $S_6(NH)_2$ isomers decompose above their melting points to give mainly S_4N_4 and S_8. These cyclic sulfur imides readily undergo condensation reactions with sulfur halides in the presence of a base. For example, the reaction of S_7NH with dichlorosulfanes produces the series $(S_7N)_2S_x$ (x = 1, 2, 3, 5) and the treatment of 1,3-$S_6(NH)_2$ with S_5Cl_2 generates small amounts of the bicyclic compound $S_{11}N_2$.[10]

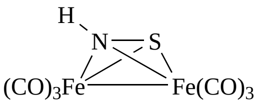
Complexes of the type $(S_4N_4H_4)M(CO)_5$ (M = Cr, W), in which the ligand is bonded to the metal by a sulfur atom, are formed by the reaction of the tetraimide with $(THF)M(CO)_5$ (*see* ***Carbonyl Complexes of the Transition Metals***).[7] The deprotonation of $S_4N_4H_4$ with strong bases produces the $S_2N_2H^-$ ion and, subsequently, $S_3N_3^-$.[19] Ring fragmentation also occurs in the reaction of $S_4N_4H_4$ with $Pt(PPh_3)_4$ to give $Pt(PPh_3)_2(S_2N_2)$.[6,7]

Nine- and ten-membered sulfur imides, S_8NH and S_9NH, respectively, are prepared by the oxidative addition of S_7NH to $Cp_2Ti(CO)_2$ to give $[Cp_2Ti(S_7NH)]$ followed by treatment with the appropriate dichlorosulfane (equation 29).[150] The structure of S_8NH is similar to that of *cyclo*-S_9 (*see* ***Sulfur: Inorganic Chemistry***), whereas the structure of S_9NH resembles the crown structure of *cyclo*-S_8 with the insertion of a SN(H) unit.

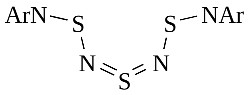
$$[Cp_2Ti(S_7NH)] + S_xCl_2 \longrightarrow Cp_2TiCl_2 + S_{7+x}NH\ (x = 1, 2) \qquad (29)$$

Six- and seven-membered sulfur imides, S_5NR and S_6NR (R = n-Oct), are obtained as yellow oils from $[Cp_2Ti(\mu\text{-}S_2)_2NR]$ and S_xCl_2 (x = 1, 2) by using the methodology shown in equation (29).[151] Molecular ions were observed in the EI mass spectra.

Monomeric sulfur imide SNH is not known, but a coordination compound $Fe_2(CO)_6(HNS)$ (**72**) has been isolated and converted to the corresponding anion $[Fe_2(CO)_6(\mu\text{-}SN)]^-$ with n-BuLi.[152] The complex (**72**) is obtained from the reaction of $Fe_3(CO)_{12}$ with $Me_3SiNSNSiMe_3$, followed by chromatography on silica. The HNS unit behaves as a six-electron ligand (*see Counting Electrons*). Mononuclear complexes of the type $(RNS)Cr(CO)_5$ (R = Me_2N, Ph_2N), in which the ligand is bonded to the metal via sulfur, have also been structurally characterized.[140]



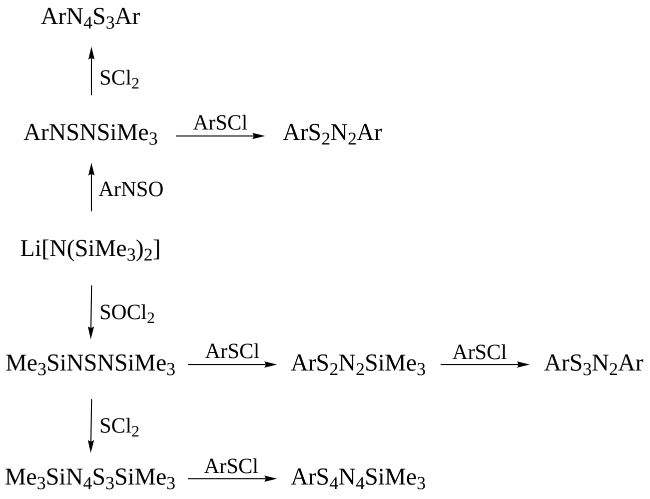
(**72**)



(**73**)

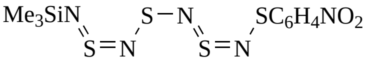
11 SULFUR–NITROGEN CHAINS AND POLYMERS[153]

The unusual properties of the polymer $(SN)_x$ have sparked interest in S–N polymers with organic groups in the backbone as well as S–N chains with terminal organic residues. The first reports of such S–N chains described the preparation of trithiadiazenes ArS_3N_2Ar (**73**), which adopt planar (cis, cis) conformations.[154,155] Since then, rational syntheses have been developed for chain lengths up to ArS_5N_4Ar (Ar = aryl) via condensation reactions involving the elimination of Me_3SiCl or $Me_3SiOSiMe_3$ (see Scheme 8).

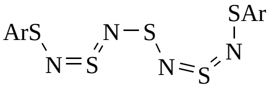


Scheme 8 Preparation of S–N chains

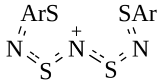
These S–N chains may be considered as small fragments of $(SN)_x$. In contrast to $(SN)_x$, however, they exhibit alternating long and short S–N bonds, as depicted in the structures of $Me_3SiN_4S_4C_6H_4NO_2$ (**74**) and ArS_5N_4Ar (**75**), consistent with a more localized structure. Cationic S–N chains, for example, $[ArS_4N_3Ar]^+$ (**76**), are also known.[156] Continuing interest in these oligomeric materials stems from their optical properties and possible applications as molecular wires. In general, the shorter chains tend to be brightly colored, yellow or orange, whereas the longer chains produce intense deep green, blue, or purple solutions and in the solid state, they have a metallic luster.



(**74**)



(**75**)



(**76**)

Conducting polymers with *p*-phenylene groups in the backbone can be prepared by the metathetical reaction shown in equation (30).[157] Doping of these polymers with acceptors such as I_2, Br_2, or AsF_5 increases the conductivity to ca. $10^{-4}\Omega^{-1}\,cm^{-1}$.

$$Me_3SiNSNC_6H_4NSNSiMe_3 + SCl_2 \longrightarrow \frac{1}{x}\,[\text{–}C_6H_4NSNSNSN\text{–}]_x \qquad (30)$$

Polymers with $–C_6H_4SNSNSC_6H_4–$ or $–C_6H_4SNSNS\,C_6H_4SNSNSC_6H_4–$segments separated by flexible spacer groups have also been synthesized.[158] These insulators are converted to semiconductors (*see* ***Semiconductors***) when doped with Br_2.

12 POLY(SULFUR NITRIDE)[2]

Polymeric sulfur nitride (or polythiazyl) (**2**) was first reported in 1910. It is prepared by the solid-state polymerization of S_2N_2 at 0 °C over several days (see Section 5.1.3).[159] The polymer is also obtained in high yield from the reaction of $(NSCl)_3$ with trimethylsilyl azide in acetonitrile or by the electrochemical reduction of $S_5N_5{}^+$ salts.

Poly(sulfur nitride) is a shiny metallic solid consisting of highly oriented parallel fibers. The crystal structure reveals an almost planar cis,trans-polymer (**2**) with adjacent S–N bond lengths of 163 and 159 pm. The conductivity of $(SN)_x$ at room temperature along the fibers ($\sigma\|$) is $1–4 \times 10^3\Omega^{-1}\,cm^{-1}$ depending on the quality of the crystals, and this value increases by about two orders of magnitude at 4 K. The conductivity across the fibers ($\sigma\perp$) is much smaller. Typical values of the anisotropy ratio $\sigma\|/\sigma\perp$ are $\approx$50 at room temperature and $\approx$1000 at 40 K. The metallic properties of $(SN)_x$ are attributed to a half-filled conducting band.[2] Single crystals of $(SN)_x$ have been investigated as an electrode material.[160]

Partial bromination of $(SN)_x$ or powdered S_4N_4 with bromine vapor yields the blue–black polymer $(SNBr_{0.4})_x$ which has a room temperature conductivity of $2 \times 10^4\Omega^{-1}\,cm^{-1}$.[2] The bromine in this polymer is present as $Br_3{}^-$ ions and intercalated Br_2 molecules. The polymer $(SNBr_{0.4})_x$ is also prepared by the reaction of $(NSCl)_3$ with Me_3SiBr in CH_2Cl_2 at $-60\,°C$. Similar highly conducting, nonstoichiometric polymers can be obtained by treating S_4N_4 with ICl, IBr, or I_2.

1 INTRODUCTION

By definition, sulfanes or polysulfanes are compounds of type X–S_n–X with $n = 1, 2, \ldots$ and X being a univalent group such as hydrogen (sulfanes), halogen (halosulfanes), organic radical R (organic polysulfanes), and so on. In a certain sense, even elemental sulfur may be called a polysulfane, for example, S_8 is *cyclo*-octasulfane. H_2S_3 is termed trisulfane and S_2Cl_2 is dichlorodisulfane. Numerous compounds of these types are known since sulfur atoms tend to form homoatomic chains and rings owing to the high S–S bond energy (265 kJ mol^{-1}).[1–2] Table 1 presents an overview of which chain lengths or ring sizes have so far been observed for various polysulfane derivatives (*see* ***Sulfur: Inorganic Chemistry***).

The organic polysulfanes described in this article are compounds of the type R–S_n–R with $n > 2$; they may be chain-like or cyclic. The organic residues (alkyl or aryl) are linked to the sulfur chain via carbon atoms. These compounds are also known as organic polysulfides.

Sulfur-rich organic polysulfanes can be viewed as intermediate between organic and inorganic compounds. On one hand, they are characterized by organic substituents R, which terminate the sulfur chain or close this chain to form a ring. On the other hand, sulfur chains of three or more sulfur atoms are 'inorganic' enough to attract the interest of inorganic chemists who have contributed much to this area. Organic polysulfanes with up to 35 sulfur atoms in a chain have been prepared in mixtures, but only those with up to 16 atoms have been obtained as pure substances. The correct nomenclature for the compounds, R–S_n–R, is bis(organyl)polysulfanes. In this article, the more convenient term organic polysulfane will also be used. Mono(organyl)polysulfanes, R–S_n–H, are sometimes termed hydropersulfides or hydrodisulfides if $n = 2$. Organylchlorosulfanes, R–S_n–Cl, are homologs of the sulfenyl chlorides R–S–Cl and will be summarized under the latter name for the sake of brevity. In the older literature, they are also termed thiosulfenyl chlorides or chloro disulfides if $n = 2$. The International Union of Pure and Applied Chemistry (IUPAC) nomenclature is, however, always based on the name sulfane even for derivatives such as R_2S and R–S–Cl.

Organic polysulfanes, which play an important role in basic research and industry, are found as natural products in organisms and occur in the inanimate world. In the latter case, they are partly of biotic, partly of abiotic (geochemical) origin and are widespread in sulfur-rich fossil fuel. Some of the polysulfanes produced by algae, mushrooms, or ascidians show biological activity that makes them interesting for the pharmaceutical industry. The main importance of organic polysulfanes comes, however, from their role in the large scale industrial vulcanization of natural and synthetic rubber with elemental sulfur, which in the early stages of the reaction results in sulfur-rich polysulfanes as will be described later.

Since the chemistry of organic polysulfanes is closely related to their oxidized derivatives, Table 2 presents the well-characterized species with up to three sulfur atoms in the chain. The systematic nomenclature based on the IUPAC recommended name *sulfanes* is also given in Table 2. In addition, conventional names for some of these compounds are shown in brackets.

In this article, we will review the preparation, structure, modern analysis, basic reactions, natural occurrence, biological activity, and practical importance of organic polysulfanes with three or more neighboring sulfur atoms in a chain or ring. Previous reviews have also included disulfanes (R_2S_2) and the emphasis was usually on the latter. The preparation of R_2S_n ($n > 2$) was reviewed by Schöberl and Wagner[3] in 1955, by Wilson and Buchanan[4] in 1976, by Field[5] in 1977, and by Gundermann and Humke[6] in 1985. Laur[7] summarized the stereochemistry of (mainly) organic sulfur compounds in 1972. The analytical chemistry or organic polysulfanes was reviewed by Cardone[8] 1972. Reid[9] published a list of 76 organic polysulfanes ($n > 2$) known in 1960. A brief account on inorganic and organic polysulfanes by Pickering and Tobolsky[10] appeared in 1972. The most recent and most comprehensive review on organic polysulfanes was published in 2002 by Steudel (390 refs.).[11] Progress in the area of trisulfanes and their oxides has been reviewed by Clennan and Stensaas in 1998.[12]

Organometallic polysulfanes such as 1,2,3-trithia-[3]ferrocenophane have not been included in this article; their chemistry has been reviewed elsewhere.[12]

Table 1 Size of sulfur rings and chains

		Isolated	NMR, HPLC evidence	Indirect evidence
cyclo-Sulfanes	S_n:	6...20	up to 30	up to 80
Sulfanes	H–S_n–H	1...8	up to 35	–
Chlorosulfanes	Cl–S_n–Cl	1...8	up to 55	–
Organylsulfanes	R–S_n–R	1...9	up to 35	–
Polythionates	$^-O_3S–S_n–SO_3^-$	1...4	up to 22	up to 50
Polysulfides	S_n^{2-}	1...9	...	–
Sulfanemonosulfonates	$^-S_n–SO_3^-$	1	–	2...13
Bunte salts	R–S_n–SO_3^-	1	–	2
Organylpolysulfides	R–S_n^-	1	2	–

Table 2 Nomenclature of polysulfanes and their oxidized derivatives (trivial names are given in parentheses)

R–S–R Monosulfane (sulfide)	R–S–S–R Disulfane (disulfide)	R–S–S–S–R Trisulfane (trisulfide)
R–S(O)–R Monosulfane oxide (sulfoxide)	R–S(O)–S–R Disulfane monoxide (thiosulfinate)	R–S(O)–S–S–R Trisulfane 1-oxide
R–S–O–R Sulfenate	R–S(O)–S(O)–R Disulfane 1,2-dioxide	R–S(O)–S–S(O)–R Trisulfane 1,3-dioxide
R–S(O)–O–R Sulfinate	R–S(O_2)–S–R Disulfane 1,1-dioxide	R–S–S(O)–S–R Trisulfane 2-oxide (dithiosulfite)
R–S(O_2)–O–R Sulfonate	R–S–SO_3^- Thiosulfate (Bunte salt)	R–S(O_2)–S–S–R Trisulfane 1,1-dioxide (sulfenylthiosulfonate)
	R–S–S–SO_3^- Disulfanemonosulfonate	R–S(O_2)–S–S(O_2)–R Trisulfane 1,1,3,3-tetroxide

2 SYNTHESIS OF ORGANIC POLYSULFANES

There are numerous reactions to prepare organic polysulfanes, which will be grouped in several sections according to the reagents used. Although there is normally no difference in principle between the preparation of chainlike and cyclic polysulfanes $R_2–S_n$, for convenience, the two types will be treated separately. Which method to choose for the synthesis of a particular polysulfane will depend on the available reagents, on the chemical reactivity of the organic group R, on the possibility of separating the reaction mixture to produce pure substances, and on the amount of material needed. The following list of synthetic procedures is in arbitrary order and should not be taken as a measure of relative importance or general applicability.

2.1 Chainlike Organic Polysulfanes

2.1.1 Reaction of Thiols, Thiolates, or Monoorganylsulfanes with Dichlorosulfanes

Alkyl and aryl polysulfanes may be prepared by the classical reactions (equations 1–3).[3–6,13]

$$2RSH + S_xCl_2 \longrightarrow R–S_n–R + 2HCl \quad (1)$$

$$2RSM + S_xCl_2 \longrightarrow R–S_n–R + 2MCl \quad (2)$$

$$2RS_yH + S_xCl_2 \longrightarrow R–S_n–R + 2HCl \quad (3)$$

However, since only SCl_2 and S_2Cl_2 are easily available, equations (1) and (2) are primarily used to make tri- and tetrasulfanes. Sulfur-rich dichlorosulfanes S_xCl_2 ($x > 2$) may be synthesized in analogous reactions from H_2S, H_2S_2, or H_2S_3 and excess SCl_2 or S_2Cl_2 (equation 4).

$$2Cl–S_x–Cl + H–S_y–H \longrightarrow Cl–S_{2x+y}–Cl + 2HCl \quad (4)$$

The longer-chain species S_xCl_2 ($x = 6–8$) are best prepared by ring-opening chlorination of *cyclo*-S_n ($n = 6–8$) with Cl_2 in CCl_4 at 0 °C (equation 5).[14–16]

$$cyclo\text{–}S_n + Cl_2 \longrightarrow Cl–S_n–Cl \qquad n = 6–8 \quad (5)$$

Reactions 1 and 3 are usually carried out in dry ether, or in a nonpolar solvent in the presence of a tertiary amine such as pyridine to bind HCl.[17–21] In reaction 2, lead thiolates have been found to be very useful.[4,6]

Substituted phenyl trisulfanes $(4\text{-}R'C_6H_4)_2S_3$ with R′ = NO_2, MeCO, EtOCO, MeS, MeO, and even NH_2 have been prepared by reaction 1. Since amino groups would also be attacked by SCl_2, this reaction was carried out in anhydrous acetic acid, resulting in protonation of the –NH_2 group to –NH_3^+, which is less reactive towards SCl_2.[21] The bisacetate obtained is converted to bis(4-aminophenyl)trisulfane by reaction with sodium hydroxide.[21]

Bifunctional thiols react with dichlorosulfanes to give cyclic organic polysulfanes (Section 2.2.1).

Reaction 2 has also been used to synthesize polysulfanes of thiocarbonic acids,[22,23] alkoxythiocarbonic acids,[24–27] (alkylthio)thiocarbonic acids,[24–26] or of alkoxydithiocarbonic acids (xanthates[28–31]) (reactions 6–8 with M = H, Na, K and $n = x + 2$).

$$2R–C(O)–SM + S_xCl_2 \longrightarrow R–C(O)–S_n–C(O)–R + 2MCl \quad (6)$$

$$2RO–C(O)–SM + S_xCl_2 \longrightarrow RO–C(O)–S_n–C(O)–OR + 2MCl \quad (7)$$

$$2RO–C(S)–SM + S_xCl_2 \longrightarrow RO–C(S)–S_n–C(S)–OR + 2MCl \quad (8a)$$

$$2RS–C(O)–SM + S_xCl_2 \longrightarrow RS–C(O)–S_n–C(O)–SR + 2MCl \quad (8b)$$

It should be noted that the polysulfanes obtained by equations (8a and 8b) are isomeric.

The monoorganylpolysulfanes RS_yH needed for equation (3) may be prepared from organylacylpolysulfanes by alcoholysis (equation 9, $n = 2$ or 3).[32]

$$R–C(O)–S_n–R' + R''OH \longrightarrow R'–S_n–H + RC(O)–OR'' \quad (9)$$

2.1.2 *Reaction of Thiols or Monoorganylpolysulfanes with Sulfenyl Chlorides*

The condensation of thiols or monoorganylsulfanes with sulfenyl chlorides, usually carried out in dry ether at 20 °C, allows the synthesis of symmetrically or unsymmetrically substituted polysulfanes. R and R′ may be alkyl, aryl, or acyl groups;[4,6] yields can be as high as 90%.

CF_3SSH reacts at 20 °C without solvent with CF_3SCl to give $(CF_3)_2S_3$, and with CF_3SSCl to yield $(CF_3)_2S_4$.[33] Unsymmetrical trisulfanes with various alkyl and aryl substituents[34–36] have been synthesized by equation (10), and bis(sulfenyl chlorides) react similarly.[37]

$$R–S_x–H + Cl–S_y–R' \longrightarrow R–S_n–R' + HCl$$
$$x = 1, 2, \ldots;\ y = 1, 2, \ldots \quad (10)$$

The sulfenyl chlorides[4] and their homologs needed for reaction 10 may be prepared by reactions (11–13). For the synthesis of alkoxycarbonyl compounds,[38] reactions (14–16) can be applied.

$$RSH + Cl_2 \longrightarrow RSCl + HCl \quad (11)$$

$$RSH + SCl_2 \longrightarrow RS_2Cl + HCl \quad (12)$$

$$RSH + S_2Cl_2 \longrightarrow RS_3Cl + HCl \quad (13)$$

$$RC(O)SCl + RC(O)SH \longrightarrow [RC(O)]_2S_2 + HCl \quad (14)$$

$$[RC(O)]_2S_2 + Cl_2 \longrightarrow RC(O)S_2Cl + RCOCl \quad (15)$$

$$RC(O)S_2Cl + R'SH \longrightarrow RC(O)S_3R' + HCl \quad (16)$$

Since the latter polysulfanes react with thiols in the presence of a base according to equation (17), they have been used to synthesize various unsymmetrical trisulfanes in good yields (25–100%).[39]

$$MeO–CO–S_3–R + R'SH \longrightarrow R–S_3–R' + MeOH + COS \quad (17)$$

Since the reaction conditions (−78 to 0 °C; base: *N*-methylmorpholine, aniline, or *N*,*N*-dimethylaniline) are mild, even trisulfanes with unsaturated (allyl) or functionalized (–OH, $–NH_2$, $–CO_2H$) substituents may be prepared.[39]

2.1.3 *Reaction of Sulfenyl Halides with H_2S, H_2S_2, or Their Salts*

Aryl- and alkyltri- and -tetrasulfanes may be obtained in good yields by reactions of the type in equation (18).[4,6] 2-Nitrophenylsulfenyl bromide or related RSBr compounds react at 20 °C in benzene with HgS, PbS, Ag_2S, or Tl_2S to give the corresponding trisulfanes in a 80–100% yield.[40] Use of H_2S in ether, acetic acid, dioxane, or ethyl acetate produces the trisulfanes in lower yield.[41] Liquid CCl_3SCl reacts in low-yield with H_2S at 20 °C to give $(CCl_3)_2S_3$ and with H_2S_2 at 85 °C to yield $(CCl_3)_2S_4$; both polysulfanes form colorless crystals.[41]

$$2R–S–X + M_2S_x \longrightarrow R–S_n–R + 2MX_x$$
$$X = Cl, Br;\ M = H, Na, Ag, Hg, Tl, Pb;\ x = 1, 2 \quad (18)$$

Bis(alkoxycarbonyl)polysulfanes ($n = 3$, 4) have been prepared from the sulfenyl chlorides ROC(O)SCl with H_2S_x ($x = 1, 2$)[24–26] or Na_2S_x ($x = 1, 2$).[24–26] It is, however, usually observed that equation (18) does not proceed in a clean way to give the tri- or tetrasulfane in high yield but, owing to secondary interconversion reactions catalyzed by SH compounds or sulfide ions (see Section 5.3), results in complex mixtures of polysulfanes R_2S_n, which can be detected by LC[42] or HPLC[24–26] (see Section 4).

The bifunctional sulfenyl chloride $ClS–C(O)–O–(CH_2)_4–O–C(O)–SCl$, dissolved in chloroform, reacts with aqueous Na_2S or Na_2S_2 at 20 °C to give corresponding polymers of the general formula $[–S_n–CO_2–(CH_2)_4–CO_2–S–]$.[43]

2.1.4 *Reaction of Sulfenyl Chlorides with Ionic Iodides*

Alkoxycarbonylsulfenyl chlorides react at 20 °C with aqueous potassium iodide primarily with halogen exchange. The sulfenyl iodides, RSI, are unstable and combine in a bimolecular reaction to give the disulfane and elemental iodine (equation 19), which is removed by washing the organic phase with sodium thiosulfate (equation 20).[24–26]

$$2R–S_x–Cl + 2KI \longrightarrow R–S_n–R + I_2 + 2KCl \quad (19)$$

$$I_2 + 2Na_2S_2O_3 \longrightarrow 2NaI + Na_2S_4O_6 \quad (20)$$

When organochlorodisulfanes are used, RS_2Cl (dissolved in dichloromethane), the product should be the corresponding tetrasulfane, but owing to secondary interconversion reactions (see Section 5), possibly catalyzed by iodine, a mixture of polysulfanes is observed (HPLC analysis; see Section 4) (equations 21 and 22).[24–26]

$$2MeO\text{–}C(O)\text{–}S_2\text{–}I \longrightarrow (MeOCO)_2S_4 + I_2 \qquad (21)$$

$$2R_2S_4 \rightleftharpoons R_2S_3 + R_2S_5 \qquad (22)$$

Therefore, depending on the reaction conditions, either the trisulfane or the tetrasulfane is isolated as the main product.[24–27] The aqueous solution of NaI and $Na_2S_4O_6$ may also be used for halogen exchange reactions of the type shown in equation (19).[44]

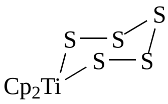
2.1.5 *Reaction of Organic Halides or Sulfenyl Chlorides with Titanocene Polysulfides*

Titanocene dichloride, Cp_2TiCl_2, reacts with alkali polysulfides to give the chelate complexes (**1**) and (**2**). These air-stable products react with inorganic sulfur chlorides to give homocyclic S_n molecules[45] (*see* ***Sulfur: Inorganic Chemistry***). Analogously, organic sulfenyl chlorides and certain organic halides react with (**1**) or (**2**) as shown in equations (23–25).[46,47] These very clean sulfur transfer reactions take place at 0–20 °C in organic solvents (CS_2, CH_2Cl_2).

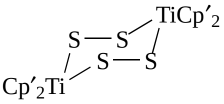
$$2R\text{–}Cl + Cp_2TiS_5 \longrightarrow R\text{–}S_5\text{–}R + Cp_2TiCl_2 \qquad (23)$$

$$2R\text{–}S_x\text{–}Cl + Cp_2TiS_5 \longrightarrow R\text{–}S_n\text{–}R + Cp_2TiCl_2$$
$$x = 1, 2;\ n = 2x + 5 \qquad (24)$$

$$4R\text{–}S_2\text{–}Cl + Cp'_4Ti_2S_4 \longrightarrow 2R\text{–}S_6\text{–}R + 2Cp'_2TiCl_2 \qquad (25)$$



(**1**)



(**2**)

Bis(triphenylmethyl)pentasulfane was obtained in 83% yield from Ph_3CCl and Cp_2TiS_5 in CS_2 at 20 °C.[48] In an analogous manner, triphenylmethylsulfenyl chloride and the corresponding disulfane RS_2Cl react with Cp_2TiS_5 to give the hepta- and nonasulfanes R_2S_n ($n = 7, 9$).[49] These reactions, and the work-up procedure, can be most conveniently followed by HPLC analysis (see Section 4).

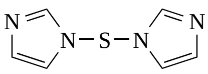
The dinuclear complex $Cp'_4Ti_2S_4$ reacts as a transfer reagent for S_2 units, and with certain organochlorodisulfanes one obtains hexasulfanes R_2S_6 (e.g. $R = Ph_3C$) (equation 25).[46,47,50] The Cp′ ligand (η^5-MeC_5H_4) is used because of the higher solubility of the corresponding dinuclear complex.

2.1.6 *Reaction of Thiols with Sulfur–Nitrogen Bonds in Sulfenamides*

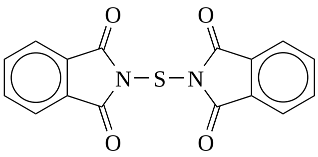
Several sulfenamides and their homologs have been used as transfer reagents for S_1 or S_2 units as shown in equations (26) and (27). Examples include the bis(imidazolo)sulfane (**3**) and the bis(phthalimido)sulfane (**4**).[6] These compounds with one or two sulfur atoms bridging the nitrogen atoms may be prepared from the NH derivatives and SCl_2 or S_2Cl_2 in a molar ratio of 2:1 in the presence of a tertiary amine. When SCl_2 is applied in a molar ratio of 1:1, the sulfenyl chloride R_2N–SCl may be isolated, from which the unsymmetrical sulfenamide needed in equation (27) is prepared by condensation with a thiol, R′SH. Alternatively, R_2NS_2R' may be prepared from R_2NH and $R'S_2Cl$.[35,51]

$$2RSH + R_2N\text{–}S_x\text{–}NR_2 \longrightarrow R\text{–}S_n\text{–}R + 2R_2NH \qquad (26)$$

$$RS_xH + R_2N\text{–}S_y\text{–}R' \longrightarrow R\text{–}S_n\text{–}R' + R_2NH$$
$$x = 1, 2;\ y = 1, 2;\ n = x + y \qquad (27)$$



(**3**)



(**4**)

Symmetrical and unsymmetrical tri- and tetrasulfanes may be synthesized by equations (26) and (27) in high yield and under mild conditions (benzene, 20 °C). Since phthalimide is insoluble in benzene, it can be simply filtered off.[35,51,52] Various other azole derivatives have also been used successfully.[53]

2.1.7 *Reaction of Thiols with Sulfur–Oxygen Bonds of Bis(Alkoxy)Sulfanes*

Bis(alkoxy)sulfanes $(RO)_2S_n$, are easily accessible from the corresponding alcohol by reaction with either (**3**) or (**4**) or with the corresponding dichlorosulfane.[54–56] Using (**1**) as a sulfur transfer reagent and RO–S_2–Cl as the alkoxy derivative, a chain length n of 9 in $(RO)_2S_n$ ($R = i$-Pr) has been achieved.[55] $(RO)_2S_n$ reacts with certain thiols at 20 °C according to equation (28), allowing the preparation of polysulfanes under mild conditions.[57] Bis(tetraacetylthioglucosyl)polysulfanes with up to 11 S atoms in a chain have been prepared in this way.[58] Equations (26–28) are typical nucleophilic displacement reactions (see Section 5).

$$2R'SH + RO\text{–}S_x\text{–}OR \longrightarrow R'\text{–}S_n\text{–}R' + 2ROH$$
$$x = 1 - 9;\ n = x + 2 \qquad (28)$$

2.1.8 Reaction of Dichlorodisulfane with Aromatic Ethers

Methoxybenzene (anisole), 1,2-dimethoxybenzene, and similar aromatic ethers react with S_2Cl_2 in dry ether or benzene at 0–20 °C within several days to give a mixture of bisarylsulfanes R_2S_n with $n = 1–3$ (equation 29). Anisole is substituted in the *para* position.[59]

$$2R\text{–}H + S_2Cl_2 \longrightarrow R\text{–}S_n\text{–}R + 2HCl \quad n = 1–3 \tag{29}$$

2.1.9 Reactions of Organic Halides, Thiols, Sulfenyl Chlorides, or Disulfanes with Elemental Sulfur or Inorganic Polysulfides[6]

Alkyl chlorides, -bromides, and -iodides can be converted to tri- or tetrasulfanes by treatment with elemental sulfur at 20 °C in the presence of KOH and traces of water; methyl-, ethyl-, isopropyl-, and allylpolysulfanes have been prepared in this manner.[60,61] Sometimes hydrazine is added to reduce S_8 to polysulfide anions.[62]

Trifluoroiodomethane reacts at 310 °C with elemental sulfur in a steel autoclave to yield $(CF_3)_2S_2$ (yield 75%), $(CF_3)_2S_3$ (12%), and $(CF_3)_2S_4$ (1%).[63] Probably CF_3 radicals are primarily formed that attack the reactive sulfur molecules[64] present in elemental sulfur at 310 °C.

Bis(4-methyl-2-nitrophenyl)trisulfane is formed in 84% yield on reaction of 4-chloro-3-nitrotoluene with molten sodium polysulfide.[65] Other aryl halogenides have also been converted to trisulfanes by ionic polysulfides.[66,67]

Alkyltri- and -tetrasulfanes may be conveniently prepared from thiols and elemental sulfur in the presence of catalytic amounts of *n*-butylamine at 25–63 °C (equation 30 with $Y = H_2S$). The products formed are determined by the molar ratio $RSH:S_8$, the polarity of the solvent (CH_2Cl_2, MeOH), the reaction time, and the temperature;[68,69] *n*-, *i*-, and *t*-alkyl thiols as well as cycloalkyl thiols have also been applied.[68–71]

$$2R\text{–}X + xS_8 \longrightarrow R\text{–}S_n\text{–}R + Y \quad X = Cl, Br, I, SH, SCl \tag{30}$$

Trichloromethylsulfenyl chloride reacts with elemental sulfur at 220 °C to give $(CCl_3)_2S_2$ and S_2Cl_2; the disulfane may be converted to $(CCl_3)_2S_3$ by reaction with sulfur at 170 °C (equations 30 and 31).[72] Alkyltrisulfanes have also been prepared from disulfanes and elemental sulfur with the addition of H_2S and butylamine or triethylamine, or P_4S_{10}.[6]

$$R\text{–}S_2\text{–}R + xS_8 \longrightarrow R\text{–}S_n\text{–}R \tag{31}$$

Diethylpentasulfane may be prepared from the trisulfane by heating with elemental sulfur to 200 °C followed by distillation in vacuum.[19,20]

See equation (32) for the preparation of organic trisulfanes from alkyl halides and alkali trisulfides;[19,20,71,73] for the preparation of polymeric polysulfanes by equation (32), see Section 7.

$$2R\text{–}X + K_2S_3 \longrightarrow R\text{–}S_3\text{–}R + 2KX \quad X = Cl, Br \tag{32}$$

2.1.10 Organosilicon- and -Tin Reagents for Sulfur Transfer Reactions

Silicon, germanium, and tin have a high affinity for chlorine and bromine, which is utilized in equations (33–36).[74–76]

$$2RSSiR'_2Cl + SCl_2 \longrightarrow R_2S_3 + 2R'_2SiCl_2 \tag{33}$$

$$R_3Sn\text{–}S\text{–}SnR_3 + 2R'SX \longrightarrow R'_2S_3 + 2R_3SnX \quad X = Cl, Br \tag{34}$$

$$\frac{1}{3}(R_2SnS)_3 + 2R'SX \longrightarrow R'_2S_3 + R_2SnX_2 \tag{35}$$

$$2R_3SnSR' + S_xCl_2 \longrightarrow R'_2S_{x+2} + 2R_3SnCl \quad x = 1, 2 \tag{36}$$

Diethyltrisulfane has been obtained in an 87% yield from ethylthiodimethylchlorosilane and SCl_2 at 20 °C (no solvent) followed by vacuum distillation (equation 33).[74] Symmetric diaryltri- and -tetrasulfanes may be prepared from triorganotin sulfides or thiolate complexes as shown in equations (34–36).[75] These reactions proceed smoothly in $CHCl_3$ or CCl_4 at 20 °C or slightly elevated temperatures and the products are obtained in yields of between 25 and 90%.[75,76] The organotin thiolates are prepared from R_3SnCl, R_3SnOH, or $(R_3Sn)_2O$ by reaction with the corresponding thiol (equations 37 and 38)[76] (*see* ***Tin: Organometallic Chemistry***).

$$R_3SnX + R'SH \xrightarrow{NaOH} R_3Sn\text{–}SR' + HX \quad X = Cl, OH \tag{37}$$

$$(R_3Sn)_2O + 2R'SH \longrightarrow 2R_3Sn\text{–}SR' + H_2O \tag{38}$$

Silicon is one of the most oxophilic elements (*see* ***Silicon: Organosilicon Chemistry***). Therefore, organosilicon sulfides react with certain sulfur–oxygen compounds, as shown in equations (39) and (40).[77]

$$R_3Si\text{–}S\text{–}SiR_3 + R'\text{–}S(O)\text{–}S\text{–}R' \longrightarrow R'_2S_3 + (R_3Si)_2O \tag{39}$$

$$R_3Si\text{–}S\text{–}SiR_3 + 2R'\text{–}S(O)_2\text{–}S\text{–}R' \longrightarrow R'_2S_3 + 2R_3Si\text{–}O\text{–}S(O)\text{–}R' \tag{40}$$

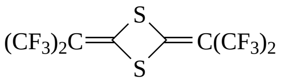
Bis(trimethylsilyl) sulfide reacts with methyl, phenyl, or other thiosulfinates (disulfane oxides), R′S(O)SR′, in anhydrous chloroform at 60 °C to give the symmetrical trisulfane and hexamethyldisiloxane; the latter is removed together with the solvent by vacuum distillation, leaving almost pure R'_2S_3 (yields 70–90%).[77] In a similar reaction,

$EtSO_2SEt$ was converted to Et_2S_3 with a 95% yield (equation 40).[51]

2.1.11 *Reaction of Alkenes with Elemental Sulfur or Sulfur-Rich Compounds*

The reactions of alkenes with elemental sulfur is of great importance because of analogies to the vulcanization of natural or synthetic rubber by sulfur in the presence of various catalysts (accelerators). This technical process, and the related model reactions of simple alkenes with sulfur, will be described in Section 7.

Sulfur may react with alkenes either by addition to the C=C double bond or by substitution of H by S with the elimination of H_2S. In both cases polysulfanes are formed. Octafluoroisobutene, $(CF_3)_2C{=}CF_2$, reacts at 60–70 °C in dimethylformamide (DMF) and in the presence of cesium fluoride with elemental sulfur to give the thioketene dimer (**5**) and the trisulfane (**6**) (yield 21% and 35% based on the alkene). Use of KF instead of CsF also produced some tetrasulfane analogous to (**6**).[78]



$(CF_3)_3C{-}S_3{-}C(CF_3)_3$

(**5**) (**6**)

Acrylonitrile, $CH_2{=}CH{-}CN$, reacts at 80 °C in DMF in the presence of NH_3 to give 1,7-dicyano-3,4,5-trithiaheptane, $(NC{-}C_2H_4)_2S_3$, in a 49% yield.[73] The latter compound may be converted to the dicarbonic acid $(HO_2CC_2H_4)_2S_3$ by hydrolysis in hydrochloric acid (90% yield).[73] Tetrafluoroethylene, C_2F_4, may be sulfurized by reaction with solid $[S_8][AsF_6]_2$ at 20 °C; after 2 days, AsF_3 and a mixture of polysulfanes, $(C_2F_5)_2S_n$ with $n = 2$ (80%), 3 (19%), and 4 (0.5%), had formed.[79]

2.1.12 *Reaction of Thiols with Sulfur(IV) and Sulfur(VI) Compounds (SO_2, Tetrahalides, Thiosulfinates, Sulfinylimides, Bunte Salts, etc.)*

Thiols are powerful reducing agents, which may be oxidized by O_2, peroxides, halogens, sulfoxides, or metal ions in high oxidation states [$FeCl_3$, $Pb(O_2CMe)_4$]; usually disulfanes are formed in these reactions.[4,6] Oxidation of thiols by sulfur(IV) or sulfur(VI) compounds often results in mixtures of polysulfanes.

Liquid SO_2 oxidizes alkanethiols in the presence of triethylamine at 20 °C to a mixture of di- and trisulfanes (ratio ca. 7:3) (equations 41–43).[80]

$$RSH + SO_2 \longrightarrow R{-}S{-}S(O)OH \qquad (41)$$

$$RSS(O)OH + RSH \longrightarrow RS{-}S(O){-}SR + H_2O \qquad (42)$$

$$2RS{-}S(O){-}SR \xrightarrow{\text{base}} R_2S_2 + R_2S_3 + SO_2 \qquad (43)$$

The postulated intermediates RS–S(O)–OH and R_2S_3O could not be observed, but trisulfane 2-oxides $(RS)_2SO$, are known from the reaction of thiols with thionyl chloride (equation 44).[62–64]

$$2RSH + SOCl_2 \xrightarrow{\text{base}} (RS)_2SO + 2HCl \qquad (44)$$

Oxidation of trisulfanes by peroxo compounds sometimes also produces trisulfane 2-oxides; see below.

Substituted aromatic thiols are oxidized by *N*-sulfinylimides to yield equimolar mixtures of di- and trisulfanes (equation 45). This reaction proceeds via the intermediate 'adduct' R′–NH–SO–SR (**7**), which in favorable cases can be isolated (e.g. with $R' = 4\text{-}O_2NC_6H_4$).[85,86] Compound (**7**) reacts with thiols according to equation (46), allowing the preparation of symmetrical disulfanes and unsymmetrical trisulfanes.

$$4RSH + R'{-}N{=}S{=}O \longrightarrow R_2S_2 + R_2S_3 + R'NH_2 + H_2O \qquad (45)$$

$$R'{-}NH{-}SO{-}SR + 3R''SH \longrightarrow R''_2S_2 + R{-}S_3{-}R'' + R'NH_2 + H_2O \qquad (46)$$

Since (**7**) does not have to be isolated, the reaction of *N*-phenylsulfinylimide with benzenethiol at −15 °C in ether followed by addition of ethanethiol in acetone resulted in $Et{-}S_3{-}Ph$, which could be isolated in a 24% yield.[85,86] Other arylalkyltrisulfanes have been prepared by analogous reactions. The reaction of alkoxythionyl chloride with thiols also proceeds via reactive intermediates, and is therefore useful for the preparation of unsymmetrical trisulfanes (equations 47–49 with R = alkyl, R′ = aryl).[83]

$$RO{-}S(O){-}Cl + RSH \longrightarrow RO{-}S(O){-}SR + HCl \qquad (47)$$

$$RO{-}S(O){-}SR + R'SH \longrightarrow ROH + R'S{-}S(O){-}SR \qquad (48)$$

$$R'S{-}S(O){-}SR + 2R'SH \longrightarrow R'{-}S_3{-}R + R'_2S_2 + H_2O \qquad (49)$$

The reduction of sulfane oxides, R–S(O)–S–S–R, by thiols R′SH results in unsymmetrical di- and trisulfanes.[87]

SCl_4 and ethanethiol react in ether at −20 °C or below according to equation (50).[88]

$$SCl_4 + 4EtSH \longrightarrow Et_2S_2 + Et_2S_3 + 4HCl \qquad (50)$$

In a similar reaction, SF_4 and potassium ethyl xanthate yield the corresponding di- and trisulfanes in benzene at 20 °C (equation 51).[30,31]

$$SF_4 + 4EtOC(S)SK \longrightarrow [EtOC(S)]_2S_2 + [EtOC(S)]_2S_3 + 4KF \qquad (51)$$

2.1.13 *Reaction of Inorganic Polysulfides with Organic Sulfur–Oxygen Compounds (Thiosulfonates, Bunte Salts, Dimethyl Sulfate)*

Dimethyl sulfate is a strong methylating agent, which reacts at 20 °C with methanolic or ethanolic solutions of sodium polysulfides to give mixtures of dimethylpolysulfanes from which Me_2S_3 may be obtained by distillation in a 80% yield (equation 52).[19,20,89]

$$(MeO)_2SO_2 + Na_2S_n \longrightarrow Me_2S_2 + Na_2SO_4 \qquad (52)$$
$$n = 3 - 5$$

Organic thiosulfates, $RSSO_3M$ (M = Na, K, etc.), are called Bunte salts and may be obtained from organic halides or thiols with aqueous thiosulfate, by cleavage of disulfanes with sulfite ions, or by reaction of thiols with tetrathionate (equations 53–55).[90–93]

$$R\text{–}X + Na_2S_2O_3 \longrightarrow R\text{–}S_2O_3Na + NaX \qquad (53)$$
$$X = Cl, Br, SH$$
$$R\text{–}S\text{–}S\text{–}R + SO_3^{2-} \longrightarrow R\text{–}SSO_3^{-} + RS^{-} \qquad (54)$$
$$RSH + S_4O_6^{2-} \longrightarrow RSSO_3^{-} + HS_2O_3^{-} + \frac{1}{8}S_8 \qquad (55)$$

Bunte salts react with aqueous sulfide under mild conditions to give trisulfanes in high yield (equations 56 and 57).

$$RSSO_3^{-} + HS^{-} \longrightarrow RSS^{-} + SO_3^{2-} + H^{+} \qquad (56)$$
$$RSSO_3^{-} + RSSH \longrightarrow R_2S_3 + SO_3^{2-} + H^{+} \qquad (57)$$

Trisulfanes with R = methyl, ethyl, allyl, benzyl, phenacyl, 4-tolyl, and 2-methylpent-2-enyl have been prepared in this way. The pH of the solution is kept at 8 using a buffer and the trisulfane is extracted by ether or hexane.[66,67,92,93] To prevent the sulfite ions liberated in equations (56) and (57) from attacking the trisulfane with formation of disulfane and thiosulfate, the reaction is carried out in the presence of an excess of formaldehyde, which at pH ∼8 traps the sulfite (equation 58).

$$SO_3^{2-} + CH_2O + H_2O \longrightarrow HOCH_2SO_3^{-} + OH^{-} \qquad (58)$$

In addition, saturation of the aqueous phase with NaCl lowers the solubility of R_2S_3, which is then more rapidly extracted into the organic phase.[92,93]

Thiosulfonates or disulfane 1,1-dioxides, R–S–SO_2–R, are thioalkylating agents as the S–S bond is weak and easily cleaved. Sulfide ions therefore react with thiosulfonates in a similar fashion as Bunte salts (see above), and symmetrical alkyl- and aryltrisulfanes may be prepared in high yields by equations (59) and (60).[42]

$$RSO_2SR + M_2S \longrightarrow RSO_2M + RSSM \qquad (59)$$
$$M = Na, K$$
$$RSSM + RSO_2SR \longrightarrow R_2S_3 + RSO_2M \qquad (60)$$

The reaction is carried out in methanol at 20 °C. It is apparent from equations (59) and (60) that the central sulfur atom originates from the sulfide. Cyclic thiosulfonates result in chainlike trisulfanes with chain-terminating –SO_2^{-} groups (equation 61).[94,95]

$$2\,\overline{O_2S\text{–}(CH_2)_4\text{–}S} + Na_2S \longrightarrow \underset{70\%}{[NaO_2S(CH_2)_4S]_2S} \qquad (61)$$

Such sulfinate compounds are water soluble and may be used as antiradiation drugs (see Section 7.4).[94–97] Bis(sulfinato)trisulfanes may be converted to the corresponding bisalkyl esters by reaction with either diazomethane or a solution of BF_3 in diethyl ether.[98,99] When sodium polysulfide is applied in equation (59) the resulting polysulfanes (equation 60) contain up to six sulfur atoms. However, bis(sulfinato)polysulfanes with more than four catenated sulfur atoms are unstable in water, and elemental sulfur is slowly precipitated.[96] When the thiosulfonate RS(O)–$(CH_2)_2$–$SSO_2C_6H_4Me$ was used in equations (59) and (60), the bis(sulfoxido)trisulfane $[RS(O)\text{–}(CH_2)_2]_2S_3$ resulted.[97]

2.1.14 *Reduction of Sulfane Oxides by Triphenylphosphane*

Trisulfane 1,1,3,3-tetroxides, RSO_2–S–SO_2R, may be prepared by equation (62)[100] or by oxidation of trisulfanes by peroxy acids (equation 63).[101]

$$RSO_2SNa + R'SO_2Cl \longrightarrow RSO_2\text{–}S\text{–}SO_2R' + NaCl \qquad (62)$$
$$R_2S_3 + 4R\text{–}CO_3H \longrightarrow RSO_2\text{–}S\text{–}SO_2R + 4R\text{–}CO_2H \qquad (63)$$

Triphenylphosphane is an oxophilic compound that reduces sulfoxides (R_2SO), disulfane oxides (RS(O)SR), disulfane dioxides (sulfones) (RSO_2SR), and trisulfane tetroxides to the corresponding sulfanes. From the products prepared by equations (62) or (63), symmetrical or unsymmetrical aryl- or alkyltrisulfanes can be obtained in high yields (refluxing in ether or benzene) (equation 64).[100]

$$RSO_2\text{–}S\text{–}SO_2R' + 4Ph_3P \longrightarrow RS_3R' + 4Ph_3PO \qquad (64)$$

Sulfoxides are intermediates in the reaction shown in equation (64). An excess of Ph_3P converts the trisulfanes, via disulfanes, to monosulfanes, R_2S (see Section 5.3).[100]

2.1.15 *Miscellaneous Reactions for the Preparation of Chainlike Polysulfanes*

Carbon disulfide reacts with iodine pentafluoride in a sealed tube at 195 °C to give a mixture of CF_4, SF_4, $(CF_3)_2S_2$, $(CF_3)_3S_3$, and probably I_2. The trisulfane was isolated by vacuum distillation in a 7% yield.[63]

Cyanosulfanes, $S_n(CN)_2$, with $n = 3–8$ have been prepared by reaction of the corresponding dichlorosulfanes with $Hg(SCN)_2$ in CS_2, sometimes in the presence of EtBr as a polar solvent (equation 65).[102–105]

$$S_xCl_2 + Hg(SCN)_2 \longrightarrow S_n(CN)_2 + HgCl_2 \quad (65)$$
$$x = 1 - 7;\ n = x + 2$$

While $S_3(CN)_2$, $S_6(CN)_2$ and $S_9(CN)_2$ are crystalline solids, the other dicyanosulfanes are oily liquids at 20 °C, but crystallize on cooling. The chainlike structures of $S_n(CN)_2$ with $n = 3$, 4, 6, and 9 have been established by X-ray diffraction on single crystals (see Section 3.1).

Aliphatic acid chlorides react with H_2S_3 in the presence of $ZnCl_2$ at 20 °C (no solvent) according to equation (66).[22,23]

$$2RCOCl + H_2S_3 \longrightarrow (RCO)_2S_3 + 2HCl \quad (66)$$

Aliphatic ketones and aldehydes react with H_2S under pressure to give a mixture of geminal dithiols and tri- and tetrasulfanes according to equations (67–69).[106]

$$RCHO + 2H_2S \longrightarrow RCH(SH)_2 + H_2O \quad (67)$$
$$R_2CO + 2H_2S \longrightarrow R_2C(SH)_2 + H_2O \quad (68)$$
$$R_2CO \xrightarrow[-H_2O]{H_2S} (R_2CH)_2S_x \quad (69)$$
$$x = 2 - 4$$

Polysulfane yields of up to 60% were obtained for this mixture. From acetylacetone, a cyclic trisulfane was prepared.[106]

Primary and secondary alkyltetrasulfanes may be prepared from ketones via hydrazones by reaction with H_2S (equations 70 and 71).[107] The mechanism and stoichiometry of equation (71) are unknown, but $MeCO_2H$ and $2NH_4^+$ are probably formed as by-products, in which case four equivalents of H_2S are needed, resulting in a tetrasulfane.

$$R–CO–R' + H_2N–NH–CO_2Me \longrightarrow RR'C{=}N–NH–CO_2Me + H_2O \quad (70)$$

$$RR'C{=}N-NH-CO_2Me \xrightarrow[90\ °C/3\ d]{H_2S/MeOH/H^+} RR'CH-S_4-CHRR' \quad (71)$$

Oxidation of monoorganyldisulfanes, RS_2H, by iodine in ethanol (equation 72), or by quinones in benzene produces tetrasulfanes in high yield.[6]

$$2RS_2H + I_2 \longrightarrow R_2S_4 + 2HI \quad (72)$$

2.2 Cyclic Organic Polysulfanes

The Hantzsch–Widman system is often used for the nomenclature of organic rings. This indicates the ring size by specific suffixes; the first suffix given is used for saturated rings, the second for unsaturated rings:

- three-membered rings: -irane, -iren;
- four-membered rings: -etane, -ete;
- five-membered rings: -olane, -ole, -olen;
- six-membered rings: -ane, -in;
- seven-membered rings: -epane, -epin;
- eight-membered rings: -ocane, -ocin;
- nine-membered rings: -onane, -onin;
- ten-membered rings: -ecane, -ecin.

Examples will be presented in the following sections.

2.2.1 *Reaction of Dithiols with Dichlorosulfanes*

The reaction of organic dithiols with dichlorosulfanes may result in the formation of rings, of oligomeric rings, or of polymers (equations 73–75).

$$HS–R–SH + Cl–S_n–Cl \longrightarrow \overline{S–R–S–S_n} + 2HCl \quad (73)$$
$$2HS–R–SH + 2Cl–S_n–Cl \longrightarrow \overline{SRS–S_n–SRS–S_n} + 4HCl \quad (74)$$
$$nHS–R–SH + nCl–S_n–Cl \longrightarrow (S–R–S–S_n) + 2nHCl \quad (75)$$

The formation of small rings (equation 73) is promoted by application of the dilution principle (simultaneous addition of both reagents to a large volume of solvent to keep the actual concentration low). Nevertheless, when the size of the desired ring is too small (≤ 5), the dimeric compound will form either exclusively, or in addition to, the monomeric ring (equation 74). Such reactions often are carried out in ether, which binds the HCl by strong hydrogen bonds, although a hydrocarbon solvent plus a tertiary amine may also be used. Rings with up to seven neighboring sulfur atoms have been synthesized by equation (73). Methanedithiol reacts with S_3Cl_2 to give pentathiane, CH_2S_5, and with S_5Cl_2 to give heptathiacyclooctane, CH_2S_7 (equation 76). Both compounds form yellow crystals,[108,109] the structure of which has been determined by X-ray diffraction (see Section 3.2).

$$CH_2(SH)_2 + S_nCl_2 \longrightarrow cyclo\text{-}CH_2S_{n+2} + 2HCl \quad (76)$$
$$n = 3, 5$$

Substituted methanedithiols also react with S_3Cl_2 according to equation (76).[110] However, when methanedithiol or

substituted derivatives are reacted with SCl_2, an eight-membered cyclic bis-trisulfane is obtained, rather than a four-membered ring (equation 74 with $n = 1$).[110]

Numerous aliphatic and aromatic dithiols have been reacted with dichlorosulfanes, and cyclic polysulfanes have been obtained in yields of up to 80%.[111–116] Sometimes the sodium salt of the dithiol is used,[117] in which case the ring size obtained may be different from what was expected as the strongly nucleophilic RS^- ions catalyze interconversion reactions (see Section 5.1).

Despite the reactivity of dichlorosulfanes towards C=C double bonds, it has been possible to synthesize cyclic organic polysulfanes with alkenic double bonds by equation (73), for example, isothiazolepentasulfane,[117] pentathiepin, $C_2H_2S_5$,[118] and norbornenepentasulfane, $C_7H_8S_5$.[118] 3,6-Dimercapto-1,4-dimethyl-2,5-dioxopiperazine reacts with S_2Cl_2 without a base to give a stable, bicyclic epitetrasulfane,[119,120] which is related to the naturally-occurring antibiotic polysulfanes gliotoxin, sporidesmin, aranotin, and chaetocin II (see Section 6.2).

2.2.2 *Reaction of Bifunctional Organic Halides, Tosylates, or Esters with Sodium Polysulfide*

The reactions depicted in equations (77) and (78) are similar to those shown in equations (73–75): depending on the sizes of the organic group R and on the polysulfide anion S_x^{2-}, either a small ring, RS_n, or a larger ring (equation 78) will form. Since aqueous polysulfide consists of various anions in equilibrium, the resulting polysulfanes may contain several different $-S_n-$units. The strongly nucleophilic polysulfide ions substitute the halide ions Cl^-, Br^-, or I^-, the tosylate anion $MeC_6H_4SO_3^-$, or the alcoholate anion RO^-.

$$\text{X–R–X} + Na_2S_x \longrightarrow \overline{\text{R–}S_n} + 2\text{Nax} \qquad (77)$$

$$2\text{X–R–X} + 2Na_2S_x \longrightarrow \overline{\text{R–}S_n\text{–R–}S_m} + 4\text{NaX} \qquad (78)$$

Aqueous sodium polysulfide of average composition $Na_2S_{2.5}$ reacts at 20 °C with diiodomethane within 5 h to give 1,2,3,5,6-pentathiacycloheptane (lenthionine; see Section 6.2), which is extracted into chloroform and purified by LC (equation 79).[121,122]

$$2CH_2I_2 + Na_2S_2 + Na_2S_3 \longrightarrow \overline{CH_2\text{–}S_2\text{–}CH_2\text{–}S_3} + 4\ \text{NaI} \qquad (79)$$

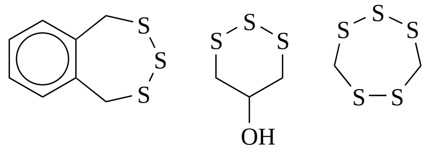
When an excess of CH_2Cl_2 is stirred into aqueous $Na_2S_{2.5}$ at pH = 8, lenthionine and hexathiacycloheptane, CH_2S_6, are obtained. At pH = 12, 1,2,4,6-tetrathiacycloheptane (tetrathiepane) and 1,2,4-trithiacyclopentane (trithiolane) are obtained.[121,122]

Various aliphatic and aromatic dichlorides and -bromides have been used to synthesize tri- and tetrasulfanes by reaction with aqueous or alcoholic sodium polysulfide. For instance, the benzotrithiepin (**8**) was obtained from the corresponding dibromide,[123] the hydroxytrithiane (**9**) from glycerol-α,α'-dichlorohydrin,[124] and lenthionine (**10**) (1,2,3,5,6-pentathiepane) from dimethyldisulfane via bis-chloromethyldisulfane (equations 80–82).[125]

$$\text{MeSSMe} + 3Cl_2 \longrightarrow 2ClCH_2SCl + 2HCl \qquad (80)$$

$$2ClCH_2SCl + 2KI \longrightarrow ClCH_2SSCH_2Cl + 2KCl + I_2 \qquad (81)$$

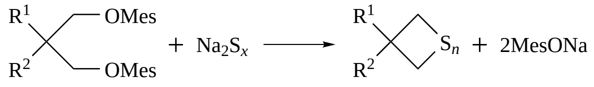
$$ClCH_2SSCH_2Cl + Na_2S_x \longrightarrow \overline{CH_2SSCH_2SSS} + 2NaCl \qquad (82)$$



(**8**) (**9**) (**10**)

An epitetrasulfane of 2,5-piperazinedione has been prepared from the dibromide and Na_2S_x.[118]

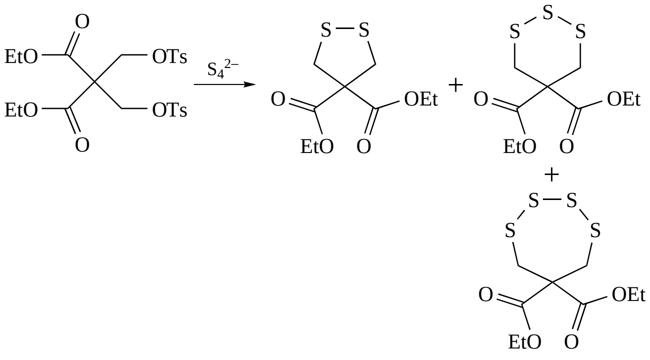
Bifunctional mesityl ethers react with aqueous sodium polysulfide to give cyclic disulfanes and trisulfanes in high yields (equation 83).[114]



R^1 = Me, Et, *i*-Bu; $R^2 = R^1$, Ph, *neo*-C_5H_{11}; $n = 2, 3$

(83)

Similarly, bifunctional tosylates yield cyclic di-, tri-, and tetrasulfanes on treatment with sodium polysulfide (equation 84).[126]

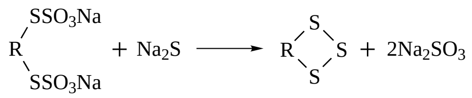


(84)

2.2.3 *Reaction of Organic Thiosulfates (Bunte Salts) or Thiosulfonates with Sodium Sulfide*

Bunte salts and thiosulfonates react with aqueous sulfide as shown in equations (56) and (57). When bifunctional Bunte

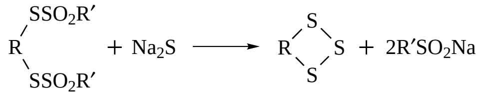
salts are used, cyclic trisulfanes are obtained (equation 85).



(85)

To prevent the sulfite from attacking the trisulfane (with formation of thiosulfate and disulfane), the reaction is carried out in the presence of formaldehyde at pH = 7 (see equation 58). Aromatic, aliphatic, and alkenic trisulfanes have been obtained in this way in high yields.[87,127]

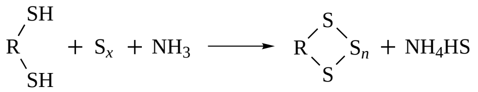
Bifunctional thiosulfonates react similarly (no CH_2O is needed) and yield cyclic trisulfanes, also in high yields (equation 86).[87]



(86)

2.2.4 *Reaction of Dihalides, Dithiols, or Thiocarbonates with Elemental Sulfur in the Presence of a Base*

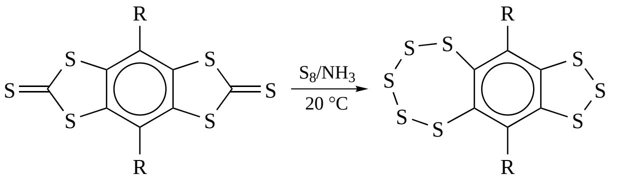
Aliphatic and aromatic dithiols react with elemental sulfur in liquid ammonia at 20 °C according to equation (87).[128–132]



(87)

Various cyclic di-, tri-, tetra-, and pentasulfanes have been prepared by equation (87); examples are given in Figure 1.

Aromatic bistrithiocarbonates have been used to synthesize cyclic bis-polysulfanes as shown in equation (88) (R = OMe, OEt, O^{i}Pr, OCH_2Ph).[128–132]



(88)

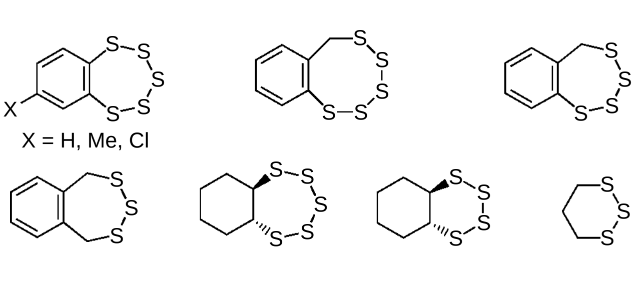


Figure 1 Cyclic polysulfanes prepared from organic dithiols and elemental sulfur in the presence of ammonia as a catalyst

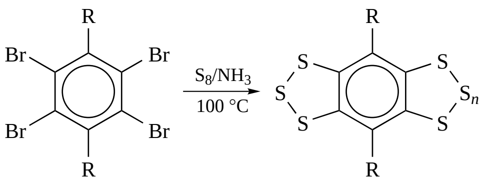
Polycyclic polysulfanes may also be obtained from aromatic tetrahalides as shown in equation (89) (R = Me, Et, n = 1, 3).[128–132]



(89)

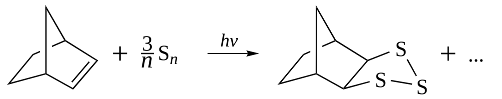
For a recent review on cyclic benzopolysulfanes, see ref.[133]

The preparation of 1,2,3-trithiane from $Br(CH_2)_3Br$ and elemental sulfur in the presence of KOH in THF has been described.[60,61]

2.2.5 *Reactions of Alkenes with Elemental Sulfur*

The reactions of sulfur with various types of organic compounds have been reviewed in 1987.[134]

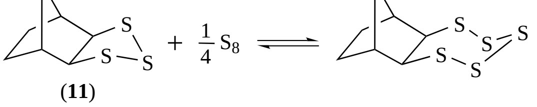
Under certain conditions, alkenes react with elemental sulfur or sulfur-rich compounds to yield cyclic polysulfanes. Tetrafluorethylene, C_2F_4, reacts with boiling elemental sulfur (445 °C) to give tetrafluoro-1,2,3-trithiolane (yield 10%) and tetrafluoro-1,2,3,4-tetrathiane (60%); both compounds are malodorous oils.[135] Ordinary hydrocarbons would yield H_2S under these conditions, therefore, a catalyst or irradiation is applied to achieve milder reaction conditions. When a mixture of norbornene and S_8 in CS_2 is irradiated (wavelength 350 nm), besides other products, the trithiolane derivative (**11**) is formed (77% yield; equation 90).[136]



(90)

Since irradiation of S_8 in CS_2 results in various reactive sulfur molecules S_n ($n < 8$),[137,138] it is not clear which molecules S_n are reacting in equation (90). Cyclohexene reacts similarly to norbornene.[136]

Heating of norbornene, dicyclopentadiene (DCPD) or tricyclopentadiene with elemental sulfur in DMF in the presence of NH_3 or triethylamine also produces the corresponding 1,2,3-trithiolane derivatives in yields of 20–85%.[139,140] For the reaction of liquid sulfur with DCPD, see Section 7. A careful investigation of the reactions of sulfur with norbornene, norbornadiene, and DCPD showed that tri- and pentasulfanes are formed and may be isolated as pure materials; in the case of norbornene these are in equilibrium in solution at 20 °C (equation 91).[141]



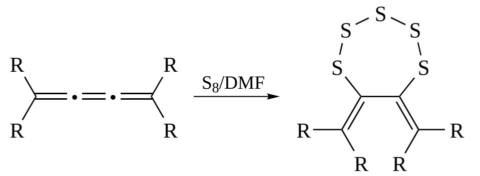
(**11**)

(91)

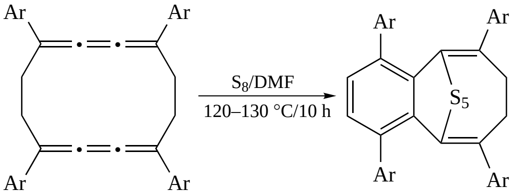
The DCPD polysulfanes with between four and eight sulfur atoms have been independently synthesized from titanocene polysulfides and DCPD sulfenyl chlorides by sulfur transfer reactions.[142]

Cycloheptatriene reacts with elemental sulfur in sulfolane at 70 °C and in the presence of pyridine in such a way that an S_3 unit is added across the 1,6-positions, resulting in 2,3,4-trithiabicyclo[4.3.1] deca-6,8-diene (21% yield).[143] Trimethylvinylsilane, $Me_3SiCH{=}CH_2$, and sulfur react at 55 °C in the presence of $Fe_3(CO)_{12}$ to give, *inter alia*, 1-trimethylsilyl-2,3,4,5,6-pentathiacycloheptane.[144] The preparation of cyclic trisulfanes from alkenes and S_8 has also been carried out by reduction with NaH in toluene in the presence of a phase transfer catalyst.[145] Indole fused pentathiepines were obtained by lithiation of indole or N-methylindole followed by thionation with elemental sulfur.[146,147]

Unusual unsaturated cyclic polysulfanes are obtained on reaction of tetraarylbutatrienes with elemental sulfur in DMF at 125 °C (equations 92 and 93).[148–150]



(92)



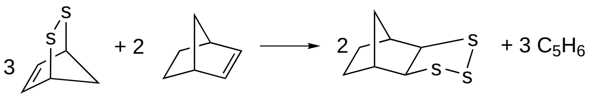
(93)

Ar = phenyl, 24%
Ar = *p*-tolyl, 24%

2.2.6 *Reactions of Alkenes with Sulfur Compounds: Sulfur Transfer Reactions*

The highly reactive S_2 molecule can be prepared by various routes in solution. Its intermediate presence has been deduced from trapping reactions with alkenes, which are turned into disulfanes,[151–154] however, tri- and tetrasulfanes are sometimes also formed; only the latter reactions will be reported here.

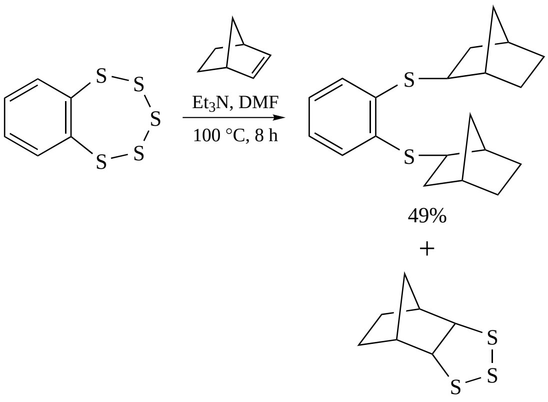
Cyclopentadiene epidisulfane reacts with norbornene, C_7H_{10}, on heating to give the trisulfane (**11**) in 61% yield (equation 94).[155]



(**11**)

(94)

The same product (**11**) is obtained when S_2 is generated from $(R_3Ge)_2S_3$ by reaction with Ph_3PBr_2.[151–154] Analogously, the enes shown in Table 3 result in cyclic trisulfanes at the yields given.[151–154] The exact pathway of these reactions is unknown.



(95)

The formation of the 1,2,3-trithiolane (**11**) has also been observed when norbornene was heated with benzopentathiepin, 1,2-$C_6H_4S_5$, in DMF in the presence of triethylamine (yield 48%, at 100 °C) (equation 95).[156,157] Benzopentathiepin, heated in the presence of R_3N, apparently

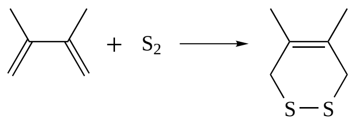
Table 3 Products of the formal addition of S_2 to cyclic alkenes[151–154]

Ene	Product(s)	% Yield
		75
		88
		15
		18
		31
		87, 13

splits into S_3 and 1,2-$C_6H_4S_2$, which have both been trapped by norbornene.[156,157] The analogous reactions of benzopentathiocin and the related benzotetrathiepin with various enes, dienes, and trienes in dimethylsulfoxide (DMSO) have been investigated, and di- or trisulfanes resulting from [2 + 3], [4 + 2], and [6 + 3] cycloaddition have been isolated in high yields.[156,157] These remarkable reactions show that on heating in polar solvents cyclic sulfur-rich polysulfanes may produce various reactive sulfur species that can be transferred to suitable alkenic acceptors; if less reactive alkenes such as cyclohexene or cyclooctene are used, elemental sulfur instead of cycloadducts is obtained.[156,157] For S_3 transfer reactions, see also Section 5.2.

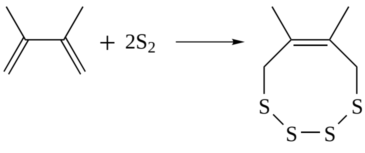
Triphenylmethylchlorodisulfane reacts with 2,3-dimethyl-1,3-butadiene to give two polysulfanes that arise from the addition of S_2 (equations 96–98).[158]

$$Ph_3C\text{–}S_2\text{–}Cl \longrightarrow Ph_3C\text{–}Cl + S_2 \qquad (96)$$



30%

(97)



35%

(98)

The actual mechanism, however, seems to involve addition of Ph_3CSSCl to the diene, with subsequent elimination of Ph_3CCl.[158] It should be remembered that the formation of free S_2 or S_3 molecules in all of the above reactions is only a working hypothesis as long as there is no direct evidence for S_2 and S_3, e.g. from spectroscopic measurements. Most of these reactions can also be explained by a direct reaction between the sulfur donor and the sulfur acceptor, without the intermediate presence of free S_2 or S_3 molecules.

2.2.7 *Reaction of Titanocene Chelate Complexes with Bis(Sulfenyl Chlorides)*

Titanocene pentasulfide (**1**) has been used as a transfer reagent for the S_5 unit to prepare numerous inorganic homo- and heterocycles.[159] More recently, cyclic organic polysulfanes have also been obtained from (**1**) by reaction with bis(sulfenyl chlorides) (equation 99).[46,47]

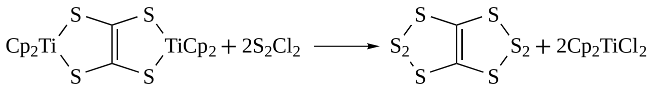
$$R(SCl_2) + Cp_2TiS_5 \longrightarrow \overline{R\text{–}S_7} + Cp_2TiCl_2 \qquad (99)$$

1,2-$C_2H_4(SCl)_2$ reacts with (**1**) to give the nine-membered ring $C_2H_4S_7$ in 31% yield.[48,50] Toluenebis(sulfenyl chloride), $MeC_6H_3(SCl)_2$, reacts similarly to give the bicyclic $MeC_6H_3S_7$.[48,50] Norbornanetrithiolan (**11**) on chlorination gives one of the two sulfenyl chlorides $C_7H_{10}(SCl)_2$ or $C_7H_{10}(SCl)(S_2Cl)$, depending on the reaction conditions. These react with (**1**) to give the previously unknown polysulfanes $C_7H_{10}S_7$ and $C_7H_{10}S_8$.[160] $C_7H_{10}S_7$ exists in solution as two conformers, as was shown by ^{1}H NMR (proton nuclear resonance) spectroscopy.[160] The DCPD polysulfanes $C_{10}H_{12}S_n$ with $n = 4–8$ were obtained using the polysulfido complexes (**1**) and $(Cp_2TiCl)_2S_3$, together with the sulfenyl chlorides $C_{10}H_{12}(S_mCl)(S_nCl)$ with $m, n = 1$ or 2.[160]

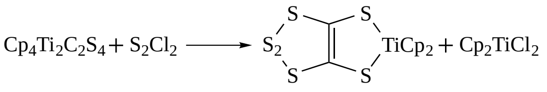
The reactions of equation (99) usually proceed quantitatively to the right and without any side reactions. The advantage of (**1**) over sodium pentasulfide is not only that it is soluble in organic solvents (CS_2, CH_2Cl_2) and does not equilibrate with other ring sizes, but also that it does not introduce nucleophilic polysulfide anions that catalyze decomposition and interconversion reactions (see Section 5.1).

On treatment with acetone and sodium sulfide, (**1**) is transformed to $Cp_2Ti(\mu\text{-}S_2)_2CMe_2$, which is also a transfer reagent. This reacts with S_2Cl_2 to give dimethylhexathiepin, Me_2CS_6 (30% yield), and with a mixture of dichlorosulfanes, S_nCl_2 ($n = 1–30$), to yield the corresponding mixture of heterocycles, Me_2CS_{n+4}, which has been analyzed by HPLC.[15,16]

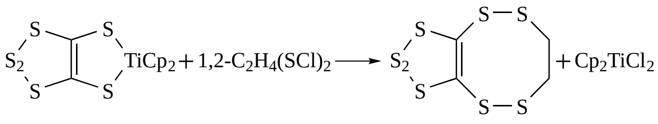
Another valuable titanocene precursor is obtained by the action of CS_2 on $Cp_2Ti(CO)_2$ at 20 °C, resulting in $Cp_4Ti_2C_2S_4$.[161] This dinuclear complex contains the $C_2S_4{}^{4-}$ ligand, which may be used to synthesize the bicyclic polysulfanes shown in equations (100–102).[162–165]



(100)

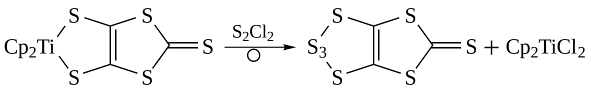


(101)



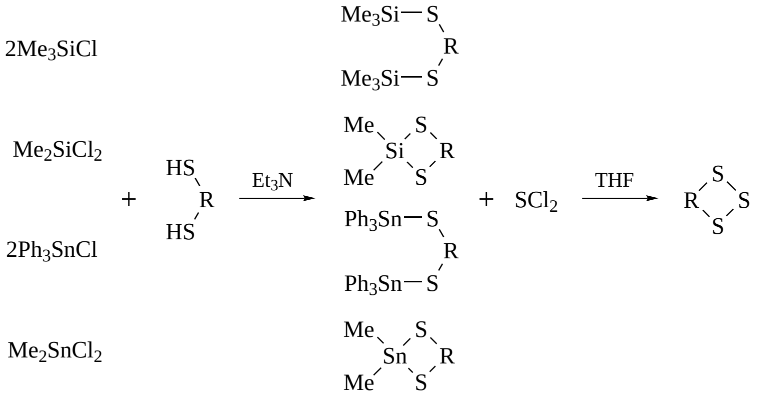
(102)

A similar reaction, shown in equation (103), yields a binary tricarbon octasulfide, C_3S_8, in a 15% yield[166,167] (rather than C_3S_7, which would be expected from the stoichiometry).



(103)

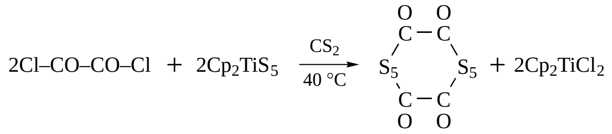
Equations (99–103) are carried out at 0 or 20 °C. At slightly elevated temperatures, Cp_2TiS_5 reacts even with certain C–Cl



R = $(CH_2)_n$; n = 2–4

Scheme 1

bonds, as equation (104) shows. The product ($C_4O_4S_{10}$) forms yellow crystals consisting of 14-membered ring molecules (yield 48%).[168,169]



(104)

More recently, the hexasulfido zinc complex [(TMEDA)Zn][S_6] has been used to prepare extremely sulfur-rich cyclic polysulfanes by reaction with 1,2-benzene-bis(sulfenyl chloride).[170]

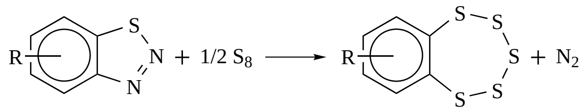
2.2.8 Cyclic Polysulfanes from Organosilicon or Organotin Sulfides and Dichlorosulfanes

As shown in Scheme 1, dithiols react with organic silicon and tin chlorides to give sulfides that can be cleaved by SCl_2 to synthesize cyclic trisulfanes.[171]

The best yields were obtained with $(Me_3SiS)_2R$ and $R = C_3H_6$ or C_4H_8. In the case of $R = C_2H_4$, oligomeric compounds were formed. The reaction with SCl_2 is carried out in THF followed by evaporation of the solvent and of Me_3SiCl and preparative TLC (Thin-layer Chromatography) separation with hexane as an eluent.

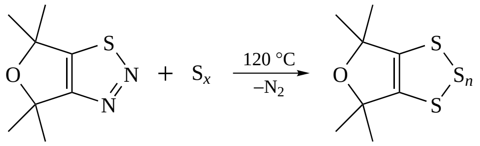
2.2.9 Reaction of Benzothiadiazoles or Related Compounds with Elemental Sulfur

1,2,3-Benzothiadiazoles are thermally stable up to 195 °C but in the presence of elemental sulfur evolution of nitrogen occurs at 160−170 °C and benzopentathiepins are formed (equation 105).[172,173]



(105)

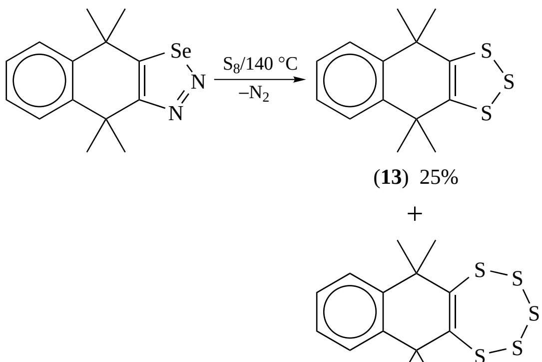
With R = H, Cl, CF_3, OMe, NMe_2, or Br, yields of up to 57% have been obtained if some diazabicyclo[2.2.2]octane (Dabco) is added.[172,173] In a similar reaction, the thiadiazole (**12**) when heated with elemental sulfur to 120 °C affords the corresponding cyclic tetra- and pentasulfanes in 18 and 22% yields, respectively (equation 106).[174–176]



(106)

(**12**) n = 2, 3

Certain selenadiazoles also react with sulfur to yield cyclic polysulfanes (equation 107).[174–176]

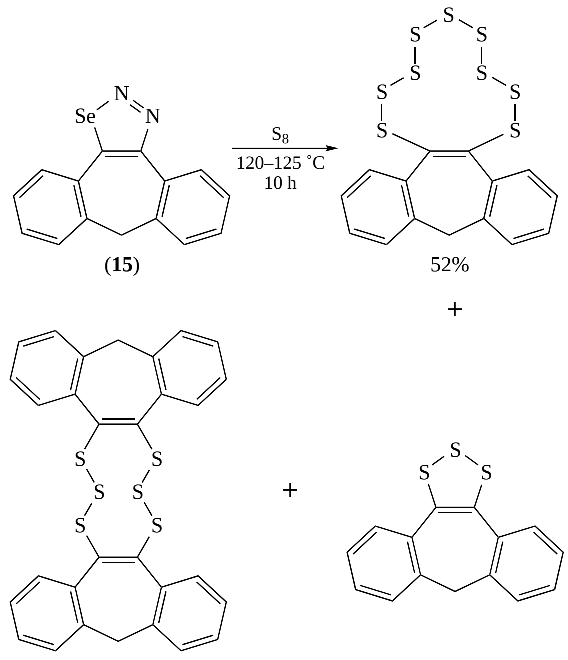


(**13**) 25%

\+ (107)

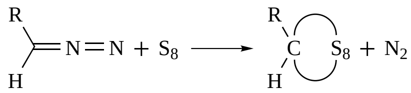
(**14**) 11%

On heating or irradiation, (**14**) is converted to (**13**) and S_8.[174–176] When the selenadiazole (**15**) is heated with sulfur, a complicated mixture of sulfurization products was obtained from which the pure polysulfanes shown in equation (108) were obtained by chromatography and crystallization.[177]



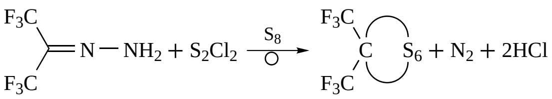
(108)

An octathionane of type $RHCS_8$ has been obtained in a 25% yield on refluxing S_8 and the monosubstituted diazomethane $RHCN_2$ in benzene with R = 2, 4,6-tris[bis(trimethylsilyl)methyl]phenyl (equation 109).[178,179]



(109)

This cyclic octasulfane is stable at 20 °C, and even in a boiling EtOH/$CHCl_3$ mixture. Related to equation (109) is the reaction of hexafluoroacetone hydrazone with S_2Cl_2, which produces the hexathiepane $(CF_3)_2CS_6$ (equation 110).[178,179]

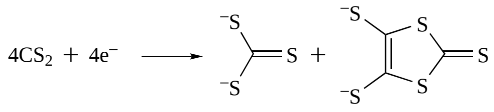


(110)

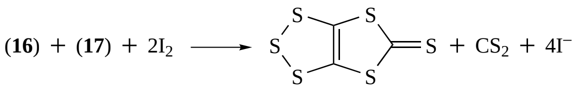
If the hydrazone is substituted with two bulky groups such as adamantyl or *t*-butyl, a tetrathiolane is obtained in the reaction with S_2Cl_2,[180] but with phenyl substituents pentathianes and hexathiepanes are formed.[181]

2.2.10 *Miscellaneous Reactions for the Synthesis of Cyclic Polysulfanes*

Electrochemical reduction of CS_2 in either DMF or MeCN yields the trithiocarbonate (**16**) and the 4,5-dimercapto-1,3-dithiole-2-thione (**17**) dianions, which on oxidation by iodine give the binary carbon sulfide C_3S_6 in good yields (equations 111 and 112).[182]



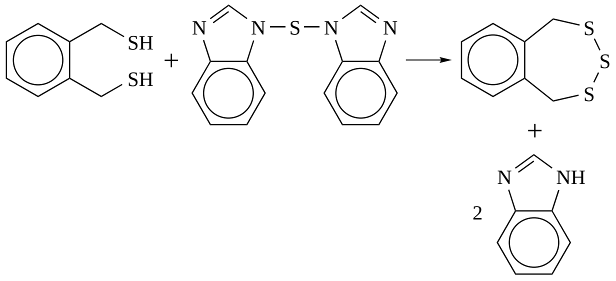
(**16**) (**17**) (111)



(112)

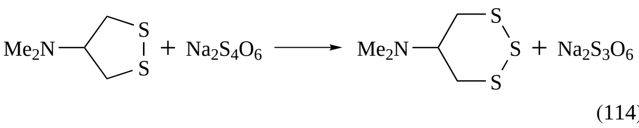
C_3S_6 is a yellow solid, sparingly soluble in CS_2.[118]

The use of N,N'-dibenzimidazolyl sulfide for the synthesis of cyclic polysulfanes by reaction with dithiols has been explored. In many cases, oligomers or low-molecular mass polymers are formed, however, α,α'-dimercaptoxylene yields the benzotrithiepin shown in equation (113) when stirred at 20 °C with the imidazolyl sulfide in benzene.[183]



(113)

4-(N,N'-Dimethylamino)-1,2-dithiolane is transformed to the corresponding trithiane by reaction with sodium tetrathionate at 20 °C and pH = 7.8 (yield 65%) (equation 114).[184]

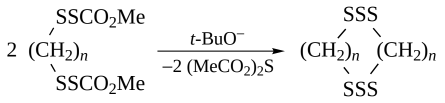


(114)

A mixture of S_8 and phosphorus(V) sulfide may also be used to sulfurize organic compounds: certain epidisulfanes are transformed to epitrisulfanes.[185,186] The reaction of SCl_2 with 1,4-diethoxybenzene, catalyzed by Al_2Cl_6, in CS_2 or $CHCl_3$, yields a bis-tetrasulfane in which two S_4 units bridge the two benzene rings.[187]

Acyclic and cyclic trisulfanes may be synthesized from sulfenyl thiocarbonates by nucleophilic displacement.

From 1,6-hexanedithiol and MeOC(O)SCl the bis-sulfenyl thiocarbonate shown on the left side of equation (115) was obtained, which on treatment with potassium *t*-butoxide in methanol resulted in a macrocyclic bis-trisulfane, (equation 115).[188]



(115)

In this reaction, the alkoxide anion displaces the MeOCO group, generating an RSS^- anion that attacks the neighboring molecule, producing a dimer that is attacked by another alkoxide ion, and so on until finally ring closure takes place. Similar reactions were observed for $n = 7$, 8, and 10, while for $n < 6$ only polymers were obtained.[188]

Certain ketones react with H_2S or sodium polysulfide to give cyclic polysulfanes. Formaldehyde and aqueous $Na_2S_{2.5}$ in the presence of chloroform result in 1,2,3,5,6-pentathiepin (lenthionine, see Section 6.2).[121,122] Cycloheptanone reacts with ammonium polysulfide at 20 °C to give the tricyclic pentathiepane derivative $C_{14}H_{24}S_5$ containing a disulfane and a trisulfane bridge between the two cycloalkyl units.[189] Various cyclic and acyclic tri- and tetrasulfanes have been obtained from the corresponding ketones, diketones, or aldehydes and H_2S at temperatures of 30–135 °C and pressures of 50–8500 bar.[106] The use of H_2S_2 for the transformation of dithiols or epidisulfanes into cyclic tri- and tetrasulfanes in good yields has also been reported.[190,191] When 1,2,4,5-tetrathiane is treated with Na_2S_4 in DMF at 20 °C, 1,2,3,5,6-pentathiepin (lenthionine) is formed in a 30% yield.[192] Substituted benzothiocarbonates may be converted to benzotrithioles by reaction with NaHS in DMSO.[193]

3 STRUCTURES OF ORGANIC POLYSULFANES

The stereochemistry of organic sulfur compounds was reviewed very extensively by Laur[7] in 1972 and that of organic polysulfides by Rahman *et al.*[194] in 1970. Since those days, however, considerable progress has been made. The molecular and crystal-structures of more than 60 cyclic and acyclic polysulfanes of type R–S_n–R have been determined by X-ray diffraction on single crystals. In rare cases, electron diffraction of the vapor of R–S_n–R molecules has been used to determine the structure (*see* ***Diffraction Methods in Inorganic Chemistry***). In addition, the structures of several acyclic polysulfane oxides such as RS–SO–SR[84,195,196] and RSO_2–S_n–SO_2R ($n = 1$, 2, 3),[197,198] and of the trisulfane cation $(MeS)_3{}^+$,[199,200] have been determined.

Chainlike organic polysulfanes with up to nine sulfur atoms have been characterized structurally, while in cyclic species the maximum number of sulfur atoms was 11, but the total number of sulfur atoms in the molecule can be as high as 16. In all cases, the –S_n– backbone was found to be unbranched. It may be characterized by the bond distances d_{SS}, the bond angles α_{SSS}, and the torsional angles τ_{SS}, which determine the overall conformation of the molecule. Typical values of these parameters in chainlike R–S_n–R are $d_{SS} = 205 \pm 4$ pm, $\alpha_{SSS} = 107 \pm 3°$, and $\tau_{SS} = 85 \pm 20°$. The torsional angles may be positive (clockwise rotation) or negative (counterclockwise rotation). A helical sulfur chain –S_n– may therefore be a right-handed (all τ positive) or a left-handed screw (all τ negative). The order of the signs of τ in such a chain is termed the motif. Thus, the motif of a helix is either $+ + + \cdots$ or $- - - - \cdots$. Less symmetrical –S_n– chains are usually obtained when the motif is less regular. In *cyclo*-octasulfane, S_8, the motif is $+ - + - \cdots$ or $(+-)_4$; in S_{12} it is $(+ + - -)_3$.[1]

Rotation around S–S bonds in acyclic organic disulfanes requires an energy of 25–40 kJ mol^{-1},[201] which is far too low to permit the isolation of the rotational isomers. In the case of R–S_2–R, these stereoisomers are mirror images or enantiomers. However, in favorable cases these stereoisomers crystallize from solutions as enantiopure single crystals (see below). The torsional barriers of organic polysulfanes R–S_n–R with $n > 2$ have not yet been accurately determined, but may be even lower than for disulfanes. This might be concluded from the results obtained for the inorganic species H_2S_n ($n = 2$–4)[202] and from the *Pseudorotation* of the cyclic S_n molecules ($n \geq 7$).[203] It therefore can be expected that acyclic organic polysulfanes show a rapid torsional isomerization in solution at 20 °C. The conformational properties of trisulfanes, R_2S_3, in the liquid and solid states have been studied by Raman spectroscopy (*see Raman Spectroscopy*).[204]

In the case of cyclic polysulfanes, it has repeatedly been observed by ^{1}H NMR spectroscopy that different conformational isomers exist in equilibrium with each other in solution.[116,160,205] However, as in the case of acyclic polysulfanes, the energy barriers between these isomers are too low to allow a preparative separation.[116]

No organic polysulfane has been observed that has a branched structure of the type –S–S(=S)–S–, however, molecules of this type have recently been subjects of sophisticated theoretical study. According to these results, branched species are considerably less stable than the unbranched isomers, and the barrier for isomerization is extremely high.[206,207]

3.1 Structures of Chainlike R–S_n– R Molecules

Table 4 compiles the structural parameters of the –S_n– backbone of 15 chainlike polysulfanes.[25,208–214] The only undisturbed free molecules investigated by electron diffraction of vapors are Me_2S_3, $(CF_3)_2S_3$, and $(CF_3)_2S_4$. All other data are derived from X-ray diffraction on single crystals. In the latter case, the molecular conformation may be influenced by intermolecular interaction (‘packing effects’). Many polysulfanes are chiral (helical chirality). While normally

[a]Owing to the symmetry of the molecule, the number of independent molecular parameters is lower than the number of internal coordinates.
[b]ED, electron diffraction; X, X-ray diffraction on single crystal; n.d., not determined.
[c]Torsion angles along the sulfur chain. For chiral molecules, the torsion angles of the other enantiomer are obtained by changing all signs to the opposite.

chiral molecules crystallize in such a manner that the unit cell contains equal amounts of both enantiomers, there are some cases known in which enantiopure crystals have been obtained. For example, the nonasulfane $S_9(CN)_2$ crystallizes from CS_2/hexane solution as enantiopure crystals despite the many conformations this molecule can adopt.[212] It should be noted that the parameters cited in Table 4 have widely differing standard deviations.

Most trisulfanes adopt a *trans* conformation with a local symmetry of C_2 for the central X–S–S–S–X unit (motif ++ or −−). The term *trans* describes the position of the two substituents X with respect to the plane defined by the three sulfur atoms. Dicyanotrisulfane is the exception to the rule since this molecule adopts a *cis* conformation in the solid state, which seems to be the result of the weak interaction of the two nitrogen atoms with the central sulfur atom of a neighboring molecule.[211] The motif of $S_3(CN)_2$ is +− (or −+ for the enantiomer (*see Enantioselectivity*), which is present in equal amounts in the unit cell). Electron density measurements on gaseous Me_2S_3 have been interpreted by a mixture of mainly *trans*- and little *cis*-Me_2S_3.[216]

The only tetrasulfane investigated in the vapor phase is most probably of C_1 symmetry (*cis-trans*) with the motif + + −. This result is in agreement with ab initio MO calculations,[32] which indicate this conformer to be slightly more stable (by 1.2 kJ mol^{-1}) than the trans−trans conformer. Electron diffraction has shown that the analogous MeO–S–S–OMe also adopts a *cis-trans* conformation in the vapor, but a *trans−trans* structure in the solid state.[217] The three solid tetrasulfanes exist in a *trans−trans* conformation with all torsional angles of equal sign. The same holds for the only acyclic pentasulfane, which has been studied structurally and which has a helical

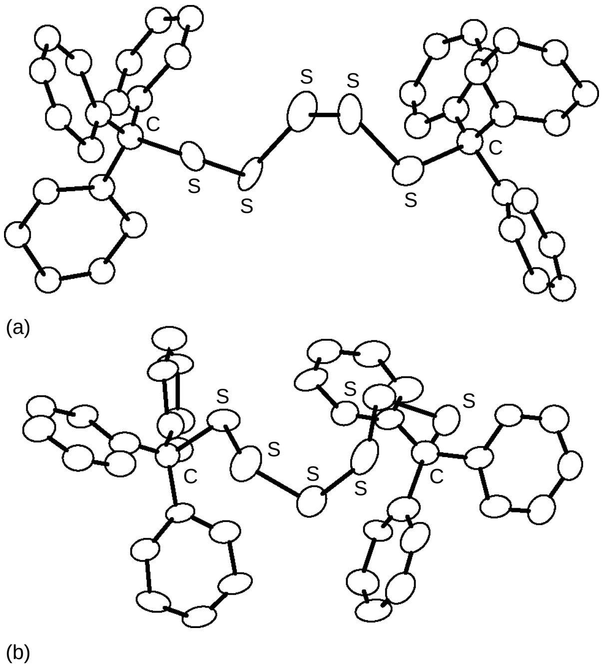

Figure 2 Molecular structures of bis(triphenylmethyl)pentasulfane (a) and -hexasulfane (b)[50]

S_n unit of motif + + ++. Interestingly, however, the two hexasulfanes listed in Table 4 do not adopt a helical but a more compact conformation with motifs + + − − + and + + − + +, respectively. It may well be that longer chain polysulfanes in the crystalline state have to have a motif of this type to allow for an efficient space-filling packing of the molecules in the crystal.

In Figure 2, the molecular conformations of $(Ph_3C)_2S_5$ and $(Ph_3C)_2S_6$ are shown to illustrate the impact of the motif on the size and shape of the molecule.

The rotational isomerism that probably exists in solution may be responsible for the fact that so far no single crystals have been obtained for organic polysulfanes with more than nine sulfur atoms in a chain. However, cyclic polysulfanes with up to 11 neighboring sulfur atoms have been structurally elucidated (see below), and the structures of homocyclic sulfur molecules with up to 20 atoms are known.[45]

The molecular parameters in Table 4 show that the accurately determined SSS bond angles range from 105 to 108°, and the absolute values of the torsional angles at the SS bonds range from 75 to 99° with the exception of $(n\text{-}C_{18}H_{17})_2S_4$, which has one torsional angle of 65°, which may be a result of the large substituents. However, if more structures are considered, these ranges are slightly larger.[11]

3.2 Structures of Cyclic R–S_n–R Molecules

More than 40 cyclic polysulfanes have been investigated by X-ray diffraction on single crystals. These compounds are monocyclic or polycyclic. All ring sizes have been studied from 5 to 12 as well as 14, 16 and 20, and the number of sulfur atoms in the –S_n– unit varies from 3 to 11. There are also systems with two independent –S_n– units ($n = 2–8$) in one ring, bridged by carbon atoms. The following are leading references: trisulfanes;[124,131,132,166,167,172,173,218–220] bis-trisulfane;[221] tetrasulfanes;[222–225] bis-tetrasulfane;[226] pentasulfanes;[131,132,144,148–150,172,173,227–230] bis-pentasulfane;[168,169] hexasulfanes;[148–150,230] heptasulfane;[50] octasulfane;[178,179] nonasulfane,[177] undecasulfane.[231]

The geometrical parameters of the –S_n– unit in cyclic organic polysulfanes may be quite different from those in chainlike polysulfur compounds since ring closure may enforce unusual valence and torsional angles and, as a consequence, the bond distances may be affected. This problem is well known from the structures of homocyclic sulfur molecules (*cyclo*-S_n), which exhibit torsional angles in the range of 0–140°, bond angles in the range of 101–111°, and bond distances in the range of 200–218 pm.[45]

The conformation of cyclic organic polysulfanes is usually as follows:

1. five-membered rings of composition C_2S_3 are envelope-shaped (four atoms C_2S_2 in a plane, one S atom out of plane);[131,132,172,173,218,220]
2. six-membered rings of composition C_3S_3, C_2S_4, or CS_5 are chairlike;[124,222,225,229,230]
3. seven-membered rings of composition C_2S_5 are chairlike as *cyclo*-S_7 or distorted (twisted) chairs;[131,132,144,148–150,172,173,219,227,228,230]
4. larger rings either resemble in shape the sulfur homocycles, like S_8, S_{10}, S_{11} and S_{12}, or are of lower symmetry.[166,167,174–179,221,223,224,226]

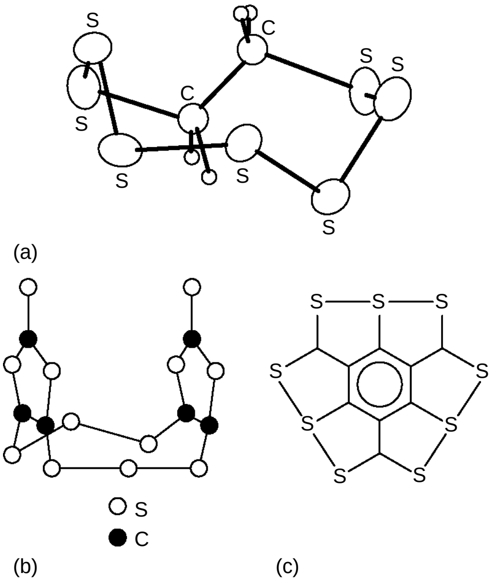

Figure 3 Molecular structures of the nine-membered ring $C_2H_4S_7$ [1,2,3,4,5,6,7-heptathionane] (a), of the tricyclic carbon sulfide C_6S_{12} (b), and of C_9S_9 (c)

The structures of some naturally-occurring organic polysulfanes will be discussed in Section 6 of this article.

To illustrate the types of cyclic structures known, the results of X-ray structural analyses of $C_2H_4S_7$ and of two binary carbon sulfides are shown in Figure 3. The structure of $C_2H_4S_7$ may be derived from the structure of S_8 by substitution of one sulfur atom by a *trans*-C_2H_4 group.[50] The carbon sulfide C_6S_{12} is a tricyclic molecule prepared only in 1989.[166,167] C_9S_9 is formally a thioketone,[232] but it contains three linear three-center bonds between adjacent sulfur atoms, resulting in an unusually symmetrical planar system of two ‘concentric rings’. The structures and bonding in compounds of the latter type have been reviewed in 1976.[233]

4 ANALYSIS OF ORGANIC POLYSULFANES

A comprehensive review on the analytical chemistry of organic di- and polysulfanes was published in 1972 by Cardone (340 pages, 1200 references).[8] The latter review summarizes the physical properties (density, boiling point, refractive index, vapor pressure, molar refraction, parachor, dipole moment, viscosity, optical rotation, crystal data) as well as the application of analytical techniques (thermal analysis, mass spectroscopy, ^1H NMR spectroscopy, infrared (IR) and Raman spectroscopy, UV–Vis spectroscopy, polarography, liquid chromatography including TLC, paper chromatography, gel permeation and ion-exchange chromatography, partition chromatography, electrophoresis, and gas chromatography). In addition, the chemical treatment of polysulfane mixtures prior to analysis (pyrolysis, reduction to RSH and H_2S,

oxidation by bromine, nucleophilic degradation by sulfite, cyanide, or tertiary phosphanes) are reviewed.[8]

The preparation of organic polysulfanes usually results in mixtures of R_2S_n molecules. Even after pure substances have been obtained these tend to decompose by equilibration with other chain lengths or ring sizes, and by formation of elemental sulfur (equations 116 and 117).

$$2R_2S_n \rightleftharpoons R_2S_{n+x} + R_2S_{n-x} \quad (116)$$

$$R_2S_{n+x} \longrightarrow R_2S_n + S_x \quad (117)$$

$$x = 6 - 8$$

These reactions are accelerated by light, heat, and numerous catalysts of which strong nucleophiles are most effective. In addition, silica gel, alumina, and other porous and finely divided solids catalyze the above reactions. Therefore, conventional liquid chromatography, including paper chromatography, may yield erroneous results. The same holds for gas chromatography since the low vapor pressure of many organic polysulfanes requires high injector and column temperatures. Equally doubtful is mass spectrometry (MS) if the sample has to be heated to evaporate or if a heated ion source is used. Reliable quantitative data about a mixture of organic polysulfanes can best be obtained by either ^{1}H NMR spectroscopy or reversed-phase high-pressure liquid chromatography (RP-HPLC).

In a chainlike compound R–S_n–R, the chemical shift of the protons of R will depend on the chain length n. This is most obvious from the NMR spectra of the inorganic sulfanes H_2S_n, which in this manner have been identified with n ranging up to 35.[234] In other words, the chemical shift of the chain-terminating hydrogen atoms depends on the chain length. Similar situations can be expected for alkyl-substituted sulfanes (methyl, t-butyl, i-propyl), which exhibit simple spectra.[235] In the case of aryl substituted or cyclic organic polysulfanes, the spectra may be too complex to analyze these mixtures of homologous compounds spectroscopically. In such cases, HPLC is the method of choice.

RP-HPLC is a particularly gentle separation technique that may be used for qualitative and quantitative analysis of mixtures of R_2S_n molecules. The resolution power of HPLC approaches that of gas chromatography if stationary phases of low particle size (10, 5, or 3 µm) are used. The most widely used stationary phase is the 'C18' phase, that is, silica gel covered by $-SiMe_2(C_{18}H_{37})$ groups that are linked to the surface by very strong disiloxane bonds (Si–O–Si). This surface modification is produced by reaction of silanol groups (SiOH) of silica gel with chlorosilanes (Cl–SiR_3).[236] The long alkyl chain of $C_{18}H_{37}$ renders the formerly polar surface of the silica gel totally unpolar, and if all OH groups have reacted, a chemically very inert but still highly porous material is obtained. The mobile phase then has to be polar and methanol or mixtures based on methanol are very often applied.[237,238]

All sulfanes have a very strong ultraviolet (UV) absorption near 220 nm, and therefore application of a UV absorbance detector operating at any wavelength between 220 and 260 nm is recommended. The high extinction coefficients of polysulfanes result in a very low detection limit, and very dilute samples may therefore be applied. In this way, no problems are to be expected with the low solubility of sulfur-rich species in the polar mobile phase. The total sample concentration may be as low as 0.1 mg L^{-1} using a 10 µL loop injector and a column of 8–10 mm inner diameter.

The main problem in HPLC is the peak assignment. LC–MS systems are available but are far from being standard equipment. Some help may be expected from a diode-array detector, which allows the measurement of the UV–Vis absorption spectrum, for example, in the range 200–800 nm, on-line during chromatographic separation. Unfortunately the absorption spectra of organic polysulfanes[17,18,32,160,239,240] are not very specific. The measurement of absorption spectra under static conditions cannot be recommended since polysulfanes rapidly decompose or react with the solvent on UV irradiation.

Peak identification normally requires reference substances. If a homologous series of compounds R_2S_n is to be analyzed, it is of great help that the retention behavior depends systematically on both R and on the number n of sulfur atoms in the ring or chain. For an unpolar molecule, the retention time t_R will be larger if either R or n is larger than in a reference molecule. It is probably the surface area of a molecule that determines the retention behavior,[236–238] in other words, t_R of Et_2S_3 is larger than that of Me_2S_3, and Me_2S_4 elutes later than Me_2S_3. Even the small size or surface area difference between isomeric alkyl groups (n-butyl, i-butyl, t-butyl) results in different retention times.

In this context, the capacity factor $k' = (t_R - t_0)/t_0$ is important: t_0 is the 'dead' time of the chromatographic system, roughly the time the pure eluent needs to travel from the injector to the detector. It may be determined by injection of a methanol/water mixture since H_2O does not show any significant retention in a C18 column. For cyclic[115,137,138,160] and acyclic[24–26,48,50,237,238] organic polysulfanes, it has been found that the logarithm of the capacity factor is a linear function of the number of sulfur atoms (equation 118).

$$\ln k' = a \times n + b \quad (118)$$

This relationship was first observed in gas chromatography of alkylpolysulfanes.[92,93] As an example, experimental retention data of bis(triphenylmethyl)polysulfanes, $(Ph_3C)_2S_n$, are shown in Figure 4. These linear relationships are extremely helpful since they allow the identification of members of a homologous series by means of inter- and extrapolation. However, sometimes a long series is characterized by *two* linear relationships of slightly differing slope, one for the first three or four members and another one for the higher members.

The retention times and capacity factors depend, of course, on the chromatographic system and its operating

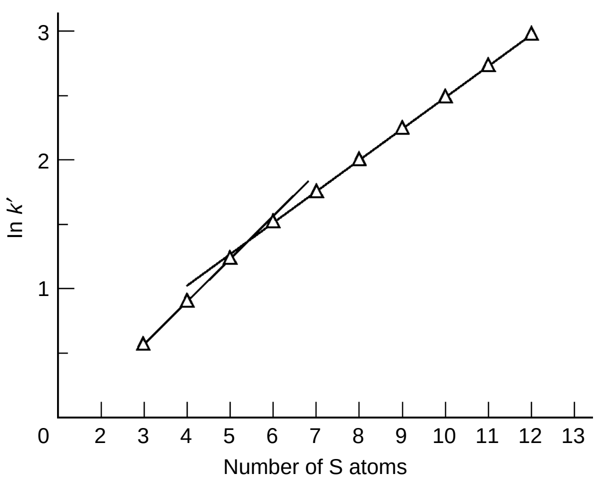

Figure 4 Relationship between the logarithm of the capacity factor k' and the number of sulfur atoms in $(Ph_3C)_2S_n$ molecules ($n = 3-13$)[50]

conditions (flow, eluent composition, temperature, column length, particle size, type of stationary phase, etc.). A more independent measure of the retention behavior is provided by the Kovats' retention indices, which are well known in gas chromatography. This index simply relates the retention time of a substance to the retention time of reference substances measured under identical conditions. The tremendous advantage of the retention index is that it is independent of the chromatographic system and only depends on the eluent composition, the type of stationary phase, and the temperature. Therefore the retention index is a similar characteristic parameter to the chemical shift in NMR spectroscopy, which is also related to the resonance signal of a reference substance.

A few retention index values of organic polysulfanes have been published.[46–48,160] They may be calculated as follows.[241] The homocyclic sulfur molecules S_6, S_8, S_9, and S_{10} are recommended as reference substances because they are easy to make (see below), have high extinction coefficients in the UV,[242] and retention times similar to those of organic polysulfanes.[243–244] To these molecules, the sulfur-based retention index values (RS values) of 600 (S_6), 800 (S_8), 900 (S_9), and 1000 (S_{10}) are assigned by definition.[241] A plot of $\ln k'$ of these four molecules versus these defined RS values gives a straight line according to equation (119).

$$\ln k' = a \times \mathrm{RS} + b \qquad (119)$$

After the parameters a and b have been determined, they are used to derive the RS value of the unknown substance. This substance is measured under identical conditions as for the sulfur rings, the capacity factor is calculated, and $\ln k'$ is used to calculate the RS value of the unknown substance from equation (119). These RS data are practically identical when determined from retention data measured with different HPLC systems in different laboratories.

The necessary solution of S_6, S_8, S_9, and S_{10} in CS_2 is prepared as follows: commercial elemental sulfur (1 g) is heated in a test tube to near 200 °C (oil bath) for 2.5 h, cooled slowly to ca. 130 °C (freezing point 115 °C), and poured into liquid nitrogen, resulting in a fine yellow powder that is extracted by CS_2 at 20 °C. The yellow solution contains all sulfur rings from S_6 to S_{25} and is stable at 4 °C in the dark if not too concentrated.[64,243–245] The peak assignment is straightforward since S_8 gives the tallest peak (besides CS_2), which is preceded by S_6 and S_7 and followed by S_9, S_{10}, and so on.[243–244] However, S_7 is not used for the calculations of RS values since it does not fit equation (119) very well.

4.1 Examples

Chainlike homologous polysulfanes with between 2 and 23 sulfur atoms have been separated by RP-HPLC,[24–26,48,50,237,238,246] while cyclic isopropylpolysulfanes Me_2CS_n, with n ranging from 5 to 34, have been separated by the same technique.[16] Furthermore, alkoxythiocarbonylpolysulfanes, $[ROC(S)]_2S_n$ (xanthates),[247] and methylthiocarbonylpolysulfanes, $[RSC(O)]_2S_n$, as well as alkoxycarbonylpolysulfanes[57] may be analyzed by RP-HPLC. The separation of cyclic methylene sulfanes by RP-HPLC has also been reported and the impact of the ring size, number of sulfur atoms, and number of C–S bonds per molecule on the

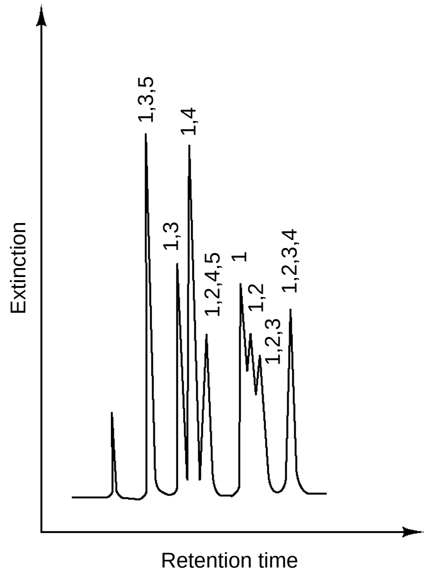

Figure 5 Chromatographic separation (RP-HPLC) of eight six-membered methylene sulfanes $(CH_2)_{6-n}S_n$ with $n = 1$, 2 (3 isomers), 3 (2 isomers), and 4 (2 isomers). The numbers give the positions of the S atoms in the ring, for example, '1,3' means '1,3-dithiane'. (Reproduced by permission of Verlag der Zeitschrift für Naturforschung from Steudel and Strauss[115])

retention time has been elucidated.[115] In Figure 5 the HPLC separation of six-membered methylene sulfanes, $(CH_2)_{6-n}S_n$ with $n = 1-5$, is shown: even the isomeric dithianes 1,2-, 1,3-, and 1,4-$(CH_2)_2S_4$ are well separated. Since the retention time is an unambiguous function of the ring size, of the number of S atoms, and of the number of heteronuclear bonds, the retention of new cyclo-methylenesulfanes can be predicted.[115]

It should be mentioned here that Raman and X-ray absorption near edge spectroscopy (XANES) spectroscopy are also suitable analytical techniques to analyze mixtures of organic polysulfanes.[11]

5 REACTIONS OF ORGANIC POLYSULFANES

Of the many reactions known for polysulfanes, only the following types will be dealt with since they are of general importance for inorganic and organic polysulfur compounds: interconversion and sulfur transfer reactions, nucleophilic displacement reactions, and oxidation reactions with conservation of chain length.

5.1 Interconversion Reactions

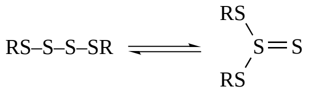
The formal exchange of sulfur atoms between like molecules containing S–S bonds is called interconversion; examples are given in equations (120) and (121).

$$2S_8 \rightleftharpoons S_7 + S_9 \quad (120)$$

$$2R_2S_4 \rightleftharpoons R_2S_3 + R_2S_5 \quad (121)$$

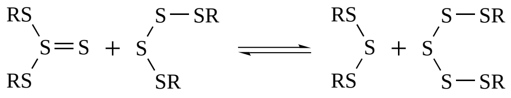
These reactions are reversible and proceed at moderate temperatures (0–120 °C) when compounds with cumulated S–S bonds (polysulfanes, elemental sulfur) are considered. The activation energy and therefore the rate of reaction at a certain temperature very much depend on the particular compound. Interconversion reactions are promoted by UV radiation as well as by cationic, anionic, and nucleophilic catalysts. The reaction mechanisms will, of course, be different in these various cases. The various reaction types possible under noncatalyzed conditions and with exclusion of light have been critically reviewed by Steudel in 1982.[248] Originally it had been thought that homolytic bond scission is the first and rate-determining step in all cases. Dissociation energies of cumulated S–S bonds[1–2] are, however, above $120\,kJ\,mol^{-1}$, while some interconversion reactions proceed slowly even at ambient or at only slightly elevated temperatures. Therefore, several alternatives for a formal exchange of S atoms between molecules have been proposed.[248]

Isomerization of an unbranched sulfur chain to form a branched structure is one possibility (equation 122) to start a sulfur transfer reaction.



(122)

The terminal sulfur atom of the thiosulfoxide may then be transferred to a neighboring molecule (equation 123).



(123)

Such isomerization reactions are, of course, endothermic but the reaction energy in the case of sulfur-rich molecules is lower than ca. $60\,kJ\,mol^{-1}$.[206,207,249] Unfortunately, the activation energy is known only for disulfanes. However, in the case of ethylene episulfide a similar sulfur atom transfer has been shown to be the lowest energy pathway for the decomposition to elemental sulfur and an alkene with an activation enthalpy of $110\,kJ\,mol^{-1}$.[250] Compounds of type X–S(=S)–X are stable at 20 °C if X = F or OR.

Another route for the exchange of sulfur atoms between polysulfanes involves a σ-sulfurane type intermediate as shown in Scheme 2.

This potential pathway has recently been studied in detail.[251] Although sulfuranes of the type SX_4 are known in large numbers with X = F, Cl, OR, R (=organyl),[252–254] the reaction shown in Scheme 2 requires an activation energy of more than $250\,kJ\,mol^{-1}$ and therefore cannot explain any interconversion reaction of organic polysulfanes at or near room temperature.[251]

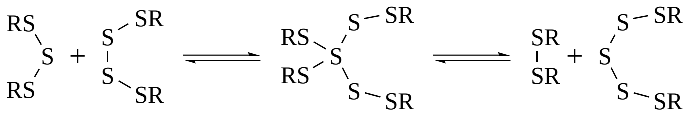
Interconversion reactions at temperatures above 100 °C will probably proceed via a radical chain reaction mechanism,[248] as illustrated by equations (124–127).

$$RS{-}S{-}S{-}SR \rightleftharpoons 2RS{-}S\cdot \quad (124)$$

$$RS{-}S\bullet + R_2S_4 \rightleftharpoons R_2S_3 + RS{-}S{-}S\bullet \quad (125)$$

$$RS{-}S{-}S\bullet + RS{-}S\bullet \rightleftharpoons R_2S_5 \quad (126)$$

$$2RS{-}S{-}S\bullet \rightleftharpoons R_2S_6 \quad (127)$$

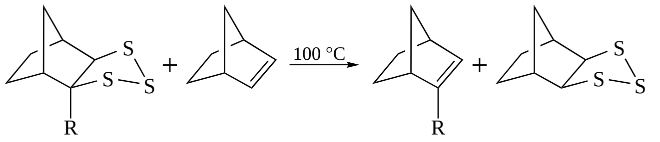


Scheme 2

Most likely, light-induced interconversion reactions also proceed by a radical chain reaction. The formation of radicals upon irradiation of elemental sulfur has been demonstrated by ESR (electron spin resonance) spectroscopy,[137,138] and the isomerization of chainlike S_2Cl_2 to the thiothionyl chloride isomer $Cl_2S{=}S$ has also been achieved by irradiation.

5.2 Sulfur Transfer Reactions

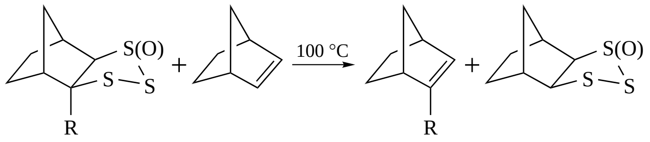
It has been known for some time that on heating certain organic di- or polysulfanes seemingly split off S_2, which may then add to a substrate to form another disulfane.[151–154] Only recently, transfer reactions for the S_3 and even the S_3O unit have been observed.[196] When a substituted ('labeled') norbornanetrisulfane is heated with norbornene in benzene to 100 °C, a clean transfer of the S_3 unit is observed for R = phenyl (equation 128).



(128)

The rate and the yield of the reaction shown in equation (128) depend on the nature of R and of the alkene to which the S_3 unit is to be transferred. If this norbornene is also substituted in the 2-position the yields differ greatly depending on the substituent: phenyl results in high, methyl in low, and methoxycarbonyl in intermediate yields. When an unsymmetrically-substituted norbornadiene is used as acceptor molecule, the two double bonds react at the same rate to give equal amounts of the two trithiolanes. Most probably, the transfer reaction proceeds by a concerted bimolecular mechanism.

Norbornanetrisulfane may be oxidized by MCPBA (3-chloroperbenzoic acid) to give the two isomeric compounds trisulfane 1-oxide and 2-oxide.[196] The 2-oxide may also be prepared from norbornanedithiol and thionyl chloride. Heating the substituted 1-oxide in benzene with norbornene for 12 h to 100 °C resulted in a 50% S_3O transfer (equation 129).



(129)

For other thermally induced sulfur transfer reactions, see Section 2.2.6.

5.3 Nucleophilic Displacement Reactions at the Sulfur–Sulfur Bond

A strong *Nucleophile* (Nu) may open an S–S bond as shown in equation (130).

$$\text{Nu} + \text{RS–S–S–SR} \rightleftharpoons \text{Nu–}\overset{+}{\text{S}}\text{–SR} + \text{RS–S}^- \qquad (130)$$

The anion RSS^- has been displaced. The relative strengths of various nucleophiles that determine the position of the equilibrium of equation (130) may be given by their 'thiophilicity'. This area has been pioneered by Foss and expertly reviewed by Davis.[255,256] The following species are very strong thiophiles that are able to open any sulfur–sulfur single bond in a polysulfane in a reaction of the type shown in equation (130): normal thiolates (RS^-), HS^-, S_n^{2-} ($n = 1, 2, \ldots$), SO_3^{2-}, CN^-, R_3P (R = alkyl, aryl, alkoxy, dialkylamino, etc.). The corresponding reactions are depicted in equations (131–135).

$$RS^- + R'_2S_3 \longrightarrow R'S^- + RR'S_3 \qquad (131)$$

$$HS^- + R_2S_3 \longrightarrow S_2^{2-} + H^+ + R_2S_2 \qquad (132)$$

$$2SO_3^{2-} + R_2S_4 \longrightarrow 2S_2O_3^{2-} + R_2S_2 \qquad (133)$$

$$2CN^- + R_2S_3 \longrightarrow 2SCN^- + R_2S \qquad (134)$$

$$R_3P + R'_2S_3 \longrightarrow R_3PS + R'_2S_2 \qquad (135)$$

As is apparent, some reagents desulfurize to the level of disulfanes, while others even give monosulfanes, R_2S. In the case of R_3P, it depends on R whether di- or monosulfanes are formed (see below). Such reactions display second order kinetics. The rate very much depends on the steric requirements and on the strain of the S–S bonds to be broken. For example, methylsulfenyl thiocyanate reacts with cyanide according to equation (136).

$$\text{Me–S–SCN} + \text{CN}^- \longrightarrow \text{Me–SCN} + \text{SCN}^- \qquad (136)$$

However, *t*-butylsulfenyl thiocyanate does not react with cyanide. Similar observations have been made with the reactions shown in equations (137) and (138), which have been studied using labeled sulfur atoms.

$$\text{R–S–S–R} + \text{R}\overset{*}{\text{S}}{}^- \rightleftharpoons \text{R–S–}\overset{*}{\text{S}}\text{–R} + \text{RS}^- \qquad (137)$$

$$\text{R–S–SO}_3^- + \overset{*}{\text{S}}\text{O}_3^{2-} \rightleftharpoons \text{R–S–}\overset{*}{\text{S}}\text{O}_3^- + \text{SO}_3^{2-} \qquad (138)$$

With R = *t*-butyl the relative rates are orders of magnitude smaller than with R = Me. Strained ring systems react much faster with thiolates than comparable chainlike compounds. For example, 1,2-dithiolane reacts about 5000 times faster with *n*-butylthiolate as does bis-*n*-butyldisulfane. The thiophilicity of thiolate ions (RS^-) very much depends on R: 2,4-dinitrophenylthiolate is much less thiophilic than phenylthiolate, which in turn is less thiophilic than

ethylthiolate.[255,256] In unsymmetrical disulfanes, RSSR′, the less basic RS^- group is displaced by an incoming nucleophile like cyanide, sulfite, or thiolate.[255,256] The nucleophiles R_3N, OH^-, $S_2O_3^{2-}$, and SCN^- are too weak to open an ordinary S–S bond.

These reactivities can be explained by the oxidative dimerization potential E_o derived for equation (139) and the base strength of the nucleophile.

$$2XS^- \rightleftharpoons X\text{–}S\text{–}S\text{–}X + 2e^- \qquad (139)$$

According to a rule by Foss,[255,256] the anions of more positive E_o will displace anions of lower E_o. Aqueous thiosulfate is not able to open S–S bonds and therefore the equilibrium shown in equation (140) is completely to the left.[255,256]

$$S_2O_3^{2-} + R_2S_3 \rightleftharpoons S_3O_3^{2-} + R_2S_2 \qquad (140)$$

The situation with OH^- and R_3N is similar. Both nucleophiles are too weak thiophiles to open an S–S bond. However, sulfur chemists know that alkalies and amines tend to decompose polysulfur compounds very effectively. This is due to secondary reactions of these nucleophiles with the ubiquitous traces of either H_2S or SO_2, resulting in the formation of the strong thiophiles HS^- or SO_3^{2-} (equations 141–144).[255,256]

$$H_2S + R_3N \rightleftharpoons HS^- + R_3NH^+ \qquad (141)$$

$$H_2S + OH^- \rightleftharpoons HS^- + H_2O \qquad (142)$$

$$SO_2 + 2OH^- \rightleftharpoons SO_3^{2-} + H_2O \qquad (143)$$

$$SO_2 + H_2O + 2R_3N \rightleftharpoons SO_3^{2-} + 2R_3NH^+ \qquad (144)$$

Sulfide and polysulfide ions have very high thiophilicities and will displace thiolate from aryldisulfanes. The reaction of sodium sulfide with S_8 in alkaline methanol is fast even at $-78\,°C$![255,256]

The reactions of tertiary phosphanes with elemental sulfur have been studied kinetically in detail.[21] While trialkylphosphanes and, even more so, trialkoxyphosphanes react with great vigor, certain arylphosphanes react slowly enough for kinetic data to be measured. It was found that diphenyl(2-tolyl)phosphane reacts with homocyclic sulfur molecules S_n ($n = 6, 7, 8, 12$) in CS_2 at -12 to $+35\,°C$ in a second order reaction to give $R_2R'PS$. The activation energies (in kJ mol^{-1}) (*see Activation*) are: 51 (S_6), 40 (S_7), 69 (S_8), and 46 (S_{12}). At 20 °C, the relative reactivities ($S_8 = 1$) are as follows:

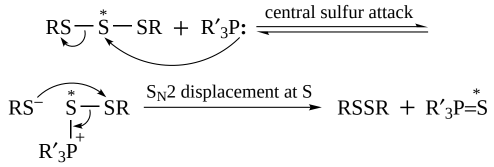
$$S_6{:}S_7{:}S_8{:}S_{12} = 10\,700{:}178{:}1{:}187.$$

Similar dramatic differences are to be expected for cyclic and linear polysulfanes as a function of ring size and inductive as well as steric effects of the substituents. In the case of cyclic species the first and rate-determining step will always be the opening of the ring, resulting in a highly reactive zwitterion, which is then rapidly degradated by additional phosphane molecules (equation 145).[255,256]

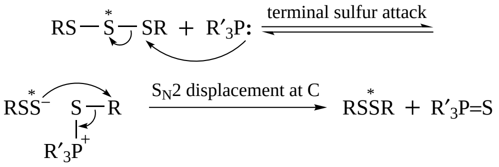
$$R_3P + S_8 \longrightarrow R_3\overset{+}{P}\text{–}S_7\text{–}\overset{-}{S} \xrightarrow{7R_3P} 8R_3PS \qquad (145)$$

The polarity of the solvent will also play an important role.

The desulfurization of di- and trisulfanes by a variety of tertiary phosphanes has repeatedly been studied in detail. In the case of trisulfanes, the initial step may be an attack of the phosphane on either the central sulfur atom or on one of the terminal S atoms (equations 146 and 147).[257,258] In both cases, a pair of ions is formed.



(146)



(147)

In the second and irreversible steps of these reactions, the anions induce a nucleophilic displacement at the cations as follows: in equation (146) the RS^- ion attacks the terminal sulfur with formation of R_2S_2, while in equation (147), the RSS^- ion attacks the carbon atom linked to the terminal sulfur. In the first case, the central sulfur atom is eliminated, while in the second case one of the terminal S atoms is eliminated. Radiochemical experiments which used trisulfanes containing the central S atom labelled by ^{35}S showed that desulfurization of dialkyltrisulfanes by triarylphosphanes results in 91–99% removal of central sulfur, essentially independent of solvent polarity (Et_2O or MeCN), reaction temperature (0–50 °C), type of trisulfane (dibenzyl or dipropyl), and *para* substituents on Ar_3P. In sharp contrast to this, desulfurization of dialkyltrisulfanes by tris(dialkylamino)phosphanes results in preferential removal of a terminal sulfur atom in Et_2O, while in MeCN more than the statistical amount (33%) of central sulfur is removed. When sterically-hindered trisulfanes are used, the rate of desulfurization decreases and the percentage of central sulfur atom removal increases, as expected.[255,256]

Initially, a phosphane attacks a trisulfane both at the central and the terminal sulfur atoms, and there is evidence that the two resulting phosphonium salts shown in equations (146) and (147) exchange their anions (equation 148).

$$[R'_3\overset{+}{P}\text{–}SR][RS\overset{-}{S}] + [R'_3\overset{+}{P}\text{–}SSR][R\overset{-}{S}] \rightleftharpoons [R'_3\overset{+}{P}\text{–}SR][R\overset{-}{S}] + [R'_3\overset{+}{P}\text{–}SSR][RS\overset{-}{S}] \qquad (148)$$

The ion pairs on the right side of equation (148) may dissociate into R_2S_2, R_2S_4, and $R_3'P$, and the formation of tetrasulfane was observed. In other words, tertiary phosphanes (including Ph_3P), like other strong nucleophiles, catalyze the exchange and interconversion (equations 149 and 150), which has been observed.[255,256]

$$RSSR + R'SSR' \rightleftharpoons 2RSSR' \quad (149)$$

$$2R_2S_3 \rightleftharpoons R_2S_2 + R_2S_4 \quad (150)$$

It depends on the phosphane and the solvent whether equation (146) or (147) prevails, and whether the final product will be a di- or monosulfane. The latter are usually obtained using $(R_2N)_3P$, but only in the case of dialkylsulfanes.[255,256] Many examples of nucleophilic displacement reactions can be found in Section 2 of this article, for example, equations (54), (56), (61), (77)–(79), (82), (85), and (86).

It has been reported that $RhH(PPh_3)_4$ in the presence of 1,2-bis(diphenylphosphino)ethylene catalyzes the exchange of sulfur atoms between elemental sulfur and organic polysulfanes at room temperature.[259] During this reaction traces of phoshpine sulfides may be formed which are strong nucleophiles.

5.4 Oxidation of Polysulfanes to Polysulfane Oxides

Sulfane oxides are compounds of type $R_2S_nO_m$ ($n > 1$, $m = 1, 2, 3\ldots$) with the oxygen atoms present as sulfoxide or sulfone groups. For the nomenclature of organic sulfur-oxygen compounds see Table 2; for reviews on oxidized sulfur chains and rings, see Steudel.[260,261] Disulfane 1-oxides, RS(O)–SR, are also known as thiosulfinates and the 1,1-dioxides are usually termed as thiosulfonates. Trisulfane 1-oxides and 1,3-dioxides, as well as tetrasulfane 1-oxides and 1,4-dioxides, have been obtained by stepwise oxidation of the corresponding sulfanes by peroxy acids (equations 151–153).[67,101,123,127,262–265]

$$R_2S_3 + CF_3CO_3H \begin{cases} \xrightarrow{1:1} \text{R–SO–S–S–R} \\ \xrightarrow{1:2} \text{R–SO–S–SO–R} \end{cases} \quad (151)$$

$$R_2S_4 + CF_3CO_3H \begin{cases} \xrightarrow{1:1} \text{R–SO–S–S–S–R} \\ \xrightarrow{1:2} \text{R–SO–S–S–SO–R} \end{cases} \quad (152)$$

$$R_2S_3 + 4R'CO_3H \longrightarrow R\text{–}SO_2\text{–}S\text{–}SO_2\text{–}R + 4R'CO_2H \quad (153)$$

With bulky substituents, the oxidation of the central sulfur atom has been observed.[266] Dimethyldioxirane and ozone (at −78 °C) may also be used to prepare such sulfane oxides.[196,266,267]

The crystal and molecular structures of disulfane 1-oxides (R = 4-tolyl)[195] and of trisulfane 2-oxides[84,195,196] have been determined by X-ray diffraction. The latter compounds are usually obtained from thionyl chloride and thiols (RSH) in ether or in the presence of pyridine (equations 154 and 155).[81–83] Unsymmetrically-substituted trisulfane 2-oxides, RS–SO–SR′, are accessible by a stepwise condensation of $SOCl_2$ with first RSH and then R′SH; the intermediate RS–SO–Cl has been isolated as a yellow solid (R = 2-naphthyl). RSSOCl reacts at 0 °C in ether with thiols to give RS–SO–SR′.[83]

$$RSH + Cl\text{–}SO\text{–}Cl \longrightarrow R\text{–}S\text{–}SO\text{–}Cl + HCl \quad (154)$$

$$R\text{–}S\text{–}SO\text{–}Cl + HSR' \longrightarrow R\text{–}S\text{–}SO\text{–}S\text{–}R' + HCl \quad (155)$$

The structure of the $–S_3O–$ group of trisulfane 2-oxides is similar to the structure of $SOCl_2$ (symmetry C_s); the S–S bond distances are considerably longer (ca. 213 pm)[84,195] than in trisulfanes (ca. 204 pm); see Section 3.

Oxidation of organic polysulfanes by an excess of peroxy acid results in disulfones (polysulfane tetroxides) (equation 153).[101] Polysulfane 1,1-dioxides (monosulfones) may be prepared by reaction of monoorganylthiosulfates with sulfenyl chlorides (equation 156).[268–270]

$$R\text{–}SO_2\text{–}SK + ClSR' \longrightarrow R\text{–}SO_2\text{–}S\text{–}S\text{–}R' \quad (156)$$

The molecular structures of several polysulfane tetroxides of this type have been elucidated by X-ray diffraction on single crystals.[197,198] The S–S bonds between the sulfone groups and the neighboring sulfane sulfur are weaker (210–214 pm) than ordinary S–S single bonds (205 pm).[1]

6 NATURAL OCCURRENCE OF ORGANIC POLYSULFANES AND THEIR BIOLOGICAL ACTIVITY

It is well known that disulfane-containing compounds, such as proteins, hormones, lipoic acid, enzymes, and other products, occur naturally and many studies on their biochemical role have been published.[271] Protein folding influenced by –S–S– bridges of cystine has been studied intensively, and it is generally accepted now that introducing disulfane bonds into proteins thermally stabilizes the folded state.

It is less well known that tri-, tetra-, penta-, and even hexasulfanes also occur in organisms or materials produced from them, including peptides. In this section, a brief overview will be presented of chainlike and cyclic organic polysulfanes, which have so far been isolated from or detected in biological materials. For sulfur-rich peptides, see refs.[272,273]

An extensive review on organic sulfur compounds from marine organisms is available.[274]

6.1 Chainlike Organic Polysulfanes

Table 5 summarizes the chainlike polysulfanes R–S_n–R, which have been identified in various natural sources or materials prepared from them. The sulfur chain length varies

Table 5 Naturally occurring chainlike bis-organyl polysulfanes, $R^1{-}S_n{-}R^2$

R^1	R^2	*n*	Source
Me[275–277]	R^1	3, 4	Shiitake mushroom
Me[282]	R^1	3	Geotrichum candidum

Methyl[284]	Complex structure	3	Calichemicin *(Micromonospora echinospora)*

between 2 (not shown) and 6, while the organic residues R are saturated or unsaturated alkyl groups or derivatives of them.[275–281]

Asafetida is the oleogum resin exudate obtained from certain *Ferula* species. It has a characteristic strong odor and is used as a flavoring in a variety of foods. The volatile oil obtainable by steam distillation is abundant in sulfur compounds. The flavor of asafetida is largely due to 2-butyl 1-propenyl disulfane, 1-methylthiopropyl 1-propenyl disulfane and 2-butyl 3-methylthioallyl disulfane, but in addition the four tri- and tetrasulfanes mentioned in Table 5 have been identified as minor components by GC/MS analysis.[277]

The edible Shiitake mushrooms (*Lentinus edodes*) are another rich source of sulfur compounds, cyclic and noncyclic. Blending of the fresh mushrooms with water at $\mathrm{pH} = 7$ followed by pentane extraction and GC/MS analysis of the extract showed Me_2S_3 as one of the major constituents (besides various disulfanes).[275,276] When the blending was carried out at $\mathrm{pH} = 9.0$, at which enzymes have their maximum activity, additional S compounds like Me_2S_4 and cyclic species (see below) were extracted and detected by GC/MS.[275,276] This result clearly shows that the work-up procedure does influence the kind of products to be detected.

A large number of organic sulfur compounds have been detected in extracts or distillates prepared from garlic, onions, or other *Allium* species. This chemistry has been reviewed by Block.[278,279] Polysulfanes have been detected in many of these preparations but most recent results show that fresh extracts of garlic, prepared under mild conditions (20 °C), did not show any polysulfanes $R{-}S_n{-}R$ ($n > 2$) when analyzed by RP-HPLC analysis.[278,279]

However, commercial garlic oil, prepared by steam distillation of garlic homogenizates, did show bis-allyl tri-, tetra-, penta-, and hexasulfanes (Table 5), detected by HPLC and GC/MS analysis. Detailed investigations showed that these polysulfanes probably originate from the very reactive bis-allyl disulfane by thermal cleavage of the S–S and C–S bonds and recombination of the RS· and $RS_2\cdot$ radicals as well as by interconversion of the polysulfanes in reactions of the type in equation (157).

$$2R_2S_n \rightleftharpoons R_2S_{n-x} + R_2S_{n+x} \qquad (157)$$

When garlic is extracted by methanol, allyl methyl trisulfane is formed.[275,279] Unsaturated polysulfanes from *Allium* species inhibit the growth of certain tumors.[278,279]

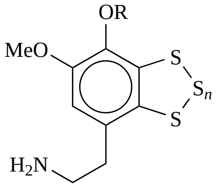
Tri- and tetrasulfanes with the unusually long, oxidized alkyl chain $C_8H_{17}{-}CO{-}C_2H_4{-}$ as substituents have been isolated as colorless needles from methanol/chloroform extracts of a Hawaiian alga (Table 5) by LC on silical gel and gel permeation chromatography followed by crystallization.[281] These compounds were characterized by ^{1}H-NMR, MS, and UV spectroscopy.

It also should be mentioned that bis-alanyl tri- and, to a smaller degree, tetrasulfane have been detected in acidic wool hydrolysates, but it is not clear whether the corresponding amino acid, $[HO_2C{-}CH(NH_2){-}CH_2{-}]_2S_3$, is part of the wool structure or is formed from cystine during hydrolysis.[280]

6.2 Cyclic Organic Polysulfanes

Lenthionine (1,2,3,5,6-pentathiepane) was the first cyclic polysulfane isolated from an organism, however, in the very first report it was stated that this compound is not present in Shiitake mushrooms, but is formed from an unknown precursor by the action of an enzyme when the mushroom was immersed in water overnight.[121,122] From 5 kg dried mushrooms, 0.44 g crystalline lenthionine (mp 61 °C) were obtained; the structure (see Table 6) was established by MS[121,122] and X-ray diffraction on a single crystal.[219] In addition, hexathiepane (Table 6) and 1,2,4,6-tetrathiepane were also isolated from the aqueous Lentinus edodes mushroom.[121,122] All three cyclic methylene sulfides can easily be prepared from CH_2Cl_2 and aqueous sodium polysulfide.[121,122] When fresh Lentinus edodes was directly extracted by chloroform (which inactivates the enzymes), fractionated by LC on silica gel, and analyzed by GC/MS or MS, the only polysulfanes detected were dimethyl trisulfane, 1,2,3,5-tetrathiane and lenthionine.[275,276] However, when the fresh mushrooms were blended at room temperature with water for 3 min and the pH adjusted to 9.0, chloroform extraction yielded 18 organic sulfur compounds including the ones mentioned above.[275,276] They all are believed to originate from lentinic acid by enzymic activity via CH_2S_2 as a reactive intermediate.[192,275,276]

Table 6 Naturally Occurring Cyclic Bis-organyl Polysulfanes

Compound	Source
 5-Methylthio-1,2,3-trithiane	*Chara globularia* (green alga)[285,286]
 Lenthionine	*Chondria californica* (red alga)[285–287] *Parkia speciosa* (mimosaceae species)[288] *Lentinus edodes* (Shiitake mushroom)[114,203,241]
	*Aplidium* sp. D (ascidian)[289]
 Hexathiepane  Hexathionane  1,2,3,5-Tetrathinane	*Lentinus edodes* (Shiitake mushroom)[121,122,275,276]
 3,6-Epipolythiopiperazine-2,5-dione	
$n = 3$; $R^1 = R^3 = Me$; $R^2 = CH_2OH$; $R^4 = CH_2Ph$	Fungus
Sporidesmine E	*Pithomyces chartarum*[190,191,194,290]
$n = 4$; $R^1 = R^3 = Me$; $R^2 = CH_2OH$; $R^4 = CH_2Ph$	*Hyalodendron* sp. (fungus); *Penicillium turbatum*[289]
Sporidesmine G	*Pithomyces chartarum*[190,191,194]
	


$n = 3$; R = H Lissoclinotoxin A	*Lissoclinum perforatum* (ascidian)[291]
$n = 3$; R = Me Varacin	*Lissoclinum vareau* (ascidian)[292–294]

Lenthionine and related cyclic methylene disulfanes of ring sizes 6–12 have also been obtained from the alga *Chondria californica* and from the seed of the mimosacea *Parkia speciosa*.[287,288]

Derivatives of 1,2,3-trithiane as well as 1,2-dithiolane are known for their biological activity.[268–270,295] Two naturally occurring trithiane derivatives are shown in Table 6. 5-Methylthio-1,2,3-trithiane has been isolated by gas-phase isopentane extraction from the green alga *Chara globulares* and identified by GC/MS, ^{1}H-MR and UV spectra.[285,286] Its synthesis is straightforward.[285,286] The second natural trithiane derivative has been extracted by methanol/water from the New Zealand ascidian *Aplidium* sp. D and isolated after RP-HPLC as a yellow gum.[289] This compound shows anti-microbial, anti-leukemic, and cytotoxic properties in vitro.[289]

Chemically related to the trithianes is the benzo-1,2,3-trithiane derivative lissoclinotoxin A, shown at the bottom of Table 6. It has been obtained by methanol extraction of the tunicate *Lissoclinum perforatum* followed by preparative HPLC on SiO_2, and forms a yellow solid of mp 245–250 °C.[291] In vitro, this material exhibits potent antimicrobial, antifungal, and modest cytotoxic activities.[291] The benzopentathiepin

derivative varacin (Table 6) has also been obtained from a tunicate; this compound bears obvious structural and biosynthetic relationships to dopamine.[292–294]

Sporidesmin is a naturally occurring polycyclic disulfane that contains the piperazinedione ring shown in Table 6. The corresponding trisulfane has been termed sporidesmin E. It has been obtained by extraction of *Pithomyces chartarum* followed by LC on silica gel.[194] From the same organism, sporidesmin G, the corresponding tetrasulfane, has been obtained.[190,191] These compounds are also biologically active.

The piperazinedione framework is also present in hyalodendrin, which is an epidisulfane with the substituents given in Table 6. The corresponding epitrisulfane has been isolated from cultures of an unidentified fungus,[290] while the epitetrasulfane was obtained from chloroform extracts of fermentations of *Hyalodendron* sp.[296,297] it is also produced by *Penicillium turbatum*.[296,297] In all cases, however, it is unknown whether these polysulfanes are present in the organisms, or resulted from the work-up procedure by decomposition of the corresponding disulfane. Such conversion reactions have in fact been observed.[296,297]

7 APPLICATIONS OF ORGANIC POLYSULFANES

For many years organic polysulfanes have been used as additives to high-pressure lubricants to prevent metals from welding together under extreme pressure.[298] At temperatures above 200 °C, the metals react with the additive to form sulfides, which have both a lower friction coefficient and a lower melting point than the metals themselves.

Organic polysulfanes are also important constituents of ‘polysulfide polymers’ of the Thiokol type, of vulcanized rubber, and of sulfur cement. In addition, there are a few special applications in the oil industry and in medicine. Sulfur-containing polymers have been extensively reviewed by Tobolsky and MacKnight in 1965 and by Duda and Penczek in 1987.[299,300]

7.1 Polysulfide Polymers

The preparation, properties, and uses of industrially-produced polysulfide polymers have been reviewed in detail by Ellerstein and Bertozzi in 1982 and by Lucke in 1992.[301,302] Synthesis is based on the reaction of aliphatic dichloro compounds with aqueous sodium polysulfide according to equation (158).

$$n\mathrm{Cl{-}R{-}Cl} + n\mathrm{Na_2S}_x \longrightarrow \mathrm{(R{-}S{-}S)}_n + 2n\,\mathrm{NaCl} \qquad (158)$$

Most of the polysulfide polymers are made from bis(2-chloroethyl)formal [bis(2-chloroethoxy)methane], which is synthesized from ethylene chlorohydrin [1-chloroethan-2-ol] and formaldehyde under acid catalysis according to equation (159).

$$\mathrm{2ClCH_2CH_2OH + CH_2O \xrightarrow{H^+} ClCH_2CH_2OCH_2OCH_2CH_2Cl + H_2O} \qquad (159)$$

Ethylene chlorohydrin is made from HCl and ethylene epoxide. When small amounts of 1,2,3-trichloropropane are added to the bis(2-chloroethyl)formal, some branching of the otherwise linear polymer structure is achieved.

The sodium polysulfide solution is customarily made by heating concentrated aqueous sodium hydroxide with elemental sulfur to 100–150 °C according to equation (160).

$$\mathrm{6NaOH} + \frac{2x+2}{8}\mathrm{S_8} \longrightarrow \mathrm{2Na_2S}_x + \mathrm{Na_2S_2O_3 + 3H_2O} \qquad (160)$$

The thiosulfate by-product does not take part in the subsequent reactions with the organic chlorides. The x value in equation (160) is referred to as the rank of the sodium polysulfide; a typical value for x is 2.25. However, since aqueous sodium polysulfide is a complex mixture containing various polysulfide anions in equilibrium, the final polymer obtained in equation (158) may contain various structural units –S_n– ($n = 1$–4). In addition, the aqueous phase contains OH^-, resulting in some terminal OH groups in the polymer. By applying an excess of sodium polysulfide (1.3 mol per mol RCl_2), the number of chain-terminating OH groups is reduced (see equation 161).

$$\cdots\mathrm{{-}RSSR{-}OH + Na_2S_2} \longrightarrow \cdots\mathrm{{-}RSSNa + HORSSNa} \qquad (161)$$

At the end of the polymerization process, the polymers are washed free of sodium chloride, excess sodium polysulfide and solubilized hydroxy-containing terminals. The molecular mass of the resultant polymer is thought to be at least 5×10^5–10^6; the yield is 80%. The polymer forms as small dispersed spheres approximately 5–15 µm in diameter, which have a higher density than the aqueous phase in which they are produced, and therefore settle to the bottom of the reactor. The polymer is washed with hot water, followed by decantation, coagulation by acidification, and drying with heat, resulting in a solid, rubbery mass.

If a liquid polysulfide (LP) polymer is desired, a chemical reduction of some of the polysulfide groups to thiol terminals is carried out, after which the polymer is cleaned, coagulated, and dried to its final liquid form. The thiol-terminated version is by far the most common form of polysulfide polymers (molecular mass 700–8000; trade name LP Thiokol). A mixture of NaSH and Na_2SO_3 is used to generate terminal SH groups from disulfane structural units (equation 162).

$$\cdots\mathrm{{-}R{-}S{-}S{-}R{-}}\cdots + \mathrm{NaHS + Na_2SO_3 + H_2O}$$
$$\longrightarrow 2\cdots\mathrm{{-}R{-}SH + Na_2S_2O_3 + NaOH} \qquad (162)$$

The sulfite not only helps in the reduction of the disulfane group to thiol groups, but it also removes the polysulfanes of rank greater than 2 (equation 163).

$$\cdots\text{–R–S–S–S–R–}\cdots + Na_2SO_3 \longrightarrow \cdots\text{–R–S–S–R–}\cdots + Na_2S_2O_3 \qquad (163)$$

The polymer is then in a stripped state in which no polysulfane group exceeds the disulfane stage. Thiokol FA is a copolymer of dichloroethane and the bis(2-chloroethyl)formal–sodium polysulfide reaction product.

The polysulfide polymers derive their utility from their unusually good resistance to solvents and to the environment and their good low-temperature properties. The solid elastomers in the vulcanized cure state are used in printing rolls, paint-spray hoses, solvent hoses, gaskets, and gas-meter diaphragms. LP polymers are used mainly in sealants, the largest application being sealants for double-pane insulating glass windows. Other applications are general sealants, and high quality sealants for construction, boat hulls and decks, printing rolls, aircraft bodies and integrated fuel tanks. The common way to convert the LP polymers to solid elastomers is to oxidize the terminal thiol groups to disulfanes. This is usually carried out in a formulation with fillers, plasticizers, and curing-rate modifiers (e.g. stearic acid). Both organic oxidizing agents, for example, *t*-butyl hydroperoxide, and inorganic oxidizing agents have been used, with most cures occurring at ambient temperature in a few hours.

7.2 Vulcanization of Rubber by Sulfur

By far the most important application for organic polysulfanes is the vulcanization of natural and synthetic rubber by elemental sulfur. More than 2×10^5 tonnes of sulfur are used for this process annually, partly in the form of polymeric sulfur (trade name 'Crystex'). The organic polymers to be vulcanized contain alkenic double bonds in varying environments (see Figure 6).

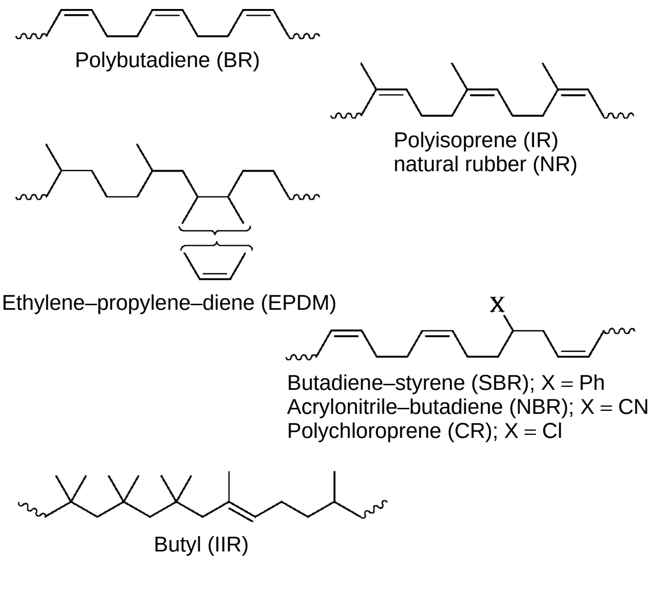


Figure 6 Polymeric alkenes, which may be vulcanized by elemental sulfur or sulfur donors

The vulcanization process involves heating the organic polymer with elemental sulfur in the presence of various accelerators and modifiers ('rubber chemicals'). A typical vulcanization mixture contains rubber (100 parts per weight), carbon black (50), zinc oxide (2–10), stearic acid (1–4), sulfur (0.5–4), and organic accelerators and antioxidants as well as retarders.[303] The vulcanization takes place at 140–160 °C and results in organic mono-, di-, and polysulfanes, some of which act as crosslinks to the polymer chains and thus generate the high-elastic properties of vulcanized rubbers (see Figure 7). The chemistry of vulcanization[304,305] and the importance of polysulfane crosslinks[306] have been reviewed. It should be recognized, however, that rubber mixtures are rather complex and difficult to analyze chemically, and the chemistry of vulcanization has therefore been worked out largely by using low-molecular mass analogs of the rubber structure (model alkenes) and then extrapolating the results to the polymeric system. These studies have considerably increased general knowledge about organic polysulfanes.[299,300,306] Several model studies have been published.[134,307–309]

7.3 Sulfur Cement and Sulfur Concrete

Elemental sulfur is an inexpensive material available in high purity and large quantities, and has repeatedly been suggested for 'new uses' in the civil engineering field. It is used as an extension to asphalt in road pavements and as an insulating material,[310] but use as a construction material requires 'modification' with additives designed to stop the embrittlement that occurs with pure elemental sulfur. If pure liquid sulfur is cooled to ambient temperature, monoclinic octasulfur (β-S_8) is instantaneously formed, which then slowly converts to orthorhombic α-S_8. Because of the difference in densities between α- and β-S_8, a brittle material results. Many additives have been proposed to modify elemental sulfur, nearly

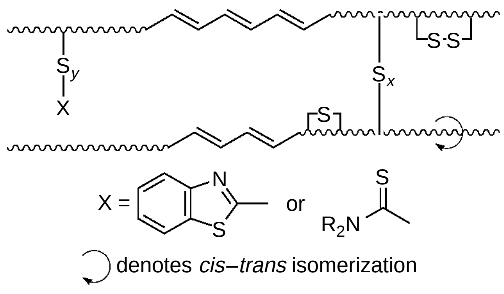

Figure 7 Schematic representation of rubber after vulcanization by sulfur, resulting in pendant groups ($-S_y-X$) as well as mono-, di-, and polysulfane bridges

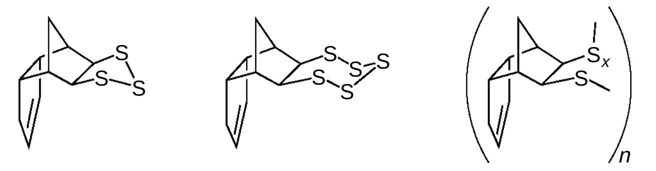

Figure 8 Molecular and polymer polysulfanes formed in the reaction of *endo*-DCPD with elemental sulfur at elevated temperatures

all of them either organic polysulfanes or substances that will react with liquid sulfur to give in situ formation of polymeric polysulfanes, for example alkenes and certain thiokols.[311]

The most important alkene in this context is DCPD or a mixture of di- and tricyclopentadienes. The addition of 5–10% by mass to elemental sulfur, followed by heating to 140 °C results in a complex mixture of polysulfanes and sulfur, which after cooling to 20 °C is no longer brittle but of extremely high mechanical strength (sulfur cement). When the liquid sulfur cement is mixed with suitable pre-heated mineral fillers and cooled to ambient temperature a very useful construction material is obtained (sulfur concrete).[311] In contrast to Portland cement and conventional concrete, sulfur cement and sulfur concrete are resistant to aqueous acids and concentrated salt solutions.

The polysulfanes formed on reaction of DCPD with liquid sulfur have been studied by extraction of sulfur cement and analysis by LC, ^{1}H-NMR, MS, and other techniques.[299,300,311–313] The initial products are trisulfane and pentasulfane derived from DCPD by addition of S_3 or S_5 units to the norbornenyl double bond. These ‘monomers’ are believed to further react with elemental sulfur to form low-molecular mass polymers (CS_2 soluble), and on further heating form an insoluble material. The cyclopentenyl unsaturation of DCPD is much less reactive and is still present in the CS_2-soluble products. *endo*-DCPD reacts more slowly with liquid sulfur at 140 °C than *exo*-DCPD, while the cyclic trisulfanes of *endo*- and *exo*-DCPD react at almost the same rate with liquid sulfur at 140 °C.[272–274] The structures of DCPD-S_3, DCPD-S_5, and the likely structure of the low-molecular mass polymer, are shown in Figure 8.

The interaction of styrene with liquid sulfur has also been studied extensively.[299,300,312]

7.4 Organic Polysulfanes as Antiradiation Drugs

Field *et al.*[314] discovered that certain di- and trisulfanes, R–S_n–R′, terminated by sulfinate functions, –S(O)–O–, protect mice against otherwise lethal effects of ionizing radiation. The preparation of these compounds has been described in Section 2.1.13. The ionic sulfinate group makes these compounds partly hydrophilic and water soluble. Neither a trisulfane nor a sulfinate by itself are significantly radioprotective but the presence of a sulfur–sulfur bond is considered a key requirement since a thiol can be engendered by a neighboring group effect of an electron-donating group. One hypothesis suggests that this ‘protective thiol’ undergoes formation of mixed disulfanes with proteins in the cells, leading to a series of disturbances including decreased oxygen consumption, decreased carbohydrate utilization, and mitotic delay by temporary inhibition of DNA and RNA synthesis, along with cardiovascular, endocrine, and permeability changes. The mitotic delay allows time for repair processes to restore normal nucleic acid synthesis.[315]

1 INTRODUCTION

A perfect superconductor is a material that, when cooled below a characteristic temperature T_c called the critical temperature, conducts electricity without any losses or any heating, and expels magnetic fields from its interior. The former property is called zero resistance, and the latter is called perfect diamagnetism. At temperatures above T_c, it is a normal metal, and is ordinarily not a very good conductor. For example, lead and tin become superconductors while copper and silver, which are much better conductors, do not superconduct.

The second characteristic property called perfect diamagnetism means that the superconductor material does not permit an applied magnetic field B to penetrate into its interior. Those that totally exclude the applied magnetic field are known as Type I, and they are the superconducting elements such as tin, mercury, and lead, which have the respective transition temperatures 3.7, 4.1, and 7.2 K. Other superconductors called Type II are also perfect conductors of electricity, but their magnetic properties are more complex. They totally exclude magnetic fields when the applied field is low, but only partially exclude them when the applied field is larger. Thus, in the region of higher magnetic fields, their diamagnetism is not perfect.

2 BRIEF HISTORY

In 1908, H. Kamerlingh Onnes started the field of low-temperature physics by liquifying helium in his laboratory at Leiden in the Netherlands. Three years later when Onnes was measuring the electrical resistance R of mercury, he expected to find a gradual decrease in R as the temperature was lowered.[1] Instead, to his surprise, he found that below 4.2 K its value dropped abruptly to zero, as shown in Figure 1. The next year Onnes discovered that when he applied a sufficiently strong magnetic field the resistance was restored to its normal value. Soon thereafter he discovered that the element lead was a superconductor below 7.2 K. This was the highest known transition temperature for 17 years until the record was surpassed by the element niobium ($T_c = 9.2$ K), as shown in Table 1.

It was not until 1933 that scientists became aware of the second distinguishing feature of a superconductor, that

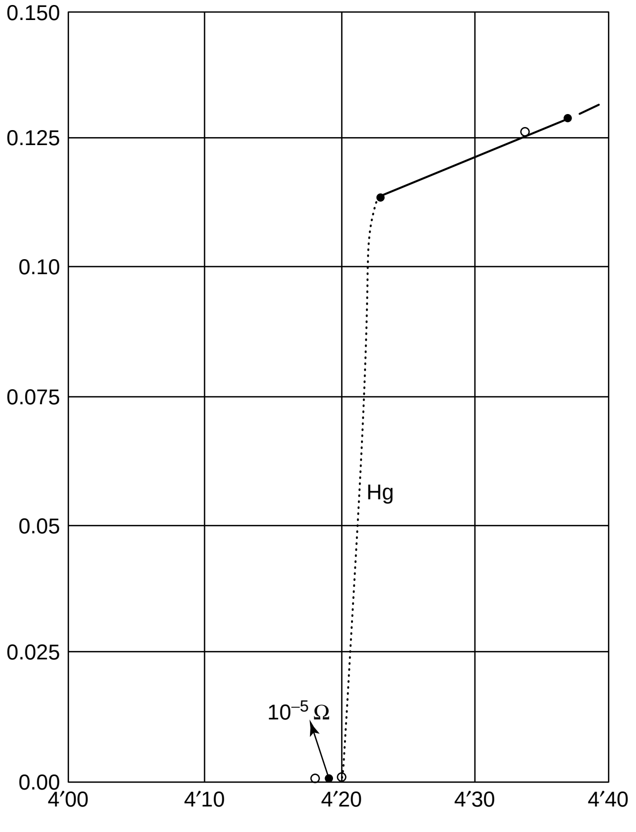

Figure 1 Resistivity versus temperature plot obtained by Kamerlingh Onnes when he discovered superconductivity in Leiden in 1911 (from Ref. 1)

Table 1 Superconducting transition temperature records through the years

Material	T_c (K)	Year
Hg	4.1	1911
Pb	7.2	1913
Nb	9.2	1930
$N_{0.96}Nb$	15.2	1950
Nb_3Sn	18.1	1954
$Nb_3(Al_{3/4}Ge_{1/4})$	20–21	1966
Nb_3 Ga	20.3	1971
Nb_3Ge	23.2	1973
$Ba_xLa_{5-x}Cu_5O_y$	30–35	1986
$(La_{0.9}Ba_{0.1})_2CuO_{4-\delta}$ at 1 Gpa	52	1986
$YBa_2Cu_3O_{7-\delta}$	95	1987
$Bi_2Sr_2Ca_2Cu_3O_{10}$	110	1988
$Tl_2Ba_2Ca_2Cu_3O_{10}$	125	1988
$Tl_2Ba_2Ca_2Cu_3O_{10}$ at 7 Gpa	131	1993
$HgBa_2Ca_2Cu_3O_{8+\delta}$	133	1993
$HgBa_2Ca_2Cu_3O_{8+\delta}$ at 25 Gpa	155	1993
$Hg_{0.8}Pb_{0.2}Ba_2Ca_2Cu_3O_x$	133	1994
$HgBa_2Ca_2Cu_3O_{8+\delta}$ at 30 Gpa	164	1994

is, its perfect diamagnetism. In that year, Meissner and Ochsenfeld[2] found that when they cooled a superconducting sphere below its transition temperature in a magnetic field it excluded the magnetic field, a phenomenon called the Meissner effect.

The report of the Meissner effect stimulated the London[3] brothers to develop the London equations, which explained this effect, and which also predicted how far a static external magnetic field can penetrate into a superconductor. The next theoretical advance came in 1950 with the theory of Ginzburg and Landau,[4] which described superconductivity in terms of an order parameter and provided a derivation for the London equations. Both of these theories are macroscopic or phenomenological in nature. In the same year, 1950, the isotope effect, whereby the transition temperature decreases when the average isotopic mass increases, was predicted theoretically by H. Fröhlich,[5] and observed experimentally by Maxwell and Reynolds *et al.*[6] This effect provided support for the then postulated electron–phonon interaction mechanism of superconductivity. Our present theoretical understanding of the nature of superconductivity is based on the BCS microscopic theory, which was proposed by J. Bardeen, L. Cooper, and J. R. Schrieffer in 1957.[7] This theory involves the coupling of conduction electrons as bound electron pairs called Cooper pairs that carry the supercurrent, and the presence of a gap between the normal and superconductive energy states. The earlier Ginzburg–Landau and London results fit well into the BCS formalism.

3 PERSISTENT CURRENTS BELOW T_C

The property of zero resistance is dramatically demonstrated by the phenomenon of persistent currents in superconducting loops. To establish an electrical current in a loop of superconducting wire, the ends of the wire can be connected to a battery in series with a resistor that limits the current,[8] as shown in Figure 2. When switch S_2 is closed, the current commences to flow in the loop, and then when switch S_1 is closed to bypass the battery and S_2 is opened to disconnect the battery, the loop resistance drops to zero and the current flow enters the persistent mode. The zero resistance property implies that the current will continue flowing indefinitely.

Many investigators have established currents in loops of superconducting wire and have monitored the strength of the associated magnetic field through the loop at later times using, for example, a magnetometer with a pickup coil, as shown in Figure 2. They find no detectable decay of the

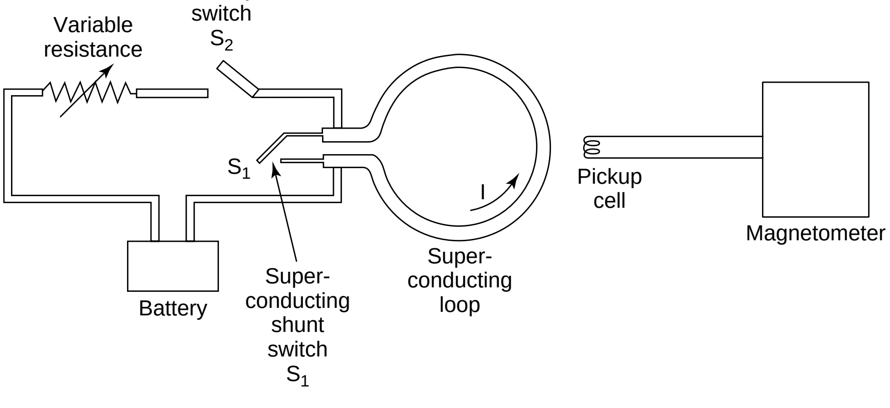

Figure 2 Experimental arrangement for establishing and measuring a persistent current. Switch S_2 is closed to send current through the loop, S_1 is closed to confine the current flow to the loop, and the magnetometer is employed to measure the magnetic field through the loop and thereby determine the current (from Ref. 8, p. 34)

current for times of the order of years. These experiments have established lower limits on the very long lifetime of the current and upper limits on the possible resistivity of superconducting materials. Several researchers have found that currents in superconductors persist for times far beyond a year, and resistivity limits as low as $\rho < 10^{-23}\,\Omega\,\text{cm}$ have been reported.

The drop to zero resistance can be explained qualitatively in terms of a two fluid model in which some of the normal electrons transform to superelectrons that move through the material without resistance. The normal and superelectrons flow side by side, both carrying current. However, the current carried by the flow of superelectrons short circuits that arising from the flow of normal electrons, and the measured resistance vanishes.

4 ISOTOPE EFFECT

When an element has more than one isotope, the transition temperature often decreases with increasing isotopic mass M in accordance with the relation

$$M^{\alpha} T_c = \text{constant} \tag{1}$$

where $\alpha = 1/2$ for the simplified BCS model. This is expected for a simple metal because the phonon frequency is proportional to the square root of the mass of the atom. For example, the electron–phonon coupling can also be mass dependent, and deviations from equation (1) are not unusual. Some elemental superconductors have isotope effect exponents α close to 1/2, such as Hg (0.50), Pb (0.489), Sn (0.47), and Zn (0.45). High-temperature superconductors ($T_c > 77\,\text{K}$) tend to have very low values of α.

5 MAGNETIC FIELDS INSIDE A SUPERCONDUCTOR

In free space, a magnetic field B, sometimes called magnetic induction, has associated with it an H-field given by the expression

$$B = \mu_o H \tag{2}$$

where $\mu_o = 4\pi \times 10^{-7}\,\text{N/A}^2$ (newtons per square ampere) is the permeability of free space. It is the B-field that is experimentally measured because it enters into the Lorentz force equation $F = q(E + v \times B)$ for the force F on an electric charge q moving at a velocity v in the presence of an electric field E and a magnetic field B. The B-field inside a material with a permeability μ is given by

$$B = \mu H \tag{3}$$

$$= \mu_o H(1+\chi) \tag{4}$$

$$= \mu_o (H + M) \tag{5}$$

where $M = \chi H$ is the magnetization or magnetic moment per unit volume. The dimensionless susceptibility χ has a small positive value for a paramagnetic material, a large positive value ($\chi \gg 1$) for a ferromagnetic material, and a small negative value for a diamagnet ($\chi < 0$). The property of perfect diamagnetism corresponds to the susceptibility $\chi = -1$. This means that the B-field is zero inside a Type I superconductor, in accordance with the Meissner effect. The magnetization M is equal in magnitude and opposite in sign to the H-field: $M = -H$. When a Type I superconductor is placed between the pole pieces of a magnet, the B-field lines from the magnet go around it instead of entering it, and its own internal field remains zero, as shown in Figure 3.

There are two aspects to perfect diamagnetism in superconductors. The first is magnetic field exclusion: if a material in the normal state is zero field cooled (ZFC), that is, cooled below T_c to the superconducting state without any magnetic field present, and then it is placed in an external magnetic field, the field will be excluded from the superconductor. The second aspect is magnetic field expulsion. If the same material in its normal state is placed in a magnetic field, the field will penetrate and have almost the same value inside and outside because the permeability μ is so close to the free space value μ_o. If this material is then field cooled (FC), that is, cooled below T_c in the presence of this applied field, the field will be expelled from the material; this is the Meissner effect that was mentioned earlier.

When a Type I superconductor is in a magnetic field, the B-field is excluded from the interior, but there is a surface layer in which this field decays exponentially from its value B_0 outside to zero inside. This is expressed quantitatively by

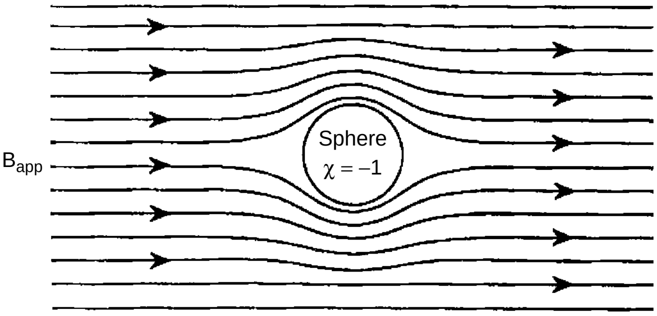

Figure 3 Curvature of magnetic field lines around a superconducting sphere in a constant applied field (from Ref. 8, p. 40)

the expression

$$B(x) \approx B_o \exp\left[\frac{-x}{\lambda}\right] \tag{6}$$

where in this equation we select $x = 0$ at the surface of the material, and the quantity λ is called the penetration depth. This is one of the two fundamental length parameters of a superconductor. The other, ξ, called the coherence length, will be introduced below. Values of λ and ξ for a number of superconductors are listed in Table 2. This exponential decay behavior is illustrated in Figure 4, where the origin of the coordinate x is now selected in the middle of the superconductor. It was mentioned above that a Type II superconductor partially excludes magnetic fields from its interior. For this case, there is an exponential falloff of the B-field from its value B_o outside to its value $B_\in$ inside, as shown in Figure 5.

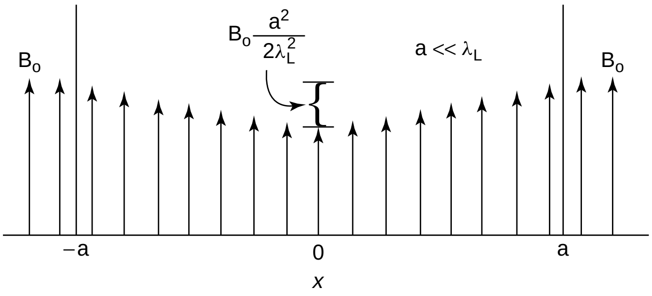

Figure 5 Magnetic field B outside and inside a Type II superconducting slab located in an applied magnetic field B_{app} oriented parallel to its surface (from Ref. 8, p. 135)

6 CRITICAL MAGNETIC FIELDS

If the external magnetic field applied to a Type I superconductor exceeds a certain value B_c, called the critical field, then the superconductor reverts to the normal state. The situation is more complicated in the case of a Type II superconductor. A Type II material becomes normal when the applied field exceeds a value B_{c2} called the upper critical field. There is also a lower critical field B_{c1} below which a Type II superconductor behaves like a Type I material and completely excludes all magnetic fields. In the intermediate range of applied fields

$$B_{c1} \leq \mathrm{B_{app}} \leq B_{c2} \tag{7}$$

the superconductor only partially excludes the applied field, in the manner illustrated in Figure 5. A Type II superconductor also has a characteristic magnetic field B_c called the thermodynamic critical field, which lies in the range $B_{c1} < B_c < B_{c2}$.

Table 2 Coherence length ξ, penetration depth λ, and Ginzburg–Landau parameter $\kappa = \lambda/\xi$ for various superconductors

Material	T_c (K)	ξ (nm)	λ (nm)	κ
Cd	0.56	760	110	0.14
Al	1.2	550	40	0.03
Pb	7.2	82	39	0.48
Nb	9.25	39	50	1.28
NbTi	9.5	4	300	75
$PbMo_6S_8$ (Chevrel)	15.	2	200	100
Nb_3Ge (A-15)	23.2	3	90	30
K_3C_{60} (fullerene)	19	2.6	240	92
$La_{0.925}Ba_{0.075}CuO_4$	37	2.0	200	100
$YBa_2Cu_3O_7$	89	1.8	170	95
$HgBaCaCuO_x$	126	2.3		
$HgBa_2Ca_2Cu_3O_{8+\delta}$	131	100		

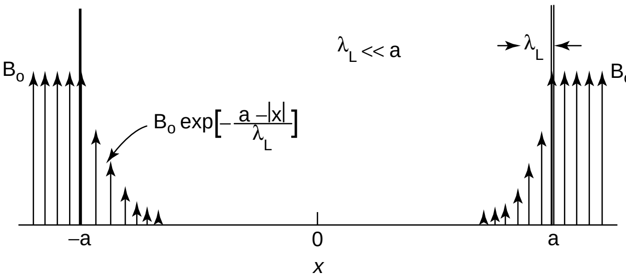

Figure 4 Exponential decay of magnetic field B in the surface layer of thickness λ of a Type I superconducting slab cylinder in an applied magnetic field B_{app} parallel to its surface (from Ref. 8, p. 135)

The values of these critical fields may be expressed in terms of the characteristic length parameters of a superconductor, that is, the penetration depth λ, the coherence length ξ, as well as in terms of the quantum of magnetic flux Φ_o. A constant magnetic field B passing through an area A perpendicular to the field direction has a quantity of magnetic flux Φ given by

$$\Phi = \mathrm{B\,A} \tag{8}$$

Since the SI unit for B is tesla (T), the units for magnetic flux are tesla meter squared. Magnetic flux is quantized, and a quantum of magnetic flux Φ_o. is a universal constant with the value

$$\Phi_{o\cdot} = \frac{\mathrm{h}}{2\mathrm{e}} = 2.068 \times 10^{-15}\ \mathrm{Tm^2} \tag{9}$$

Expressed in terms of the flux quantum the critical fields have the values

$$B_c = \frac{\Phi_{o\cdot}}{2\sqrt{2}\pi\lambda\xi} \tag{10a}$$

$$B_{c1} = \frac{\Phi_{o\cdot}\ell n\kappa}{4\pi\lambda^2} \tag{10b}$$

$$B_{c2} = \frac{\Phi_{o\cdot}}{2\pi\xi^2} \tag{10c}$$

where $\kappa = \lambda/\xi$ is the Ginzburg–Landau parameter. A superconductor is Type I if $\kappa < 1/\sqrt{2}$, and Type II if $\kappa > 1/\sqrt{2}$

7 SUPERCURRENT

If Maxwell's inhomogeneous curl equation $\nabla \times H = J + \partial D/\partial t$ is invoked with the electric field term $\mathrm{D} = 0$, then we obtain

$$\nabla \times B = \mu_o J_{sh} \tag{11}$$

where the quantity J_{sh} is called the shielding current. The presence of the curl operator $\nabla \times$ means that B and J_{sh} are everywhere mutually perpendicular to each other. The shielding current J_{sh} flows in the surface layer of a superconductor located in a magnetic field where B is decaying exponentially from its value B_0 outside to its final value inside. The presence of this current is the mechanism that shields the interior from the applied magnetic field B outside. Figure 6 shows the flow of this shielding current in the surface layer of a superconducting cylinder of thickness λ located in an external magnetic field directed along the axis of the cylinder.

When an applied current, called a transport current, is caused to flow through a superconductor it induces magnetic fields near it. For a Type I superconductor, this current flows in a surface layer of thickness λ, where λ is the penetration depth, corresponding to an area $\mathrm{A} = 2\pi \mathrm{R}\lambda$. The current $\mathrm{I} = AJ$ is given by

$$\mathrm{I} = 2\pi R\lambda J \tag{12}$$

where J is the current density, and this current produces a magnetic field at the surface of the conductor with the value

$$B_{surf} = \frac{\mu_o \mathrm{I}}{2\pi \mathrm{R}} \tag{13}$$

If the current is gradually increased in magnitude, then eventually B will reach the value of the critical field B_c and the superconductor will go normal. The current density J that is present when the superconductor goes normal is called the critical current density J_c, Its value is obtained by inserting equation (12) into equation (13) to give

$$B_c = \mu_o \lambda J_c \tag{14}$$

This expression depends on the temperature

$$B_c(T) = \mu_o \lambda(T) J_c(T) \tag{15}$$

At absolute zero, $T = 0$, we have $B_c(0) = \mu_o \lambda(0) J_c(0)$, and this is usually what is meant by equation (14). The existence of a critical current in a superconducting wire above which it goes normal is called the Silsbee effect.

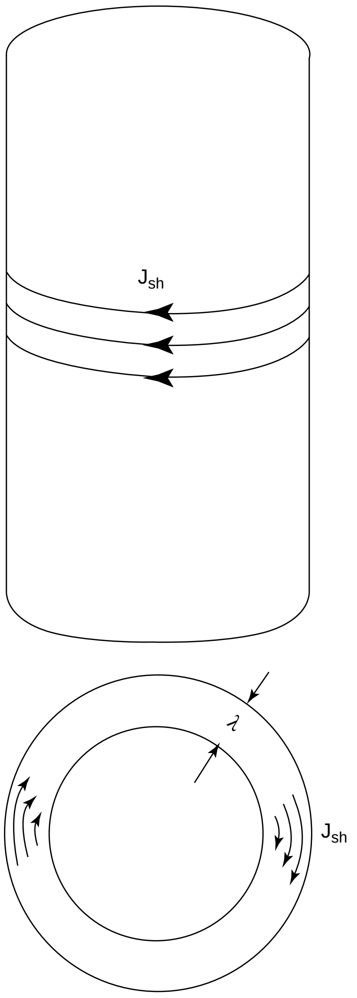

Figure 6 Shielding current flow J_{sh} in a surface layer of thickness λ around a Type I superconducting cylinder in an axial applied magnetic field B_{app} (from Ref. 8, p. 43)

These temperature dependencies often have the form

$$B_c(T) = B_c(0)\left[1 - \left(\frac{T}{T_c}\right)^2\right] \tag{16a}$$

$$\lambda(T) = \lambda(0)\left[1 - \left(\frac{T}{T_c}\right)^4\right]^{-1/2} \tag{16b}$$

$$J_c = J_c(0)\left[1 - \left(\frac{T}{T_c}\right)^2\right]\left[1 - \left(\frac{T}{T_c}\right)^4\right]^{1/2} \tag{16c}$$

We will also mention here the temperature dependencies of the energy gap E_g

$$E_g(T) \approx 3.52\, k_B T_c \left[1 - \left(\frac{T}{T_c}\right)\right]^{1/2} \tag{17}$$

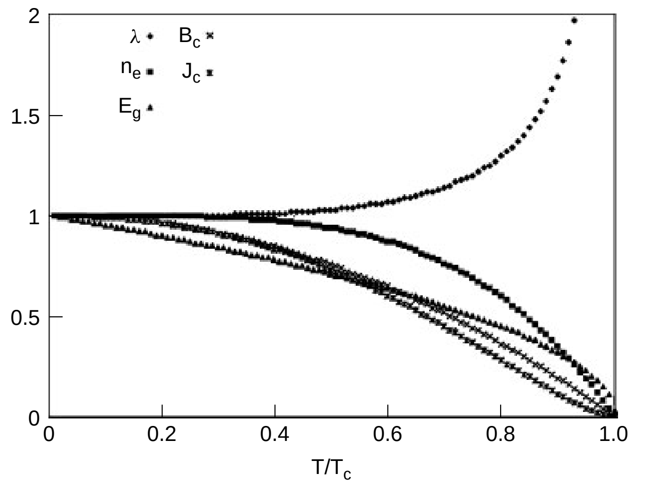

Figure 7 Temperature dependence of the relative values of the critical current density $J_c(T)$, critical field $B_c(T)$, energy gap Eg, density of superconducting electrons n_s, and penetration depth λ (T) in the Type II superconducting state below the transition temperature T_c

and the concentration n_s of superconducting electrons or Cooper pairs

$$n_s \approx n\left[1-\left(\frac{T}{T_c}\right)^4\right] \tag{18}$$

These temperature dependencies are sketched in Figure 7.

8 ELEMENTS AND ALLOYS

The earliest superconductors that were studied were elements and alloys (*see* ***Alloys***). All of the elements that superconduct except niobium are Type I superconductors, whereas niobium, alloys, and compounds are Type II. Elements with transition temperatures T_c above 2 K are: Tl (2.4 K), In (3.4 K), Sn (3.7 K), Hg (4.15 K), Ta (4.4 K), V (5.4 K), La (6.0 K), Pb (7.2 K), Tc (7.8 K), and Nb (9.25 K). Some elements become superconducting only as thin films, under pressure. The great majority of the superconductor elements have crystallographic structures of very high symmetry, either face-centered cubic (fcc), hexagonal close-packed (hcp), or body-centered cubic (bcc). Niobium, which has the highest transition temperature of an element, is also a constituent of many higher T_c compounds like Nb_3Ge ($T_c = 23.2$ K), but it has not appeared prominently in the newer cuprate high-temperature superconductors. Tables 1 and 2 list transition temperatures T_c for a number of elements, alloys, and compounds,

Random binary alloys in which two transition elements are mixed in all proportions have several possibilities: the transition temperature can be higher than that of both elements, between the T_c values of the constituents, or lower than either one alone The number of valence electrons N_e has a strong influence on the T_c values of transition elements and their alloys. Studies carried out with sequences of transition metals that are adjacent to each other in the periodic table show that T_c tends to have a maximum value near $N_e = 4.7$ and near $N_e = 6.5$. The elements Ta, V, and Nb with $N_e = 5$, and T_c with $N_e = 7$, have relatively high transition temperatures Other properties such as the electronic specific heat factor γ, the magnetic susceptibility χ, and the pressure derivative dT_c/dP have regular dependencies on the electron concentration.

9 COMPOUNDS

The phenomenon of superconductivity is common in several particular types of compounds. Thus more than two dozen binary compounds with the fcc sodium chloride (NaCl) structure are superconducting. The carbides AC and nitrides AN, such as NbN with $T_c = 17$ K, have the highest transition temperatures of this group, and the metallic A atoms with T_c values above 10 K were Nb, Mo, Ta, W, and Zr. The NaCl-type superconductors are compositionally stoichiometric but not structurally so. In other words, these compounds have a small to moderate concentration of vacancies in the lattice. For example, YS has 10% vacancies, which means that its chemical formula should properly be written $Y_{0.9}S_{0.9}$. Nonstoichiometric NaCl-type compounds such as $Ta_{1.0}C_{0.76}$ also exist. Ordinarily the vacancies are random, but sometimes they are ordered.

The highest transition temperatures of the older superconductors were obtained with intermetallic compounds A_3B, which have the cubic A-15 structure, and extensive data are available on them. Nb_3Sn can be considered the prototype of this class. These compounds have a cubic structure with the two B atoms at the body center and apical positions of the unit cell, and the six A atoms paired on each face in a configuration that amounts to the presence of chains of A atoms with spacings of one half of the lattice constant a. The A atom is one of the transition elements, and the B element is either a transition element or it is in row III, IV, V, or VI of the periodic table. High transition temperatures occur when B is either a metal (Al, Ga, Sn) or a nonmetal (Si, Ge), but not a transition element. Figure 8 shows T_c data for 8 A elements and 18 B elements for a total of 144 possibilities, and 43% of them superconduct.[9] The figure demonstrates the close correlation between the transition temperature and the valence electron concentration N_e that was mentioned above. High values of T_c occur for $N_e = 4.5$ (Nb_3Ga, $T_c = 20.3$ K), $N_e = 4.75$ (Nb_3Ge, $T_c = 23.2$ K), $N_e = 6.25$ (Nb_3Pt, $T_c = 9.9$ K) and $N_e = 6.5$ (Nb_3Au, $T_c = 11.5$ K).

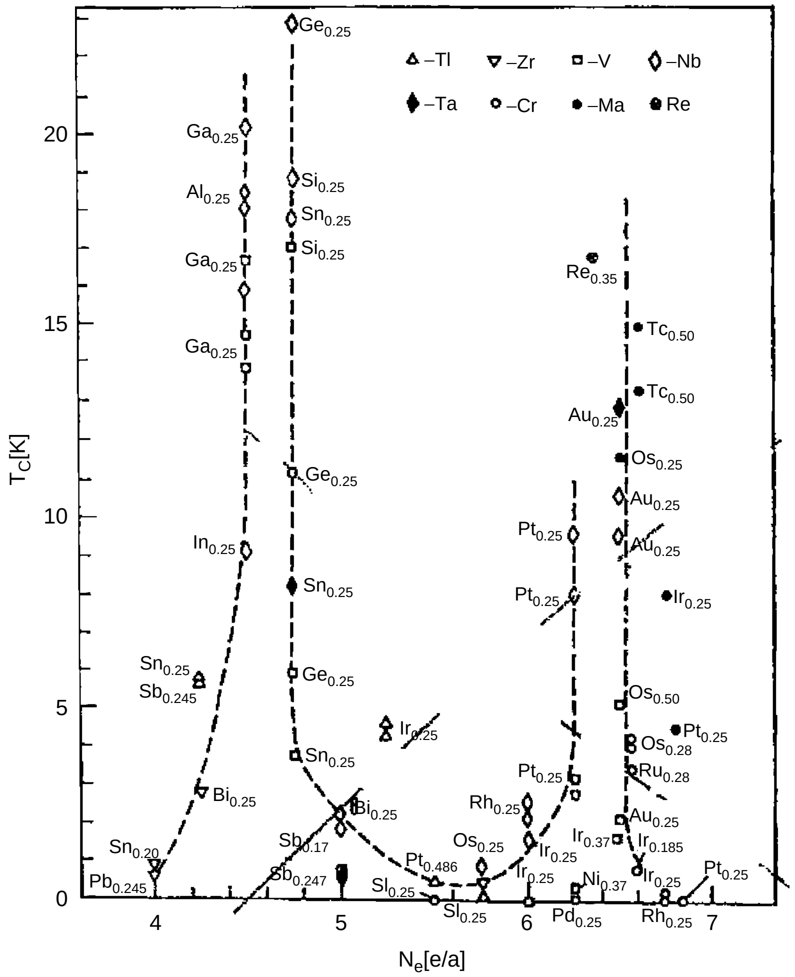

Figure 8 Dependence of the transition temperature T_c on the number of valence electrons Ne in $A_{0.75}B_{0.25}$ compounds of the A15 structure (from Ref. 9, p. 269)

There are several dozen metallic AB_2 compounds called Laves phases that are superconducting; they have either cubic or hexagonal crystal structures. Some have critical temperatures above 10 K and high upper critical magnetic fields B_{c2}. For example, $Zr_{1/2}Hf_{1/2}V_2$ has $T_c = 10.1$ K, $B_{c2} = 24$ T, and a compound with a different Zr/Hf ratio has similar T_c and B_{c2} values with the critical current density $J_c \approx 4 \times 10^5$ A/cm^2. These materials also have the advantage of not being as hard and brittle as some other intermetallics and alloys with comparable transition temperatures.

The Chevrel phases $A_xMo_6X_8$ are mostly ternary transition metal chalcogenides (*see* ***Chalcogenides: Solid-state Chemistry***) where X is S, Se, Te and A can be almost any element. These compounds have relatively high transition temperatures and critical fields B_{c2} of several tesla. However, the critical currents, typically 2 to 500 A/cm^2, are rather low. The trigonal structure sketched in Figure 9 is a simple cubic arrangement slightly distorted along the (111) axis of Mo_6X_8-group building blocks, each consisting of a deformed cube with large X atoms at the vertices and small Mo atoms at the centers of the faces. The Mo_6X_8 group may be considered as an Mo_6 octahedron inscribed in an X_8 cube. Mo_6X_{12} group building blocks are also found. The parameter x in the formula $A_xMo_6X_8$ assumes various values such as $x = 1$ (e.g. YMo_6S_8, $LaMo_6S_8$), $x = 1.2$ (e.g. $V_{1.2}Mo_6\ Se_8$), $x = 1.6$ ($Pb_{1.6}Mo_6S_8$) and $x = 2$ (e.g. $Cu_2Mo_6\ Se_8$). This parameter can vary because there are so many available sites between the cubes for the A cations. Most of the space is occupied by the large chalcogenide anions that have the radii S: 0.184, Se: 0.191, and Te: 0.211 nm. The electronic and superconducting properties depend mainly on the Mo_6X_8 group. Magnetic order and superconductivity are known to coexist in Chevrel phase compounds when A is a rare earth ion since its magnetic state does not influence the superconducting properties.

The compound $Ba_{1-x}K_xBiO_{3-y}$ with $T_c \approx 30$ K for $x \approx 0.4$ has the cubic perovskite structure. It is the first oxide superconductor without copper with a transition temperature above that of all of the A-15 compounds. The

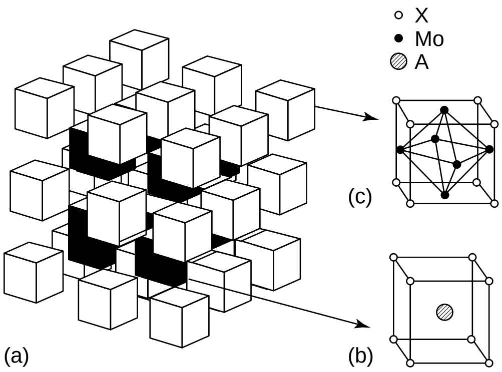

Figure 9 Structure of the Chevrel phase $A_xMo_6X_8$ (from Ref. 9, p. 431)

perovskite structure of this compound may be considered as a prototype of that of the high-temperature superconducting cuprates, which have a distorted perovskite type of atom arrangement.

10 CARBON CONTAINING SUPERCONDUCTORS

Organic compounds and polymers are ordinarily electrical insulators, but a few of them are good electrical conductors, such as organic compound 7,7,8,8-tetracyano-*p*-quinodimethane, called TCNQ for short, which forms highly conducting salts with a number of compounds. Several $(TMTSF)_2X$ charge transfer salts (tetramethyltetraselenafulvalene) superconduct under pressure, where TMTSF is an electron donor and the monovalent counterion X^- is, for example, $AsF_6{}^-$, $ClO_4{}^-$, $FSO_3{}^-$, $PF_6{}^-$, $ReO_4{}^-$, $SbF_6{}^-$, and $TaF_6{}^-$. The electrical properties of organic conductors are often highly anisotropic. TCNQ salts behave as quasi one-dimensional conductors, and salts of other organics such as bis(ethylenedithio)tetrathiafulvalene, called ET for short, exhibit low dimensional behavior, with T_c reported in excess of 13 K. In addition, the superconducting properties of the organics such as the critical fields and the coherence length are often anisotropic. For example, the triclinic compound ß-$(ET)_2I_3$ has the upper critical fields $B_{c2} = 1.78$, 1.70 and 0.08 T along the a, b and c crystallographic directions, respectively, The coherence lengths are $\xi_{plane} = 350$ Å in the conducting plane and $\xi_z = 23$ Å perpendicular to this plane, the latter being close to the longest lattice constant c = 15.3 Å.

The fullerenes,[10] the third isotropic form of carbon, (*see* ***Carbon: Fullerenes***) have a basic C_{60} molecule, which consists of sixty carbon atoms at the apices or vertices of a regular truncated icosahedron (32 sided figure) 7.1 Å in diameter, as shown in Figure 10. This structure contains 12 regular pentagons and 20 hexagons, and all of the carbon atoms are equivalent to each other. It might be called the world's smallest soccer ball! Because of its resemblance to the geodesic dome of architect R. Buckminster Fuller, it has been referred to as Buckminsterfullerene, or fullerene for short. The dual resemblances have prompted the sobriquet Buckyball. There are other fullerenes C_n with, for example, $n = 70$, 76, 78, 84, ..., but none of these are superconductors.

The compound C_{60} is not itself a superconductor, but when alkali metals are added it becomes superconducting. The doped compound forms a face-centered cubic lattice with a lattice constant of 10.04 Å, and this structure has two tetrahedral holes and one octahedral hole per C_{60} molecule. If all of these holes are occupied by alkali metals A, the resulting compound is A_3C_{60}. An example of such a compound is K_2RbC_{60} with potassium in the smaller tetrahedral holes and rubidium in the larger octahedral holes. The transition temperatures of these doped fullerenes range from 19 to 47 K. The compound Rb_3C_{60} was found to have an isotope effect exponent $\alpha = 0.37$, somewhat less than the BCS value 0.5.

11 THE CUPRATE HIGH-TEMPERATURE SUPERCONDUCTORS

Until now we have been discussing the properties of superconductors in general, and the examples that we have given were usually classical types with transition temperatures T_c below 24 K, and which usually were studied with liquid helium (at 4.2 K) as the refrigerant. The discovery of the cuprate materials[11] that superconduct above 77 K raises the possibility of commercial applications using liquid nitrogen as the cooling fluid. This considerably reduces

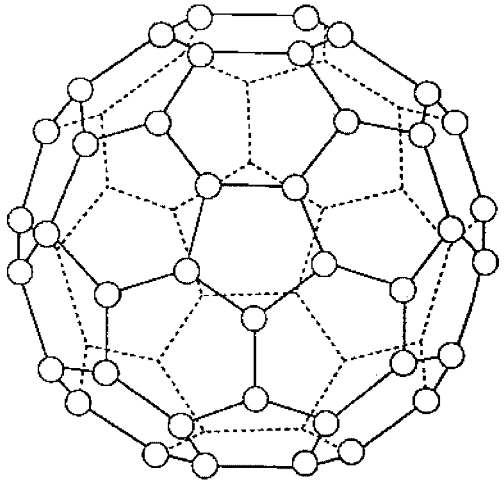

Figure 10 Structure of the Buckminsterfullerene molecule (from Ref. 8, p. 88)

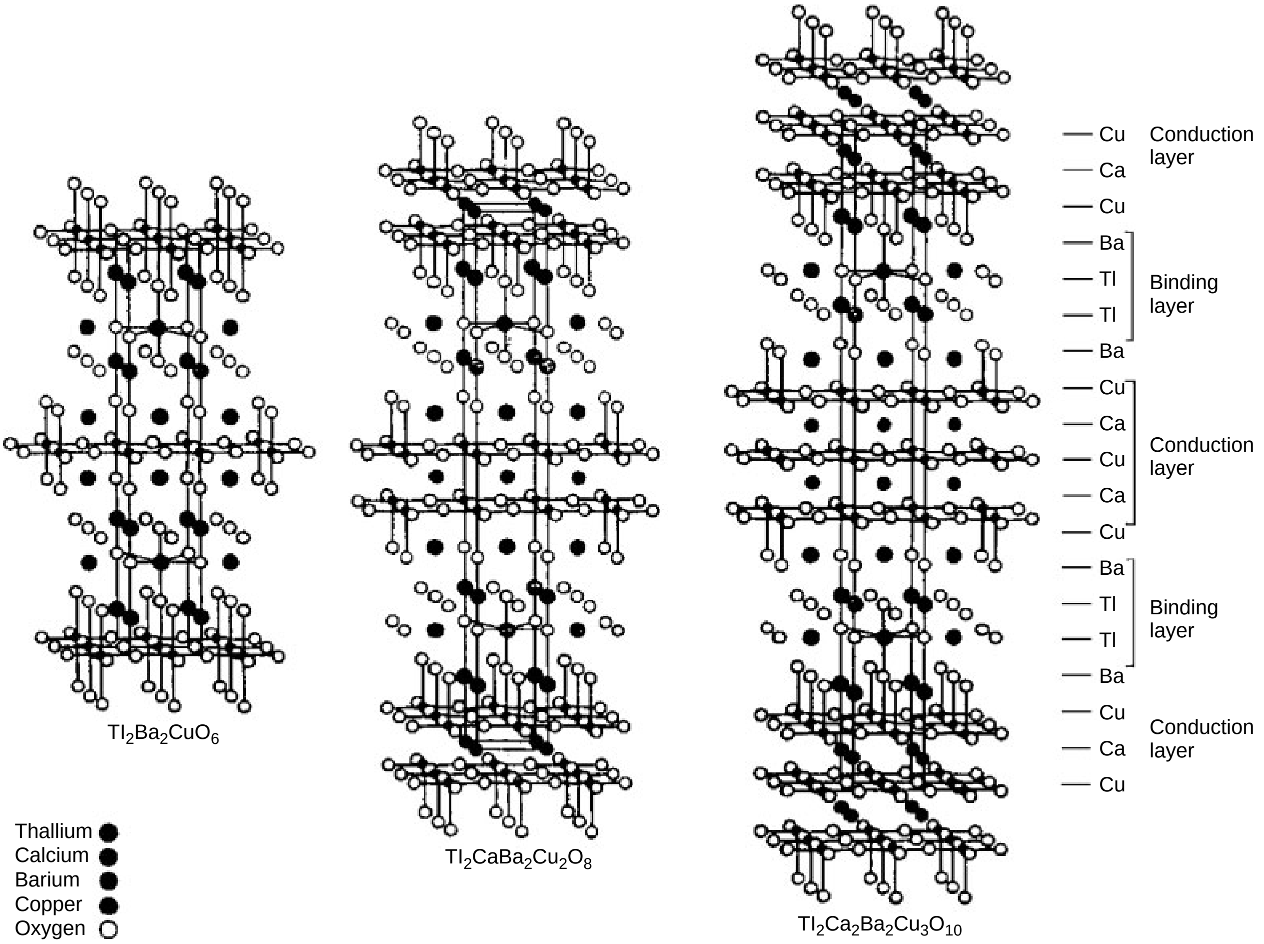

Figure 11 Layering schemes of three thallium compound superconductors $Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+6}$, where there are $n = 1$, 2, 3 CuO_2 planes in the conduction layers, from left to right. (Reprinted with permission from C.C. Torardi, M.A. Subramanian, J.C. Calabrese, J. Gopalakrishnan, M.K. Morrissey, T.R. Askew, R.B. Flippen, U. Chowdhry and A.W. Sleight, *Science*, 1988, **240**, 631. © 1988 AAAS. Y-hotlink to www.sciencemag.org)

the high cost of operation since expensive liquid helium cryostats would no longer be needed. In addition, it is much more economical to use liquid nitrogen, which sells for 25¢ a liter, rather than liquid helium, which costs $4 a liter.

The cuprate superconductors all have the same layered structure[12] that is sketched in Figure 11 for three thallium cuprates, which have one, two, and three copper oxide planes, that is, $n = 1$, 2, and 3 in their chemical formula $Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+4}$. There are alternating conduction layers where the flow of supercurrent takes place, and binding layers that support and hold together the conduction layers. The conduction layers contain copper oxide (CuO_2) layers of the type sketched in Figure 12, where each copper ion Cu^{2+} is surrounded by four oxygen ions O^{2-}.[13] These planes are held together in the structure by calcium Ca^{2+} ions located between them. An exception to this is the yttrium compound in which the intervening ions are yttrium Y^{3+} instead of calcium. These CuO_2 planes are very close to being flat. In the normal state above T_c the conduction electrons released by the copper atoms move about on these CuO_2 planes and carry the electric current. In the superconducting state below T_c these same electrons form the Cooper pairs that carry the supercurrent along the planes.

Each particular cuprate compound has its own specific binding layer consisting mainly of sublayers of metal oxides MO where M is a metal atom. Figure 11 shows the binding layers of the thallium compounds $Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+4}$ that contain BaO and TlO. The analogous bismuth compounds contain BaO and BiO, while the mercury compounds have BaO and HgO. Planes of LaO and NdO, respectively, form the binding layers of the lanthanum and neodymium superconductors. These binding layers are sometimes called charge reservoir layers because they contain the source of charge that is called upon to bring about the hole doping of the conduction planes through the following interaction

$$Cu^{2+} \longrightarrow Cu^{3+} + e^- \qquad (19)$$

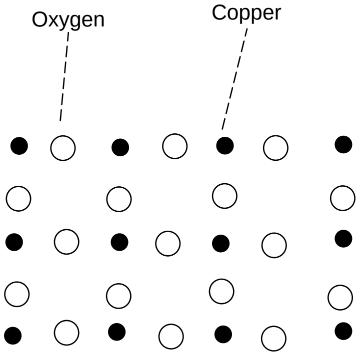

Figure 12 Arrangement of copper and oxygen atoms in a CuO_2 plane of the conduction layer (from Ref. 13, p. 99)

taking place in a copper oxide plane. Most cuprate compounds contain 1, 2, or 3 copper oxide planes, and Table 3 gives the transition temperatures of 11 of these compounds that superconduct. The dashes in the table designate compounds that either do not exist or do not superconduct. We see from this table that the mercury compounds are the best, with the thallium ones second, but the bismuth compounds seem to be more easily made into wire, and they may be preferable for applications. However, the yttrium compound, because of its ease of synthesis and interesting properties, has been the most widely studied of the group. We also see from this table that increasing the number n of CuO_2 planes in the conduction layers raises T_c, but unfortunately T_c begins to decrease for further increases in this number beyond 3.

12 HOLE TYPE COOPER PAIRS

In classical superconductors, the electric current is carried by paired electrons called Cooper pairs, with a charge of −2e. However, in most of the new cuprate materials the Cooper pairs have the positive charge +2e; in other words they are paired positive 'holes' designated by h. By holes we mean absent electrons in an energy level that is otherwise filled with electrons. A plus one hole would be formed in a level that is one electron short of being filled. The charge transfer process of equation (19) can be written in the equivalent way

$$Cu^{2+} + h^{+} \longrightarrow Cu^{3+} \tag{20}$$

where hole notation is employed. The ion Cu^{3+} can be viewed as a Cu^{2+} ion containing a hole. Successive electron exchange interactions of the type

$$Cu^{2+} = Cu^{3+} + e^{-} \tag{21a}$$

$$Cu^{3+} + e^{-} = Cu^{2+} \tag{21b}$$

can cause the hole on Cu^{3+} to hop from Cu^{2+} ion to Cu^{3+} ion as it moves along a line of divalent copper ions in the conduction layer.

Another way to see that we are dealing with a hole conduction process is to consider the outermost electronic shell of the copper ions, which is called a 3d level in the notation of atomic spectroscopy. This level can hold a maximum of 10 electrons, and is filled for the ion Cu^{+}. The ion Cu^{2+} has only nine electrons in its 3d level, which corresponds to 10 electrons plus one hole, and Cu^{3+} has 8 electrons, or 10 electrons plus two holes. Electrical current in the normal state is carried by these holes, which are in the conduction band, via the hopping mechanism of equation (21). Electric current in the superconducting state is carried by Cooper pairs formed from these holes.

The number of holes in the copper oxide planes depends on the ratio of ions with Cu^{3+} to those with Cu^{2+} valence states. To see how this can be controlled by doping, consider La_2CuO_4 as a purely ionic compound composed of two La^{3+} ions, one Cu^{2+} ion and four O^{2-} ions. If 10% of the trivalent La^{3+} is replaced by divalent Sr^{2+} to form the compound $(La_{0.9},Sr_{0.1})_2CuO_{4-x}$, there are two ways to achieve electrical neutrality, that is, to make the positive charges balance the negative charges in the compound. One way is to let all of the copper remain as Cu^{2+} and reduce the amount of oxygen, and if we do this we obtain the compound $(La_{0.9},Sr_{0.1})_2CuO_{3.9}$. The copper oxide planes are not changed by this process since all of the copper is still in the Cu^{2+} state. The other way to keep the oxygen content the same corresponding to the formula $(La_{0.9},Sr_{0.1})_2CuO_4$ and to achieve charge neutrality is by converting 20% of the divalent Cu^{2+} ions to trivalent Cu^{3+}. This results in copper oxide planes with many holes arising from the presence of so many Cu^{3+} ions. The charge balance equation for achieving charge neutrality in this manner is

$$La^{3+} + Cu^{2+} \longrightarrow Sr^{2+} + Cu^{3+} \tag{22}$$

In practice, both processes can occur; there can be some decrease of oxygen and some conversion to Cu^{3+} ions. The concentration of holes on the copper oxide planes can be calculated when the parameter x in the formula $(La_{0.9},Sr_{0.1})_2CuO_{4-x}$ is known. This superconductor is often called the lanthanum compound. The superconducting transition temperature depends on the hole concentration in

Table 3 Superconducting transition temperatures of the cuprates

		Number of Cu_2O planes		
Compound	Formula	$n = 1$	$n = 2$	$n = 3$
Lanthanum	$(La_{0.9}Sr_{0.1})_2CuO_4$	35	–	–
Neodymium	$(Nd_{0.9}Ce_{0.1})_2CuO_4$	35	–	–
Yttrium	$YBa_2Cu_3O_7$	–	92	–
Bismuth	$Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$	0	84	110
Thallium	$TlBa_2Ca_{n-1}Cu_nO_{2n+4}$	90	110	125
Thallium	$Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+4}$	90	110	125
Mercury	$HgBa_2Ca_{n-1}Cu_nO_{2n+4}$	95	133	133

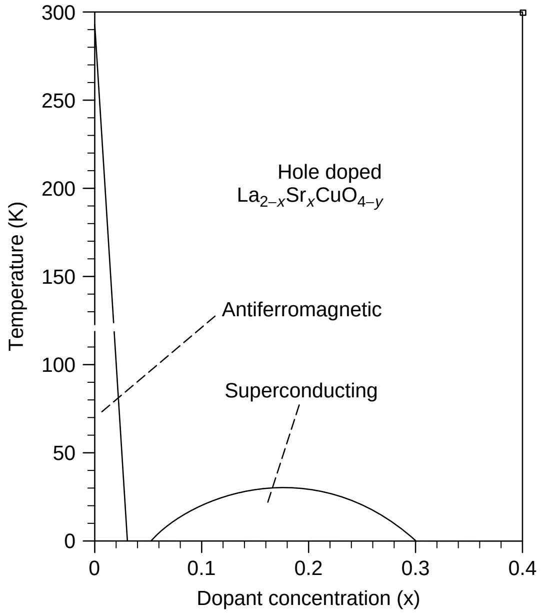

Figure 13 Plot providing the superconducting transition temperature versus the strontium content x of the compound $La_{2-x}Sr_xCu_{4-y}$. The region of antiferromagnetic behavior is also indicated. (Ref. 13, with kind permission of Springer Science & Business Media)

the manner indicated in Figure 13. The graph shows that superconductivity only occurs over a certain range of hole concentrations, and there is an optimum concentration for the highest T_c. The figure also shows that there is an ordered antiferromagnetic phase at low Sr contents.

One of the consequences of a hole hopping process involving a two dimensional array of copper ions is that the superconducting current is very directional dependent or anisotropic. The hopping tends to occur between the copper ions that have the smallest separation from each other, that is, those in the plane. The distance between copper ions in adjacent planes is much larger than within the planes, and hence charge hopping between planes is much less efficient. This means that the current flows much more easily within a plane than it does perpendicular to the planes. In a single crystal the measured current above T_c and the critical current density J_c below T_c will depend on the direction in which the determination is made. Many other properties of cuprate superconductors such as the critical fields B_{c1} and B_{c2}, the penetration depth λ and the coherence length ξ are also dependent on the direction.

13 CERAMICS AND PEROVSKITES

Although the new superconductors have been widely referred to as ceramics, they are more properly classified as perovskites since their structures resemble that of the mineral

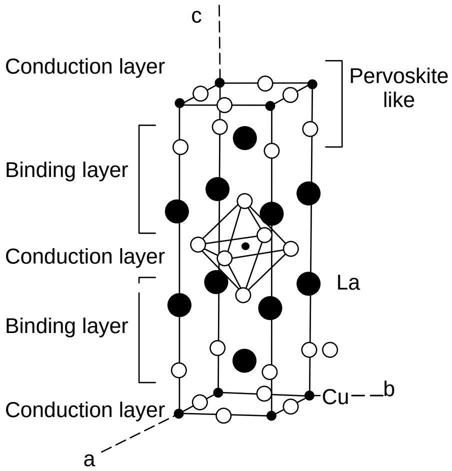

Figure 14 Atom positions in the tetragonal unit cell of the La_2CuO_4 compound. In the superconducting compound $La_{1-x}Sr_xCuO_4$ strontium replaces lanthanum in some of the La sites (from Ref. 13, p. 109)

perovskite, or calcium titanate $CaTiO_3$. The atom positions in the upper (and lower) parts of the lanthanum compound unit cell of Figure 14 are similar to those in perovskite with Cu present in the titanium (Ti) sites of perovskite, La in the centrally located calcium positions, and oxygen at the same location in both structures.

In contrast to this, the ceramic designation was not based on structural grounds, but rather emerged from the similarity between the way the cuprate superconducting compounds and ceramics are made. For example, La–Sr–Cu–O is made by heating mixtures of lanthanum oxide, strontium carbonate, and copper oxide in air at 900 to 1000 °C for 20 h. The proportions of atoms in the initial mixture should be the same as in the end product, and for the compound $(La_{0.9}Sr_{0.1})_2CuO_4$ the ratio La:Sr:Cu is 1.8:0.2:1. The materials are usually ground to a fine mixture before heating. After the heating in air, they are cooled, pressed into pellets, and reheated from 900 to 1000 °C for several more hours.

14 THE YTTRIUM COMPOUND

The discoveries that generated the extensive news coverage in early 1987 were the initial report of superconductivity in the lanthanum compound by Bednorz and Müller,[11] and the observation of superconductivity in the compound $YBa_2Cu_3O_{7-x}$ at 92–94 K, well above the boiling point (77 K) of liquid nitrogen. The latter result was the outcome of a collaboration between the research groups of C. W. Chu[14] of the University of Houston and M. K. Wu[15] of the University of Alabama.

Like the lanthanum compound that we just described, the present material is deficient in oxygen, and the x in the chemical formula denotes the possibility of different amounts

of oxygen in the crystal lattice. The parameter x is zero when all of the oxygen sites are full, and x is about 0.1 for the highest T_c. Many of the important electrical, magnetic, and other properties are also sensitive to the amount of oxygen in the crystal. As the oxygen content is varied, the relative amounts of Cu^{3+} to Cu^{2+} change to keep the crystal electrically neutral. The structure is orthorhombic with lattice constants a $\approx$ b, in the superconducting region, and tetragonal with a = b for $x < 0.4$ where it no longer superconducts. There are two copper oxide planes in the conduction layer, with yttrium ions between these two planes. The middle of the binding layer also has copper ions, and they form chains Cu–O–Cu–O–...... along the crystallographic b axis that may contribute to the superconducting properties.

The substitution of first transition series ions such as zinc or nickel for copper in $YBa_2Cu_3O_x$ generally causes a sharp reduction of the transition temperature, which underlines the important role that copper plays in the superconducting mechanism. The deterioration of the superconducting properties is greater when the nonmagnetic zinc ion is substituted for copper compared to the magnetic nickel ion, hinting at the importance of the magnetic nature of copper in the superconducting mechanism. Most of the rare earth elements can replace yttrium without a significant change in the superconducting properties.

15 THE BISMUTH AND THALLIUM COMPOUNDS

In this family of bismuth[16] and thallium[17] compounds, there are many compositional variations that give superconductivity, some of them involving, for example, the addition of lead. Table 3 lists transition temperatures for some members of these series of compounds

$$Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4} \quad Bi22(n-1)n \quad n = 1, 2, 3, 4 \tag{23a}$$

$$Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+4} \quad Tl22(n-1)n \quad n = 1, 2, 3, 4 \tag{23b}$$

where n is the number of copper atoms that are present, which corresponds to the number of planes in the conduction layer. The binding layers for the thallium family are shown in Figure 11. The transition temperature rises as n increases from 1 to 3, and then decreases for $n = 4$, as indicated in Figure 15, with Tl 2223 or $Tl_2Ba_2Ca_2Cu_3O_{10}$ having the highest value $T_c = 125$ K. The similarity of all the structures having different n values has resulted in another problem. It is difficult to synthesize materials that are entirely of a single phase, having only one n value. Most of the fabrication processes result in a mixed phase product.

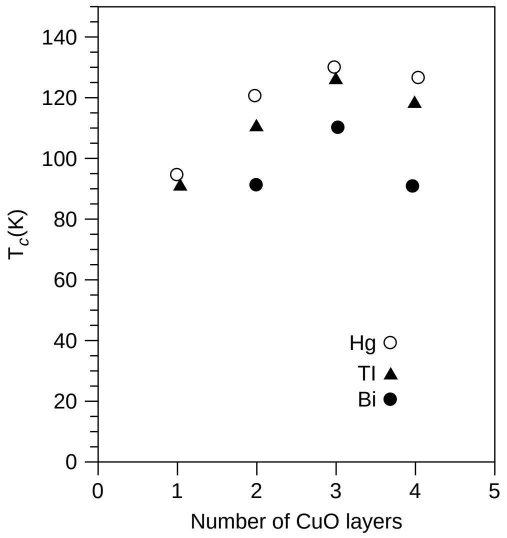

Figure 15 The superconducting transition temperature of the $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4}$, $Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+4}$ and $HgBa_2Ca_{n-1}$-Cu_nO_{2n+2} compounds versus the number n of copper oxide planes in the conduction layers. (Ref. 13, with kind permission of Springer Science & Business Media)

16 THE MERCURY COMPOUNDS

In the spring of 1994, a new superconductor was synthesized that had zero resistance at 133 K and some samples had an onset of superconductivity as high as 140 K. The material is $HgBa_2Ca_2Cu_3O_{8+x}$. The structure of this copper oxide superconductor is tetragonal. There is a small additional amount of oxygen in the mercury layer that is not strongly bonded in a particular site in this layer, but can diffuse between them. However, a more stable lead substituted version of this material $Hg_{0.7}Pb_{0.3}Ba_2Ca_2Cu_3O_{8+x}$ with about 1/3 of the mercury sites substituted by lead has been synthesized. This is because an oxygen at a site between lead and mercury is more strongly bonded than one between two mercury atoms. Table 3 and Figure 15 show the dependence of T_c on the number n of copper oxide planes.

There is much interest in this superconductor for two reasons. Measurements of the effect of pressure on the material indicate that the onset transition temperature increases to 147 K when the pressure is raised to 230 000 times atmospheric pressure (23.5 giga Pascal). The result excited many researchers because pressure on a material can be created chemically by replacing some fraction of an ion by a similar ion of smaller radius. The obvious choice in this case was to replace the larger barium with smaller strontium. This had worked with the lanthanum compound discussed earlier. Unfortunately nature is not always so predictable. Replacement of barium by strontium reduced T_c to 127 K instead of increasing it beyond 133 K. The other reason for the interest in this material seems much more important. Resistance measurements in dc magnetic fields have shown

that fields up to 10 tesla do not increase the resistance at 77 K. This means that the flux is more strongly pinned in this superconductor than it is in the other cuprates at 77 K. This is good for applications because critical currents can reach higher values.

17 SUMMARY OF PROPERTIES OF THE CUPRATES

We have discussed the characteristics of a number of copper oxide superconductors, a group of materials that have many properties in common. These shared properties might well provide the key to the development of an explanation of the mechanism of high-temperature superconductivity. The most important common features are:

1. presence of magnetic copper ions
2. arrangement of copper and oxygen ions in two dimensional arrays
3. hole hopping conduction largely confined to copper oxide planes
4. presence of binding layers providing a source for hole doping of copper oxide planes
5. dependence of transition temperature and superconductivity of concentration of holes
6. evidence for short range antiferromagnetic ordering in copper oxide layers

1 INTRODUCTION

Supported organotransition metal complexes have important applications in the design and modeling of new catalysts. They are of interest in the modification of surface properties of solids, including electrodes, and as stoichiometric reagents.

A catalyst may be defined as homogeneous or heterogeneous depending on the phase of matter that contains the catalytically active species. Heterogeneous catalysts comprise those systems in which the catalytically active species is in a separate phase from the substrate. For true heterogeneous catalysts, the catalytic reaction occurs at the interface between the two phases. Typically, the catalyst is a solid and substrates are liquids or gases, although it is possible to devise liquid/liquid and liquid/gas systems. A catalyst is defined as homogeneous when it is in the same phase as the substrate. Reactions catalyzed by organotransition metal complexes are generally homogeneous with all reactants, and the catalyst, dissolved in an appropriate solvent.

Heterogeneous catalysts are usually considered to have a technological advantage over homogeneous catalysts in that the products and the catalyst are easily separated. Homogeneous catalysts often have the advantage of milder reaction conditions and greater selectivity, but suffer in the ease of removal of the catalyst from products. In an effort to combine the relative merits of homogeneous and heterogeneous catalysts, organotransition metal complexes have been supported, that is, immobilized, on solids. The literature also refers to these complexes as 'heterogenized.' Immobilized organotransition metal complexes of this type comprise the largest class of supported complexes. Supported organotransition metal complexes can serve as models for heterogeneous catalysts or can be used synthetically as precursors for heterogeneous catalysts.

There are other instances when supporting an organotransition metal complex may have an advantage over its homogeneous counterpart. For example, when designing stoichiometric reagents for organic transformations, a solid reagent can be easily removed from a reaction by filtration.

Organometallic complexes are used as precursors for thin films generated by chemical vapor deposition techniques. Supported organotransition metal complexes can serve as both models for film growth and as precursors to films and other materials.

The literature of supported transition metal complexes has been thoroughly reviewed.[1–6] In this article, the chemistry of supported complexes is covered in general terms by class of solid support; these include metal oxides, clay minerals, zeolites, polymers, and ion-exchange resins.

2 SOLID SUPPORTS

2.1 Inorganic Metal Oxides

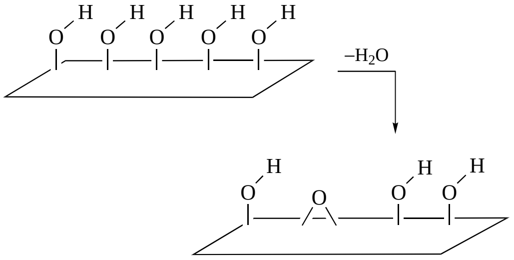
Many metal oxides, such as TiO_2 and Al_2O_3, can be prepared with relatively high surface areas. The exposed surfaces of metal oxides are typically terminated with oxo or hydroxy groups. A dehydroxylated surface is one from which most of the surface OH groups have been removed by heating (see below). Full or partial dehydroxylation may expose cation sites.

Several strategies have been employed in supporting metal complexes on oxide surfaces. For example, surface oxo and hydroxyl groups may be used as ligands; the surface may be modified by reaction of the hydroxyl groups to introduce ligands to the surface, and more recently amorphous metal oxides, such as silica, have been imprinted via sol-gel techniques to generate shape selective cavities.[7,8]

Identification of the types of oxo and hydroxyl groups, which can exist on a metal oxide surface, is important in developing strategies for the immobilization of organometallics. Models for the surface can be constructed by terminating the crystal lattice along a known face and determining the types of groups that can reasonably exist. Often the surface is not

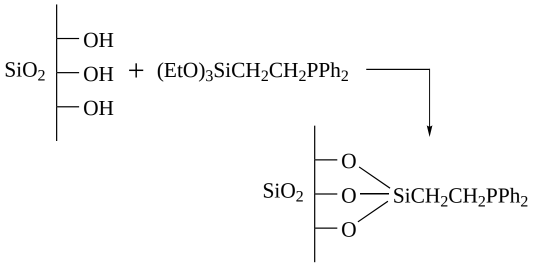
well defined as, for example, in gamma alumina, γ-Al_2O_3, and amorphous silica–alumina. In these cases, an empirical model for the surface is postulated from assumptions about the expected structure of the metal oxide. The viability of the surface model can be tested spectroscopically by titrating the surface with appropriate acids and bases and examining shifts in IR, Raman, or NMR parameters.

For example, five types of hydroxyl groups are predicted to occur on the (100), (111), and (110) surfaces of aluminas,[9] as depicted in Figure 1. The relative concentration and distribution of these groups depends on the exposed faces. Dehydroxylation of the surface, according to equation (1), yields surface oxo groups and exposes aluminum cations. The surface hydroxyl groups have Brønsted acidity, while exposed metal cations behave as Lewis acids.[9] Alumina surfaces with Lewis acidity can be prepared from aluminum alkoxides under mild conditions by protecting the incipient Lewis acid site with amines.[10]

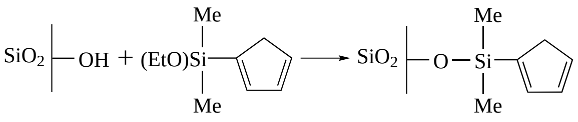


(1)

Surface hydroxyl groups on TiO_2 and SiO_2 are typically less acidic than those on alumina.[11] On silica surfaces, hydroxyl groups are associated with tetrahedrally coordinated silicon atoms. Functionalization of the surface silanols is readily achieved by reaction with chloro- or alkoxysilane reagents. Reactions such as those in equations (2) and (3) may be used to add phosphine, cyclopentadienyl, and other functionalities to the surface.[5,12,13]



(2)



(3)

Zeolites, $(SiO_2)_x(AlO_2)_yNa_y{\cdot}nH_2O$, are use extensively as supports for organotransition metal complexes. The presence of framework AlO_2^- groups requires an extraframework cation to balance the negative charge; thus zeolites have cation-exchange capability. Faujasites are the most commonly used zeolite support for metal complexes and catalysts.[14,15] A

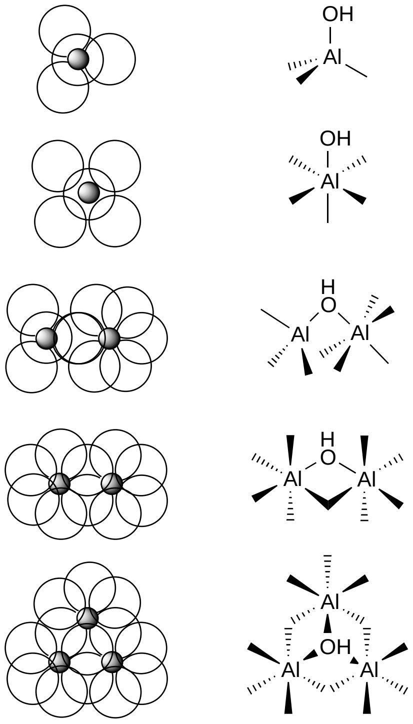


Figure 1 Representations of the five types of surface hydroxyl groups proposed to occur on γ-alumina. On the left is the view from directly above the surface with the open circles representing either O^{2-} or OH^- and the smaller filled circles representing aluminum

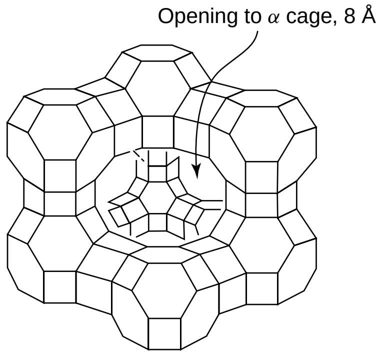

Figure 2 A portion of the faujasite framework. Each vertex represents either a silicon or an aluminum site, each line represents a bridging oxygen. The opening into the supercage is approximately 8 Å in diameter; it consists of 12 metal sites and 12 bridging oxygens

schematic representation of the faujasitic framework is shown in Figure 2.

The pore opening in faujasites is estimated to be ca. 8 Å, while the large cavity, that is, the supercage or α-cage, is estimated to have a diameter of 13 Å.[14] Small molecules can readily enter the pores and large molecules can be synthesized within the supercage. Clusters such as $Rh_6(CO)_{16}$[16] and the Schiff base complex, VO(saloph),[17] can be prepared within the faujasite supercage. (Saloph =

N,*N'*-*o*-phenylenebis(salicylide naminato).) More commonly, zeolites are used to support small aggregates of metal atoms.[15]

The interlayer regions of clay minerals also have cation-exchange capability and can be modified by organotransition metal compounds.[18] Montmorillonite[19] is typical of these materials and is readily intercalated with transition metal complex ions. The layered structure of montmorillonite is shown in Figure 3.

2.2 Polymers as Supports

A wide variety of polymeric materials have been used for the immobilization of organotransition metal complexes, including ion-exchange resins[20] and linear and crosslinked polystyrene, polyethylene, and many other polymers.[21,22]

Polymers can be modified by methods similar to those described above for metal oxides.[23,24] For example, chloromethylated polystyrene reacts with diphenylphosphide to yield a phosphinated polystyrene (equation 4).[23] The modified polymer can then be used as a ligand for a variety of

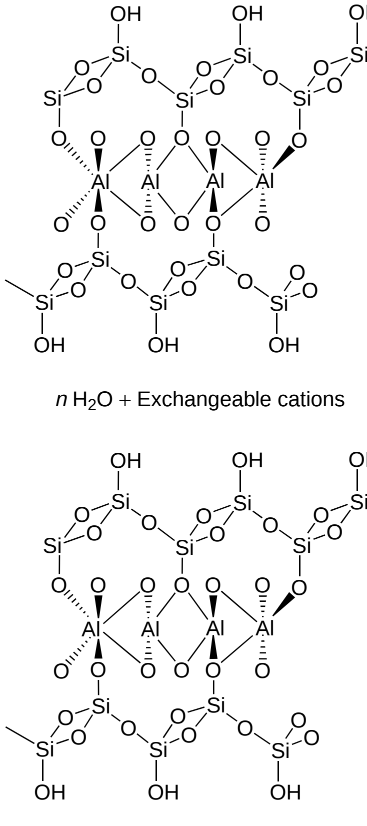

Figure 3 The layered structure of smectite clays such as montmorillonite or hectorite is represented. The aluminum sites are octahedral and the silicon sites are tetrahedral. The interlayer space is filled with water and metal cations

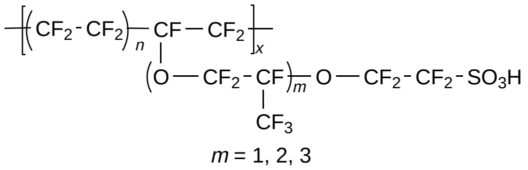

Figure 4 The Nafion backbone and side chains. The sulfonic acid groups are hydrophilic and cluster together. This gives Nafion a relatively porous structure. Nafion swells in polar solvents, such as methanol and water

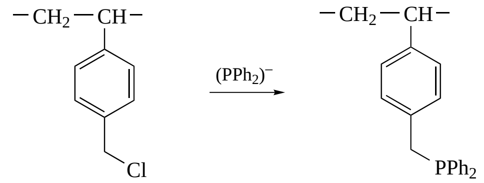
transition metal compounds.



(4)

Cyclopentadienyl groups can be incorporated in a manner similar to that shown in equation (4) for phosphines.[19] Metallocene derivatives (*see Metallocene Complexes*), in turn, can be incorporated into these modified polymers. Also, chiral phosphines such as DIOP and BINAP have been immobilized on polymers to be used in asymmetric hydrogenation catalysis and related reactions.[25]

Nafion, a perfluorinated polymer with pendant sulfonic acid groups, has been used as a support for the immobilization of catalysts. The material phase separates into hydrophobic and hydrophilic regions comprising $-CF_2CF_2-$and $-SO_3H$ groups respectively;[26] the polymer morphology is thought to resemble a reverse micelle with the sulfonate groups aggregated inside the polymer matrix. The solid polymer is porous and, as such, the sodium salt acts as an ion conductor. The composition of nafion is shown in Figure 4.

Metal complexes bound to soluble polymers act as homogeneous catalysts; they can be selectively precipitated and separated from products, and thus behave as immobilized homogeneous catalysts because of the ease with which they can be separated from reaction products.[21] Alternatively, complexes can be physically trapped within the pores of swellable polymers. In this manner, they can be effectively immobilized without a direct bond to the support.[27] Polymers may be imprinted to give additional selectivity in the reactions of the supported metal catalysts and reagents.[28,29]

3 COVALENTLY BOUND ORGANOTRANSITION METAL COMPOUND

This comprises by far the largest class of supported organometallic reagents. Some of the earliest examples in

the field can be classified as covalently bound. As described in Section 2.2, the bond to the transition metal complex can be from a ligand group that is inherently a part of the support or a ligand can be added to the surface by chemical modification of the support.

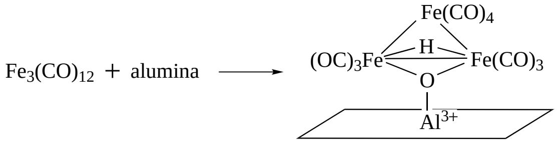
3.1 Unmodified Metal Oxide Supports

It was observed in the early 1960s that $Mo(CO)_6$ supported on aluminum oxide yields a catalyst for what is now known as the *Alkene Metathesis* reaction.[30] The reaction of molybdenum hexacarbonyl with the surface proceeds as in Scheme 1.[31]

Direct evidence for both the alumina-supported molybdenum pentacarbonyl and the molybdenum tricarbonyl species has been obtained by cross-polarization magic angle spinning (CP-MAS) ^{13}C NMR spectroscopy.[32,33] On other supports, the group 6 metal carbonyls do not appear to give well defined supported carbonyl fragments. For example, on TiO_2, molybdenum hexacarbonyl loses all of its CO ligands at 200 °C. Temperature-programmed desorption shows no evidence for stable metal subcarbonyl fragments.[34]

Ruthenium and rhenium tricarbonyl groups are formed on alumina surfaces from the decomposition of $Ru_3(CO)_{12}$ and $H_3Re_3(CO)_{12}$ respectively.[35] The supported carbonyl fragments serve as precursors to supported particles of the respective metals. $HRe(CO)_5$ decomposes on MgO to yield isolated rhenium tricarbonyl groups, while the cluster precursor, $H_3Re_3(CO)_{12}$, is thought to give ensembles of three rhenium tricarbonyl groups.[36] These are assigned as $Re(CO)_3\{OMg\}\{HOMg\}_2$ groups on the basis of gas evolution during adsorption.[37] The bracketed ligands, {OMg} and {HOMg}, represent surface oxo and hydroxy groups bonded to the rhenium carbonyl fragment.

The reaction of $Fe_3(CO)_{12}$ with hydroxylated metal oxide surfaces yields $HFe_3(CO)_{10}$(ads)[38,39] as determined by stoichiometry and CP-MAS ^{13}C NMR (equation 5).[38,39]



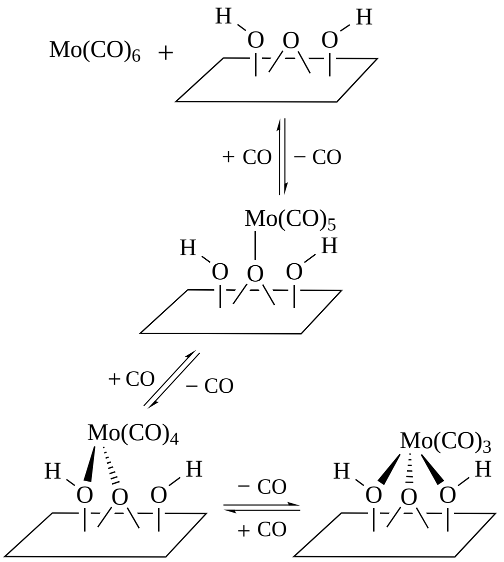
(5)

Ruthenium and osmium analogs of the μ-oxo bound cluster are known. For example, (μ-H)$Ru_3(CO)_{10}$(μ-$OSiEt_3$)[40] and (μ-H)$Os_3(CO)_{10}$(μ-$OSiEt_3$)[41] have been prepared, and the (μ-oxo)-bound triruthenium and the triosmium clusters can be selectively prepared on the surface of silica and alumina.[40,42]

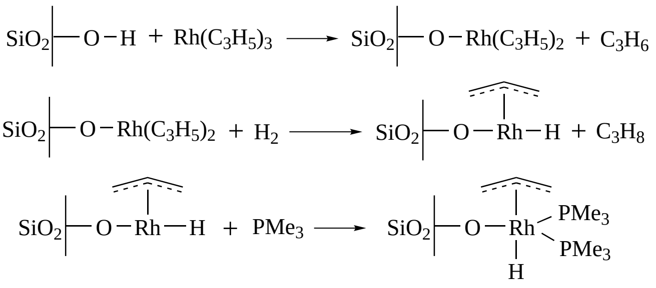
Large metal clusters have been supported on many metal oxides. For example, the carbido-cluster anion $[Os_{10}C(CO)_{24}]^{2-}$ has been adsorbed directly onto MgO.[43] This cluster anion can also be prepared in situ on MgO by the *Reductive Carbonylation* of adsorbed H_2OsCl_6.[43] The adsorbed osmium cluster anion appears to be ionically bound to the surface.

In addition to the CO displacement reactions illustrated above for metal carbonyl derivatives, other reactive organometallic precursors have been used to yield supported organometallic complexes. For example, hydroxylated surfaces, such as silica, react with $Rh(C_3H_5)_3$ to yield propene and (surface)$Rh(C_3H_5)_2$.[44] Hydrolysis is suggested to generate a surface hydride. The reactions shown in Scheme 2 are illustrative of the surface complexes that can be formed from $Rh(C_3H_5)_3$. The supported rhodium hydrides are active for the hydrogenation of a variety of internal and terminal alkenes.[44] The trimethylphosphine complex shows reduced hydrogenation activity.

The imprinting of metal oxides is a relatively new method for the immobilization of metal complexes. The case of $Rh_2(CO)_4Cl_2$ on silica is illustrative.[8] The dimer is first adsorbed onto the surface of silica, most likely through a surface hydroxyl group, and then reacted with trimethylphosphite, $P(OMe)_3$. Amorphous silica is then



Scheme 1

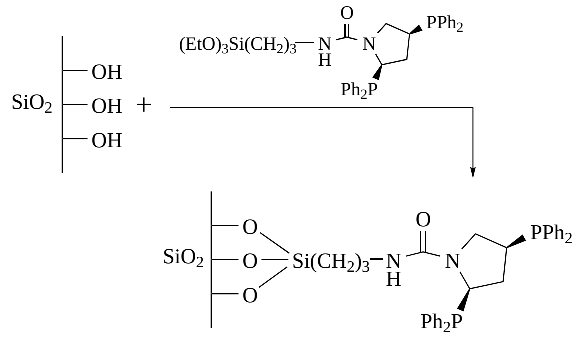


Scheme 2

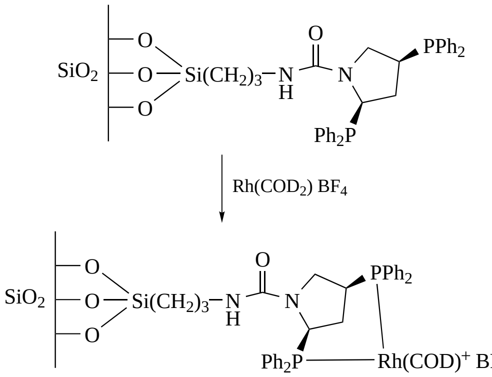
formed around the supported metal by the reaction of $Si(OMe)_4$ and water under chemical vapor deposition conditions. The trimethylphosphite is then removed thermally to generate a templated void space in the amorphous oxide. Rhodium catalysts generated in this manner are active for the hydrogenation of olefins.[8]

3.2 Ligand-modified Metal Oxide Supports

Silica, SiO_2, has been modified with a variety of phosphines by methods similar to those discussed above. For example, chelating phosphines have been bound to hydroxylated silica surfaces using $(EtO)SiMe_2–C_6H_4–O–CH(PPh_2)CH_2PPh_2$ according to equation (6).[45] The use of chelating phosphines in immobilizing transition metal complexes has the advantage of reducing the likelihood of metal leaching from the support. The formation of rhodium complexes is represented in equation (7).



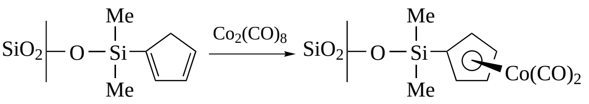
(6)



(7)

Rhodium catalysts supported via chelating phosphines as described above have been used as Asymmetric Hydrogenation catalysts.[45]

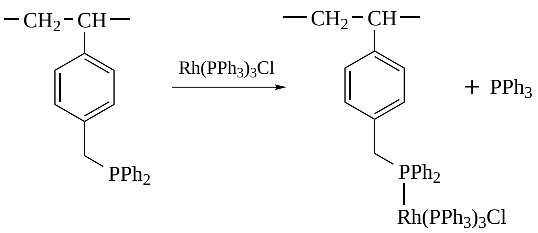
Cyclopentadienyl-modified silica reacts with $Co_2(CO)_8$ to yield cyclopentadienylcobalt dicarbonyl according to equation (8). The supported complex is characterized by IR spectroscopy by analogy with its homogeneous counterpart.[13]



(8)

3.3 Polymer-supported Organotransition Metal Complexes

Metal–phosphine complexes can be immobilized on phosphinated polymers through simple ligand exchange reactions. *Wilkinson's Catalyst*, $Rh(PPh_3)_3Cl$, has been supported on phosphinated polystyrene as shown in equation (9).[24] The supported complex can be used as an alkene hydrogenation catalyst.

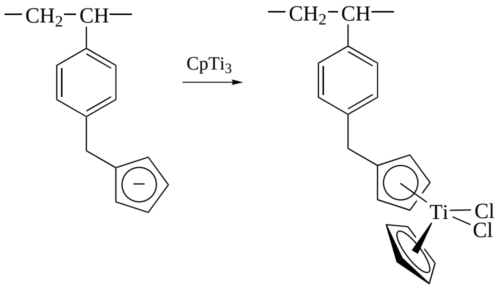


(9)

Bimetallic complexes, such as $RuPt(CO)_5(PPh_3)_3$, have been immobilized on phosphinated poly(styrene–divinylbenzene) by a similar ligand-substitution reaction (equation 10).[46] The resulting supported bimetallic complexes have been characterized by IR spectroscopy and are found to act as ethylene *Hydrogenation* catalysts.

$$\text{Polymer-PPh}_2 + \text{RuPt(CO)}_5(\text{PPh}_3)_3 \longrightarrow \text{RuPt(CO)}_5(\text{polymer-PPh}_2)_x(\text{PPh}_3)_{3-x} \qquad (10)$$

The preparation of silica- and polymer-supported cyclopentadienyl groups is discussed above. These modified solids can be used to generate a wide variety of immobilized metal complexes.[1,2,13,47] Reaction of a cyclopentadienyl-modified polystyrene with $(C_5H_5)TiCl_3$ yields supported titanocene dichloride (equation 11).



(11)

Direct reaction of soluble polymers that contain phenyl groups, for example, polystyrene, with chromium atoms leads to polymers crosslinked with bis(benzene)chromium.[48] Oxidation leads to aggregates of Cr_2O_3 imbedded with the polymer.

CP-MAS ^{31}P NMR can be used to characterize supported complexes, for example, the polypropylene-*p*-styryldiphenylphosphine-bound rhodium complex [(polymer)-PPh_2]Rh(acac)(CO) has been characterized in this manner.[49] Free and complexed phosphines are clearly

distinguished. The bound complex is spectroscopically similar to its molecular analog, $(PPh_3)Rh(acac)(CO)$.

Anionic polymerization of ethylene has been used to prepare terminally functionalized ethylene oligomers. The reaction proceeds as shown in equation (12).[21] Phosphite as well as phosphine-functionalized ethylene oligomers have been prepared. Nickel(0) phosphine complexes can be bound to such a functionalized oligomer. The bound complexes have similar activity as their homogeneous counterparts for the cyclooligomerization of butadiene.[21]

$$H_2C{=}CH_2 \xrightarrow{RLi} R(CH_2CH_2)_nCH_2CH_2Li \xrightarrow{PPh_2Cl} R(CH_2CH_2)_nCH_2CH_2PPh_2 \quad (12)$$

The imprinting of polymer supports is an exciting development in the immobilization of transition metal complexes.[28,29] The process involves the copolymerization of an inorganic or an organic template into a crosslinked polymer network. In a subsequent step, the template is chemically removed leaving an imprint of molecular dimensions in the resin. Ideally, the imprint retains chemical information related to the size and shape of the template. This approach has been used to prepare chiral imprints in otherwise achiral polymer networks. The method is outlined in Scheme 3.[28,29]

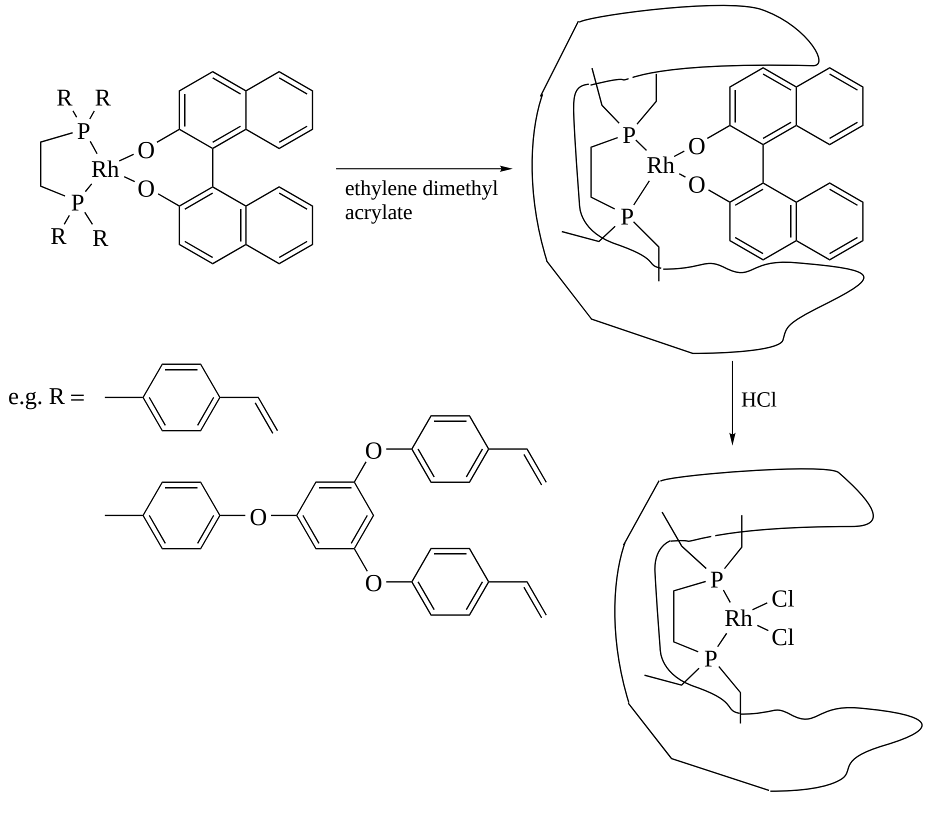
4 PHYSICALLY IMMOBILIZED ORGANOTRANSITION METAL COMPLEXES

Organotransition metal complexes are physically immobilized on a solid when there is no direct covalent or ionic interaction between the complex and the solid. The complex may, for example, be dissolved in a stationary phase on a solid or entrapped with a solid matrix.

4.1 Immobilization in a Supported Liquid Phase

Adsorption of a high-boiling solvent onto a high-surface-area microporous solid yields a supported liquid phase that can be removed from the solid only by extraction with a second solvent or by distillation at high temperature under vacuum. Under typical reaction conditions, a solid that contains a supported liquid phase looks and behaves as a solid, yet it can dissolve small quantities of a metal complex into the supported phase. One of the first examples of this arrangement was achieved with the immobilization of $Rh(CO)(PPh_3)_2Cl$ in benzyl butyl phthalate on silica.[50] The supported complex was successfully used to effect the gas-phase hydroformylation of propene.

In a similar manner, the complexes $HRh(CO)(PR_3)_3$ have been dissolved in supported liquid phases, where the ligand, PR_3, forms the liquid phase. In one specific example,



Scheme 3

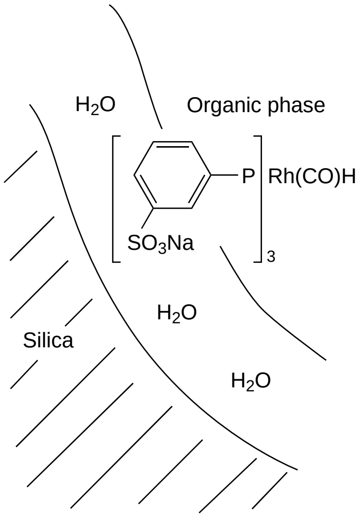


Figure 5 Rendering of the silica–water–substrate phase in the supported aqueous phase catalysts

$HRh(CO)(PPh_3)_3$ was supported in molten PPh_3 for use as a heterogeneous catalyst for the hydroformylation of propene.[51]

Recently a supported aqueous phase has been used in place of the high-boiling liquid phase for the immobilization of water-soluble metal complexes, such as $HRh(CO)(P(C_6H_4$-m-$SO_3Na)_3)_3$.[52,53] Catalytic applications proceed with water-soluble substrates by virtue of an increase in surface area between the catalytic-supported aqueous phase over that of a simple two-phase reaction, and by the inherent surface activity of water-soluble complexes based on sulfonated phosphines. The polar sulfonate groups are strongly bound to the supported aqueous phase, keeping the complex immobilized. The surface is schematically represented in Figure 5.

Alternatively, polar liquids other than water can be used to generate supported liquid-phase catalysts with sulfonated ligands. For example, supported liquid-phase Pd-TPPTS catalysts have been prepared on silica with ethylene glycol as the liquid phase.[54]

4.2 Entrapment of Metal Complexes within a Solid Matrix

Zeolites (molecular sieves) make ideal supports for the physical immobilization of organotransition metal complexes. The pores and cages of zeolites are of molecular dimensions, and several zeolites are available for which the cages have significantly larger dimensions than the pores or entrances to the cages. Under these circumstances, it is possible to envisage that a metal complex could be constructed to fill the cage of a zeolite, and thus be too large to leave via the smaller pore. Thus, a chemical bond to the zeolite is not required to keep the metal complex bound to the zeolite. This immobilization technique has been recently reviewed.[55]

For an organotransition metal complex, such an intrazeolitic synthesis was first accomplished with the preparation of $Rh_6(CO)_{16}$ within the faujasite framework.[14] Specifically, $[Rh(NH_3)_6]^{3+}$ was cation exchanged onto the zeolite, and the complex ion was reductively carbonylated to yield the rhodium cluster within the zeolite cages. The general technique has been referred to as ‘molecular ships in bottles’ in the context of forming $Ni(CO)_{4-x}L_x$ (L = phosphine) complexes with zeolites, such that the resulting substituted nickel complexes are too large to be removed from the zeolite.[56]

Long-range electron transfer is postulated to occur from ferrocene to tris(bipyridine)iron(III) constructed within the pores of a NaY zeolite.[57] The iron bipyridine complex is too large to move throughout the faujasite pores to the surface, thus requiring the long-range transfer. The asymmetric catalyst, titanium tartrate, has been prepared inside NaY and used as an immobilized catalyst for the epoxidation of cinnamyl alcohol.[58]

Discrimination between surface and intrazeolite sites is often difficult. The chemical reactivity of zeolite-bound complexes to reagents of different sizes is helpful in determining the location of an immobilized complex.[59] For example, in rhodium faujasites prepared from $Rh(allyl)_3$ and H–Na–X (i.e. the faujasite Na–X in which a fraction of the sodium ions have been replaced with protons), catalytic activity for hydrogenation can be limited to the intrazeolite sites only when $P(n\text{-}Bu)_3$ is used to poison the surface rhodium sites. Tri-n-butylphosphine is too large to penetrate the zeolite pores, thus the rhodium complexes within the zeolite remain catalytically active.

Polymers can also be used for the physical immobilization of metal complexes. For example, the degree of swelling observed for 1% crosslinked polystyrene varies with solvents; more swelling is observed in THF than in methanol. Thus, the cationic complex $[(diphos)Rh(NBD)]PF_6$ can be adsorbed onto polystyrene in THF. When dried and extracted with methanol, the complex is bound within the polystyrene matrix. The immobilized complex is a catalyst for the hydrogenation of 1-hexene in methanol.[21]

5 IONICALLY IMMOBILIZED ORGANOTRANSITION METAL COMPLEXES

Many inorganic and organic materials have an ion-exchange capacity. Zeolites and clay minerals, for example, contain exchangeable cations. These may be replaced with cationic transition metal complexes, which may be used directly as catalysts or used synthetically for the in situ preparation of a supported complex. Organic resins are available, which have either a cation or anion-exchange capacity. The cation-exchange resins typically have bound sulfonate groups, while anion-exchange resins are based on materials with bound quaternary ammonium anions.

5.1 Clay Minerals

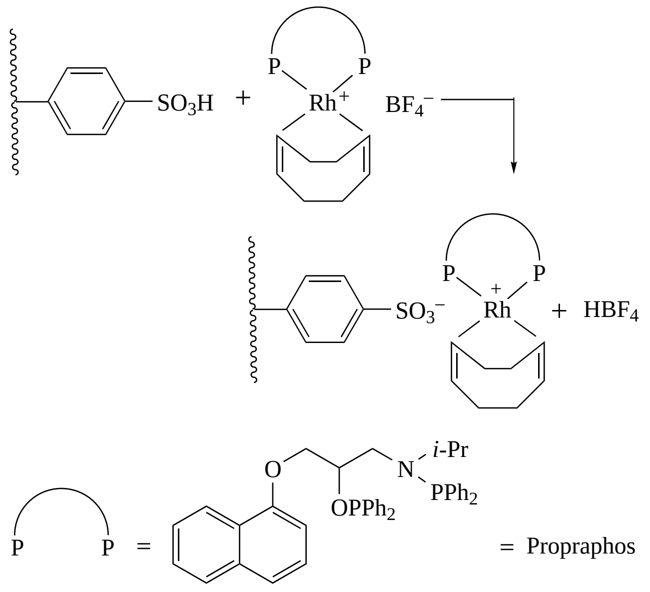
The cationic ligand $[Ph_2P(CH_2)_2PPh_2(CH_2Ph)]^+$ $(P-P^+)$ has been used to incorporate rhodium within the layers of hectorite, a layered clay mineral.[18] A 1:1:0.5 ratio of $P-P^+:PPh_3:[Rh(cod)Cl]_2$ is used to generate a hectorite-supported catalyst for the hydrogenation of 1-hexene. Similarly, prepared materials generated from $[Rh(cod)Cl]_2$, $P-P^+$, and hectorite yield catalysts suitable for the hydroformylation of 1-hexene.[60] The supported complex is thought to be $HRh(CO)_x(P-P^+)_2$.

A series of cluster complexes has been intercalated into hectorite, again with $P-P^+$ as the cationic ligand. Typical is the formation of $Ir_4(CO)_9(P-P^+)_3$ within the clay.[51] Intercalation of the clusters within the clay causes an increase in the interlayer spacing to as large as 17.5 Å.

5.2 Ion-Exchange Resins

Anionic metal complexes, for example $[Rh(CO)_2I_2]^-$, can be exchanged onto the anion-exchange resin Dowex 1-X8.[61] The supported rhodium carbonyl iodide complex functions as an immobilized methanol *Carbonylation* catalyst. Metal complexes of the water-soluble phosphine TPPTS and its monosulfonated analog have also been exchanged onto anion-exchange resins.[62] The pendant sulfonate groups provide the electrostatic attraction to the support.

Inherently cationic complexes of the type $[L_2Rh(cod)]^+$ can be directly exchanged onto sulfonated divinylbenzene–styrene resins, where L_2 is a chiral chelating phosphine; for example, $[(propraphos)Rh(cod)]^+$ can be cation exchanged according to Scheme 4.[63]



Scheme 4

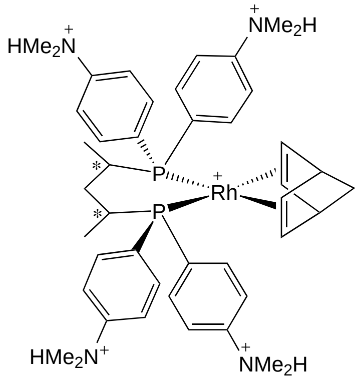


Figure 6 A cationic chiral rhodium complex with NMe_2 groups added to the BDPP ligand. The amine groups can be protonated to give a complex with a net charge of 5+. The protonated complex can be supported on the acid form of a cation-exchange resin

Additional cationic functionality can be added to this class of complexes via pendant quaternary amine groups on the phenyl groups of the phosphine. Typical is the $BDPP(–NMe_2H)_4$ ligand and its rhodium complex shown in Figure 6. This complex can be immobilized by reaction of the basic form of the compound with the acid form of a cation-exchange resin, for example, Nafion-H.[64] The net 5+ charge on the complex ensures strong binding to the resin. The immobilized chiral rhodium compounds are effective for the asymmetric hydrogenation of cinnamic acid derivatives.[63,64]

Glossary

Adsorbate: an atom, molecule, or molecular fragment held at a surface by attractive forces
Chemisorption: the process of adsorption on to a surface through the formation of a chemical bond; for molecules the process can be dissociative
Physisorption: the process of adsorption on to a surface induced by van der Waals or electrostatic forces between an adsorbate and the surface
Work function: the energy required to remove one electron from the highest filled energy level to a point of zero kinetic energy in a vacuum

1 INTRODUCTION

Surfaces can be broadly described as the boundary between a condensed phase (solid, liquid) of matter and another material (solid, gas, or liquid). Surfaces are encountered in most aspects of life, from the contact of a car's wheel with the pavement (solid–solid interface) to the evaporation of a water droplet (liquid–gas interface). Equally as important, surfaces play a fundamental role in many chemical processes including catalysis, thin film coatings, and electrochemical oxidation and reduction.

In the realm of chemical processes, surfaces are encountered in a number of forms and environments. Catalytic processes involve the reaction of liquids or gases at the surface of finely divided metal or metal oxide particles. Electrochemical reactions occur at the interface of a metal electrode and a solution. Many coating technologies involve the deposition of a compound from the gas phase on to a solid substrate. Zeolites are microporous aluminum silicates displaying enormous reactivity and selectivity based upon the structure and volume of their internal surfaces. The oxidation of metals involves diffusion and reaction of oxygen with a surface of changing composition.

In all of these systems, certain aspects of the reactions can be uniquely related to the properties of a surface. Surface properties may include those representative of the bulk material, ones unique to the interface because of the abrupt change in density of the material, or properties arising from the two-dimensional nature of the surface. In this article, the structural, thermodynamic, electrical, optical, and dynamic properties of solid surfaces are discussed in instances where properties are different from those of the bulk material. Predominantly, this discussion focuses on metal surfaces and their interaction with gas-phase atoms and molecules. The majority of fundamental knowledge of molecular-level surface properties has been derived from such low surface area systems. The solid–gas interface of high surface area materials has received much attention in the context of separation science, however, will not be discussed in detail here. The solid–liquid interface has primarily been treated from an electrochemical perspective and is discussed elsewhere (*see* ***Electrochemistry: Applications in Inorganic Chemistry***). The surface properties of liquids (liquid–gas interface) are largely unexplored on the molecular level; experimental techniques for their study have begun only recently to be developed. The information presented here is a summary of concepts; a more complete description can be found in one of several texts which discuss surface properties in more detail.[1–4]

2 TECHNIQUES FOR SURFACE STUDIES

The study of surfaces has led to the development of an entire class of experimental techniques capable of deriving information that is specific to the properties of the surface. Much of the effort in such experiments entails distinguishing surface signals from bulk phase signals or achieving the sensitivity to signals arising from the relatively few number of surface species (10^{15} atoms cm^{-2}) as compared to the bulk (10^{22} atoms cm^{-3}). The important parameters in doing so vary from one technique to another; however, several practices have been adopted in the effort to understand surface properties. One practice is the use of single crystal material in surface science studies.

2.1 Single Crystals

While 'real-world' surfaces can be far removed from that of an ideal single crystal, studying single crystal surfaces provides an ordered array of atoms of specific coordination and

geometry, greatly reducing the number of possible interactions (see Section 3). The number of surface sites or atoms can be estimated from the bulk density. Most materials have densities on the order of one gram cm^{-3}. This value is equivalent to a molecular density (ρ) of 10^{22} atoms cm^{-3}. The concentration of atoms exposed to the surface is proportional to $\rho^{2/3}$, assuming a cube-like packing, and thus is on the order of 10^{15} atoms cm^{-3}. For the study of a surface or chemical reactions on a surface, this value establishes a limit to the number of species probed in an experiment. While much of the information discussed in this article focuses on information derived from single crystal studies, many of the techniques discussed here can also be applied to noncrystalline samples. This, however, complicates the interpretation of the findings and at times prevents a structurally specific understanding of the surface and its properties.

2.2 Vacuum Environment

Another practice common to many modern surface science studies is performing experiments in an ultrahigh vacuum ($<10^{-9}$ Torr) environment. The development of vacuum technology came largely as a result of space exploration research in the United States during the 1950s. From that time and initial knowledge base, the surface science community has developed a repertoire of techniques for preparing and handling samples in a vacuum environment. The advantages of working in a vacuum environment are mainly two-fold: (1) providing an appropriate environment for the use of electron- and ion-based spectroscopies; and (2) preparing and maintaining a clean surface. Many surface analytical techniques make use of electrons and ions incident on the surface which requires a mean free path of at least 10 cm. A vacuum of less than 10^{-3} Torr must be achieved to fulfill this condition.

Although a surface in an ambient environment may appear clean, in reality the surface is covered with a layer or layers of adsorbed species. These species may be either physically or chemically adsorbed to the surface, but in both instances prevent the study of a truly clean surface. Under a vacuum environment, such surface contaminants can be removed into the gas phase by sputtering the surface with energetic ions. Once the surface contaminants have been removed, ultrahigh vacuum conditions are required to keep the sample clean. For example, at a pressure of 1×10^{-6} Torr, a sample receives a flux of approximately 5×10^{14} molecules s^{-1} cm^{-2}. Assuming a surface density of 10^{15} atoms cm^{-2} and a sticking probability of 1 for the adsorption of the gas phase species, the sample would be covered by one monolayer of adsorbed species in seconds. Conversely, by working at pressures below 1×10^{-9} Torr, a sample can be easily maintained free of contaminants for times on the order of hours, the time frame required for most surface science experiments.

2.3 Overview of Techniques

A complete description of the numerous techniques that have been developed for the study of surfaces is beyond the scope of this article; however, several generalizations can be made about the approach of modern surface science techniques. The basic premise of studying surfaces involves probing species on a well-characterized surface with a species of known energy. Photons, electrons, atoms, or molecules can be scattered after undergoing collisions or reactions on the surface or producing secondary photons, electrons, atoms, or molecules. The outgoing product is then energy or mass analyzed for information regarding the interaction at the surface. The possible combinations of excitation sources and emitted 'particles' are numerous; however, the majority of these techniques provide some information concerning three fundamental properties of interfacial species: (1) the relative location of adsorbate and surface atoms, (2) the electronic character of both solid and adsorbate, and (3) the nature of the chemical bonding at the interface. Many techniques provide complementary information and it is rare when only one technique is capable of providing a complete picture of the interface. Thus these high vacuum techniques used together comprise modern surface chemical analysis. A listing of the majority of these techniques and the information gained from them is given in Table 1.[5] References to many of these techniques will be made in the description of surface properties that follow.

3 SURFACE STRUCTURE

3.1 Structure Determination

While many materials may appear flat or highly reflective, and thus ordered to the human eye, the surfaces of most 'real' materials are rough or disordered on the atomic scale. Therefore the determination of surface structure generally implies studying crystalline materials where the surface can be described in terms of the structure of the underlying solid. By definition, a surface represents the termination of the bulk structure. Therefore the simplest case of surface structure is where atoms exist in bulk-like positions, however with lower coordination. The picture of this model of a surface is represented by a perfectly flat plane of well ordered atoms. Any deviation of the surface plane from the crystallographic plane will induce the presence of steps or kinks where the atoms have even lower coordination (Figure 1). Surface structure is of great importance in understanding interfacial reactions with gases, liquids, and other solids. A complete description of surface structure on the atomic scale involves the determination of the relative location of surface atoms (distance from nearest neighbor), number of nearest neighbors, and the nature (directionality, charge distribution, strength) of the chemical bonds between atoms.[6]

Table 1 Surface science techniques that are used frequently

Name	Acronym	Description	Primary surface information
Adsorption or selective chemisorption	Adsorption	Atoms or molecules are physisorbed and their concentration measures total surface area. Chemisorption of atom or molecules on sites yield surface concentration of selected elements or atomic sites.	Surface area site concentration and composition
Atom or helium diffraction	AD	Monoenergetic beams of thermal energy neutral atoms are elastically scattered off ordered surfaces and detected as a function of scattering angle. This gives structural information on the outermost layer of the surface. Atom diffraction is extremely sensitive to surface ordering and defects.	Atomic structure
Auger electron appearance potential spectroscopy	AEAPS	The AEAPS cross-section is monitored by Auger electron intensity. Also known as APAES.	Electronic structure
Auger electron spectroscopy	AES	Core-hole excitations are created, usually by 1–10 keV incident electrons, and Auger electrons of characteristic energies are emitted through a two-electron process as excited atoms decay to their ground state. AES gives information on the near-surface chemical composition.	Composition
Atomic force microscopy	AFM	Similar to STM. An extremely delicate mechanical probe is used to scan the topography of a surface by measuring forces exerted by surface atoms. Light interference is used to measure the deflection of the mechanical surface probe. This is designed to provide STM-type images of insulating surfaces or to detect mechanical properties at the molecular level.	Atomic structure
Appearance potential Auger electron spectroscopy	APAES	See AEAPS.	
Appearance potential X-ray photoemission spectroscopy	APXPS	The EAPFS excitation cross-section is monitored by fluorescence from core-hole decay (also known as SXAPS).	Electronic structure
Angle-resolved Auger electron spectroscopy	ARAES	Auger electrons are detected as a function of angle to provide information on the spatial distribution or environment of the excited atoms (see AES).	Composition
Angle-resolved photoemission fine structure	ARPEFS	Electrons are detected at given angles after being photoemitted by polarized synchrotron radiation. The interference in the detected photoemission intensity as a function of electron energy $\sim$100–500 eV above the excitation threshold gives structural information.	Electronic structure
Angle-resolved photoemission spectroscopy	ARPES	A general term for structure-sensitive photoemission techniques, including ARPEFS, ARXPS, ARUPS, and ARXPD.	Electronic structure
Angle-resolved ultraviolet photoemission spectroscopy	ARUPS	Electrons photoemitted from the valence and conduction bands of a surface are detected as a function of angle. This gives information on the dispersion of these bands (which is related to surface structure) and also structural information from the diffraction of the emitted electrons.	Valence band structure
Angle-resolved X-ray photoemission diffraction	ARXPD	Similar to ARXPS and ARPEFS. The angular variation in the photoemission intensity is measured at a fixed energy above the excitation threshold to provide structural information.	Electronic structure
Angle-resolved X-ray photoemission spectroscopy	ARXPS	The diffraction of electrons photoemitted from core levels gives structural information on the surface.	Electronic structure
Conversion-electron Mössbauer spectroscopy	CEMS	A surface-sensitive version of Mössbauer spectroscopy. Like Mössbauer spectroscopy, this technique is limited to some isotopes of certain metals. After a nucleus is excited by γ-ray absorption, it can undergo inverse β-decay, creating a core hole. The decay of core holes by Auger processes within an electron mean free path of the surface produces a signal. Detecting emitted electrons as a function of energy gives some depth-profile information, because of the changing electron mean free path.	Oxidation state
Disappearance potential spectroscopy	DAPS	The EAPFS cross-section is monitored by variations in the intensity of electrons elastically backscattered from the surface.	Electronic structure

(cont'd overleaf)

Table 1 cont'd

Name	Acronym	Description	Primary surface information
Electron appearance potential fine structure	EAPFS	A fine-structure technique (see EXAFS). Core holes are excited by monoenergetic electrons at ~1 eV. The modulation in the excitation cross-section may be monitored through adsorption, fluorescence or Auger emission.	Atomic structure
Electron energy-loss near-edge structure	ELNES	Similar to NEXAFS, except monoenergetic high-energy electrons of ~60–300 keV excite core holes.	Atomic structure
Electron energy loss spectroscopy	ELS	Monoenergetic electrons of ~5–50 eV are scattered off a surface and the energy losses are measured. This gives information on the electronic excitations of the surface and adsorbed molecules (see HREELS). Sometimes called EELS.	Electronic structure
Electron spectroscopy for chemical analysis	ESCA	Now generally called XPS.	Composition, cooxidation state
Electron-stimulated ion angular distribution	ESDIAD	Electrons break chemical bonds in adsorbed atoms or molecules, causing ionized atoms or radicals to be ejected from the surface along the axis of the broken bond by Coulomb repulsion. The angular distribution of these ions gives information on the bonding geometry of adsorbed molecules.	Molecular orientation
Extended X-ray adsorption fine structure	EXAFS	Monoenergetic photons excite a core hole. The modulation of the adsorption cross-section with energy 100–500 eV above the excitation threshold yields information on the radial distances to neighboring atoms. The cross-section can be monitored by fluorescence as core holes decay or by the attenuation of the transmitted photon beam. EXAFS is one of many 'fine-structure' techniques.	Local atomic structure coordination number
Extended X-ray energy-loss fine structure	EXELFS	A fine-structure technique similar to EXAFS, except that 60–300 eV electrons rather than photons excite core holes.	Atomic structure
Field ionization microscopy	FIM	A strong electric field ($\mathrm{V\,Å^{-1}}$) is created at the tip of a sharp, single-crystal wire. Gas atoms, usually He, are polarized and attracted to the tip by the strong electrostatic field, and then ionized by electrons tunneling from the gas atoms into the tip. These ions, accelerated along radial trajectories by Coulomb repulsion, map out the variations in the electric field strength across the surface with atomic resolution, showing the surface topography.	Atomic structure and surface diffusion
Fourier-transform infrared spectroscopy	FTIR	Broad-band IRAS experiments are performed and the IR adsorption spectrum is deconvoluted by using a Doppler-shifted source and the Fourier analysis of the data. This technique is not restricted to surfaces.	Molecular structure
High-energy ion scattering	HEIS	High-energy ions, above ~500 keV, are scattered off of a single-crystal surface. The 'channeling' and 'blocking' of scattered ions within the crystal can be used to triangulate deviations from the bulk structure. HEIS has been especially used to study surface reconstructions and the thermal vibrations of surface atoms. (See also MEIS and ISS.)	Atomic structure
High-resolution electron energy-loss spectroscopy	HREELS	A monoenergetic electron beam, usually ~2–10 eV, is scattered off a surface, and energy losses below ~0.5 eV to bulk and surface phonons and vibrational excitations of adsorbates are measured as a function of angle and energy (also called EELS).	Molecular structure
Ion neutralization spectroscopy	INS	Slow-ionized atoms, typically He^+, are incident on a surface where they are neutralized in a two-electron process that can eject a surface electron, a process similar to Auger emission from the valence band. The ejected electrons are detected as a function of energy, and the surface density of states can be determined from the energy distribution. The interpretation of the data is more complicated than for SPI or UPS.	Valence band
Infrared reflection adsorption spectroscopy	IRAS	Monoenergetic IR photons are reflected off a surface and the attenuation of the IR intensity is measured as a function of frequency. This yields a spectrum of the vibrational excitations of adsorbed molecules. Recent improvements in the sensitivity of this technique allow IRAS measurements to be made on single-crystal surfaces.	Molecular structure

Table 1 cont'd

Name	Acronym	Description	Primary surface information
Infrared emission spectroscopy	IRES	The vibrational modes of adsorbed molecules on a surface are studied by detecting the spontaneous emission of infrared radiation from thermally excited vibrational modes as a function of energy.	Molecular structure
Ion scattering spectroscopy	ISS	Ions are inelastically scattered from a surface and the chemical composition of the surface is determined from the momentum transfer to surface atoms. The energy range is ∼1 keV to 10 MeV, and the lower energies are more surface sensitive. At higher energies this technique is also known as Rutherford backscattering (RBS).	Composition
Low-energy electron diffraction	LEED	Monoenergetic electrons below ∼500 eV are elastically backscattered from a surface and detected as a function of energy and angle. This gives information on the structure of the near-surface region.	Atomic structure and molecular structure
Low-energy ion scattering	LEIS	Low-energy ions, below ∼5 eV, are scattered from a surface and the ion 'shadowing' gives information on surface structure. At these low energies the surface-atom ion scattering cross-section is very large, resulting in large surface sensitivity. Accuracy is limited because the low-energy ion scattering cross-sections are not well known.	Atomic structure
Low-energy positron diffraction	LEPD	Similar to LEED with positrons as the incident particles. The interaction potential for positrons is somewhat different than for electrons, so the form of the structural information is modified.	Atomic structure
Medium-energy electron diffraction	MEED	Similar to LEED, except the energy range is higher (∼300–1000 eV).	Atomic structure
Medium-energy ion scattering	MEIS	Similar to HEIS, except that incident ion energies are ∼50–500 keV.	Atomic structure
Neutron diffraction	ND	Neutron diffraction is not an explicitly surface-sensitive technique, but neutron diffraction experiments on large-surface-area samples have provided important structural information on adsorbed molecules and also on surface phase transitions.	Molecular structure
Near-edge X-ray adsorption fine structure	NEXAFS	A core hole is excited as in fine structure techniques (see EXAFS), except the fine structure within ∼30 eV of the excitation threshold is measured. Multiple scattering is much stronger at low electron energies, so this technique is sensitive to the local three-dimensional geometry, not just the radial separation between the source atom and its neighbors. The excitation cross-section may be monitored by detecting the photoemitted electrons or the Auger electrons emitted during the core-hole decay.	Atomic structure
Nuclear magnetic resonance	NMR	NMR is not an explicitly surface-sensitive technique, but NMR data on large-surface-area samples ($\geq$1 m^2) have provided useful data on molecular adsorption geometries. The nucleus magnetic moment interacts with an externally applied magnetic field and provides spectra that are highly dependent on the nuclear environment of the sample. The signal intensity is directly proportional to the concentration of the active species. This method is limited to the analysis of magnetically active nuclei.	Molecular structure
Normal photoelectron diffraction	NPD	Similar to ARPEFS with a somewhat lower energy range.	Atomic structure
Rutherford backscattering	RBS	Similar to ISS, except the main focus is on depth profiling and composition. The momentum transfer in backscattering collisions between nuclei is used to identify the nuclear masses in the sample, and the smaller, gradual momentum loss of the incident nucleus through electron–nucleus interactions provides depth-profile information.	Composition
Reflection high-energy electron diffraction	RHEED	Monoenergetic electrons of ∼1–20 keV are elastically scattered from a surface at glancing incidence and detected as a function of angle and energy for small forward-scattering angles. Back-scattering is less important at high energies and glancing incidence is used to enhance surface sensitivity.	Atomic structure
Surface electron energy-loss fine structure	SELFS	A fine-structure technique similar to EXELFS, except the incident electron is more surface sensitive because of the lower excitation energy.	Atomic structure

(cont'd overleaf)

Table 1 cont'd

Name	Acronym	Description	Primary surface information
Surface-enhanced Raman spectroscopy	SERS	Some surface geometries (rough surfaces) concentrate the electric fields of Raman scattering cross-section so that it is surface sensitive. This gives information on surface vibrational modes and some information on geometry via selection rules.	Molecular structure
Surface-extended X-ray adsorption fine structure	SEXAFS	A more surface-sensitive version of EXAFS, where the excitation cross-section fine structure is monitored by detecting the photoemitted electrons (PE-SEXAFS), Auger electrons emitted during core-hole decay (Auger−SEXAFS) or ions excited by photoelectrons and desorbed from the surface (PSD−SEXAFS).	Atomic structure
Sum frequency generation	SFG	Similar to SHG. One of the lasers has a tuneable frequency that permits variation of the second-harmonic signal. In this way the vibrational excitation of adsorbed molecules is achieved.	Molecular structure
Second-harmonic generation	SHG	A surface is illuminated with a high-intensity laser and photons are generated at the second-harmonic frequency through a nonlinear optical process. For many materials, only the surface region has the appropriate symmetry to produce an SHG signal. The nonlinear polarizability tensor depends on the nature and geometry of adsorbed atoms and molecules.	Electronic structure and molecular orientation
Secondary ion mass spectroscopy	SIMS	Ions and ionized clusters ejected from a surface during ion bombardment are detected with a mass spectrometer. Surface chemical composition and some information on bonding can be extracted from SIMS ion fragment distributions.	Composition
Surface penning ionization	SPI	Neutral atoms, usually He, in excited states are incident on a surface at thermal energies. A surface electron may tunnel into the unoccupied electronic level, causing the incident atom to become ionized and eject an electron, which is then detected. This technique measures the density of states near the Fermi level and is highly surface sensitive.	Electronic structure
Spin-polarized low-energy electron diffraction	SPLEED	Similar to LEED, except the incident electron beam is spin-polarized. This is particularly useful for the study of surface magnetism and magnetic ordering.	Magnetic structure
Scanning tunneling microscopy	STM	The topography of a surface is measured by mechanically scanning a probe over a surface with angstrom resolution. The distance from the probe to the surface is measured by the probe-surface tunneling current. Also known as scanning electron tunneling microscopy (SETM).	Atomic structure
Soft X-ray appearance potential spectroscopy	SXAPS	Another name for APXPS.	
Transmission electron microscopy	TEM	TEM can provide surface information for carefully prepared and oriented bulk samples. Real images have been formed of the edges of crystals where surface planes and surface diffusions have been observed. Diffraction patterns of reconstructed surfaces, superimposed on the bulk diffraction pattern, have also provided surface structural information.	Atomic structure
Thermal desorption spectroscopy	TDS	An adsorbate-covered surface is heated, usually at a linear rate, and the desorbing atoms or molecules are detected with a mass spectrometer. This gives information on the nature of the adsorbate species and some information on adsorption energies and the surface structure.	Composition, heat of adsorption and surface structure
Temperature-programmed desorption	TPD	Similar to TDS, except the surface may be heated at a nonuniform rate to obtain more selective information on adsorption energies.	Composition and heat of adsorption
Ultraviolet photoemission spectroscopy	UPS	Electrons photoemitted from the valence and conduction bands are detected as a function of energy to measure the electronic density of states near the surface. This gives information on the bonding of adsorbates to the surface (see ARUPS).	Valence band structure
Work-function measurements	WF	Changes in the work function during the adsorption of atoms and molecules provide information on charge-transfer and chemical bonding.	Electronic structure
X-ray adsorption near-edge structure	XANES	Another name for NEXAFS.	

Table 1 cont'd

Name	Acronym	Description	Primary surface information
X-ray photoemission spectroscopy	XPS	Electrons photoemitted from atomic core levels are detected as a function of energy. The shifts of core-level energies give information on the chemical environment of the atoms (see ARXPS, ARXPD).	Composition and oxidation state
X-ray diffraction	XRD	X-ray diffraction has been carried out at extreme glancing angles of incidence where total reflection assures surface sensitivity. This provides structural information that can be interpreted by well-known methods. An extremely high X-ray flux is required to obtain useful data from single-crystal surfaces. Bulk X-ray diffraction is used to determine the structure of organometallic clusters, which provide comparisons to molecules adsorbed on surfaces. X-ray diffraction has also given structural information on large-surface-area samples.	Atomic structure

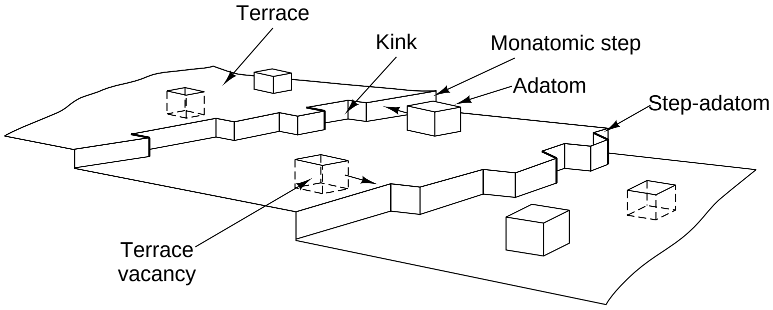

Figure 1 Model of a heterogeneous solid surface depicting different surface sites

The technique of low energy electron diffraction (LEED) has been the most widely used tool in the study of surface structure. LEED experiments involve the scattering of monoenergetic and collimated electrons from a crystal surface and detection of elastically diffracted electrons in a backscattering geometry (Figure 2). The characteristic diffraction pattern in LEED arises from constructive interference of electrons when scattered from ordered atomic positions. The diffraction pattern represents a reciprocal map of surface periodicities and allows access to surface unit cell size and orientation. Changes in the diffraction pattern from that of a clean surface can be indicative of surface reconstruction or adsorbed overlayers.

A LEED crystallography study to determine exact atomic geometries requires fitting spot intensities to theoretical calculations for a series of electron energies. Information about the internal structure of the unit cell may be gained by monitoring the intensity of diffraction spots as a function of incident energy. The analysis of such intensity versus voltage ($I-V$) curves can reveal the local structure of surface atoms or adsorbed molecules as well as the structure of subsurface layers. Analysis is carried out by comparison to curves generated by a theoretical treatment of the diffraction process. With the presence of multiple scattering events, this is a computationally complex task. The most recent advances in LEED theory include the use of automated search routines using linear expansions of structural parameters to solve for surface structures (tensor LEED).[7] An additional degree of complexity exists in both experiment and theory if a surface is disordered. In this case, intensity versus energy spectra are recorded by scanning the diffuse intensity at a constant reciprocal lattice position. Structural determination of a disordered layer involves the simulation of large unit cells and comparison to extensive experimental data sets.

Field ion microscopy (FIM) has also been used to study the surface structure of metals and metal–adsorbate systems. The experimental setup of FIM involves etching a very fine wire to a sharp tip with a radius of curvature of the order of nanometers. The tip is held in a vacuum at a high potential in the presence of a partial pressure of helium. As the helium atoms come into contact with the surface, they are ionized and then accelerated away from the tip by the large local electric field. The ions are detected on a phosphor screen creating a highly magnified real-space image of the tip. FIM has also been used to study the surface structure properties relating to thermal disordering, adsorbate overlayer structure, and atomic surface diffusion.

Recently, surface structure studies have been aided by the development of scanning tunneling microscopy (STM) and atomic force microscopy (AFM).[8] In STM, a very sharp metallic tip is brought into close proximity of a conducting sample through the use of piezoelectric scanners (Figure 3).

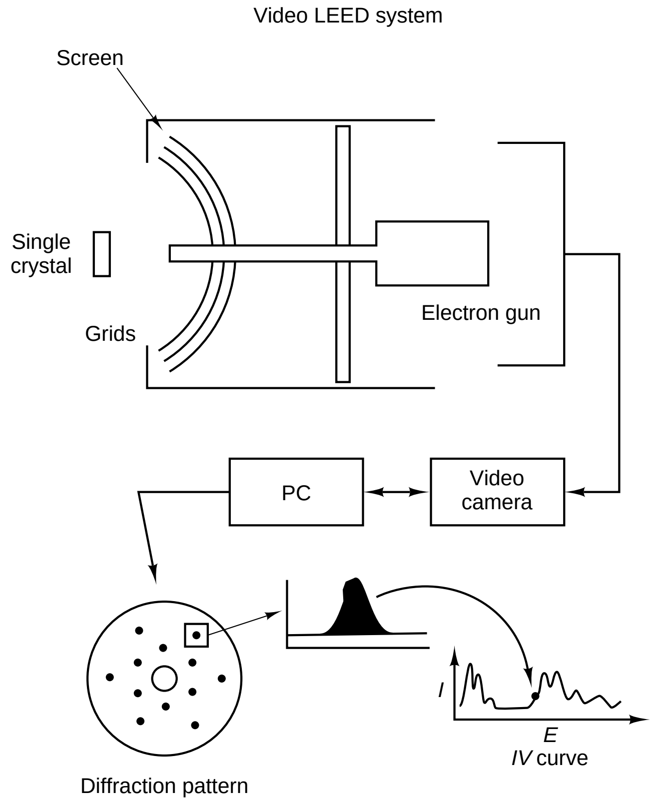

Figure 2 Schematic diagram of a video LEED system used to generate intensity versus voltage curves of electrons diffracted from ordered surfaces. The $I-V$ curves are compared to theory in solving a surface structure

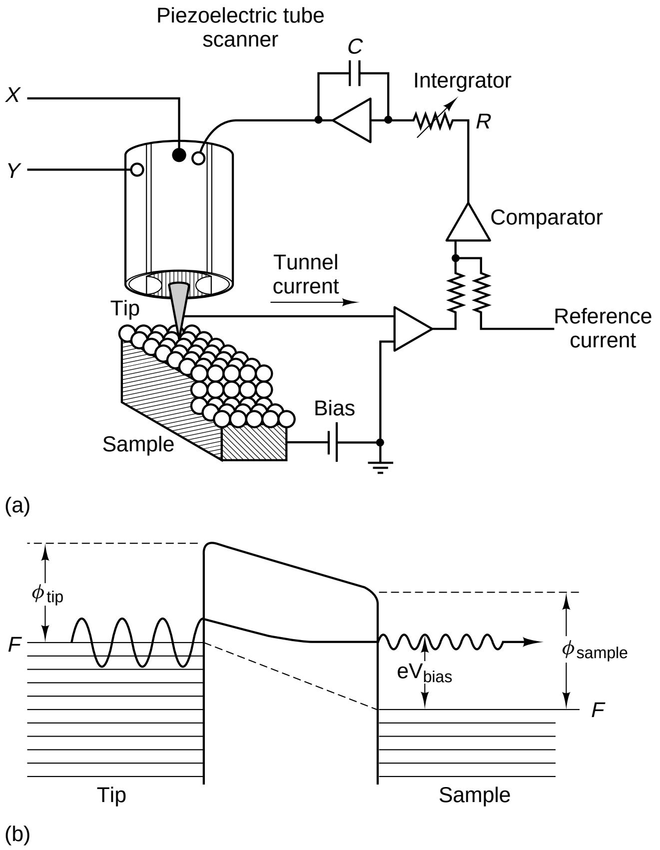

Figure 3 (a) Scanning tunneling microscope depicting tip and piezoelectric scanner. (b) With the tip in close proximity to the surface, tunneling between tip and surface electronic states can occur

Under certain biasing conditions, electrons are found to tunnel from the tip to the sample (or vice versa) across a potential barrier. By detecting the tunneling current as the tip is rastered across the surface, a real-space two-dimensional map of the surface is generated. Alternatively, the tunneling current can be held constant as the tip is rastered over the sample by fixing the tip to sample distance. In turn, variations in the voltage signal to the piezo scanner holding the tip sample distance constant is used to generate a topographic image of the surface. While such maps show symmetries and corrugations of atomic dimensions, the interpretation of regions of high and low tunneling current is dependent on the knowledge of the local density of states which is not fully understood at this time.

The AFM operates in an analogous fashion. A sharp tip mounted on a weak cantilever is rastered across the sample. Light interference or reflection is used to measure the deflection of the cantilever. The light signal measured as a function of sample location is used to generate a map of the surface topography. Because mechanical forces are responsible for the deflection of the probe arm, conductors as well as insulators can be studied.[9,10] STM and AFM provide local real space images of the surface and are thus complimentary to the information gained from LEED studies. In addition, both have the advantage of being able to work under a range of environmental conditions including liquid and ambient atmospheres.

Other techniques used in surface structure determination include extended X-ray absorption fine structure (EXAFS), ion scattering, electron forward focusing, and helium atom diffraction.

3.2 Surface Structure at the Solid–Vacuum Interface

A complete discussion of surface structure includes the use of a shorthand notation describing the location of surface atoms. This abbreviated representation of the surface is based upon a projection of the bulk structure on to the surface plane. From this projection the surface structure is described in terms of the unit cell vectors of the bulk material (***a, b***):

$$\boldsymbol{a}' = m_{11}\boldsymbol{a} + m_{12}\boldsymbol{b} \tag{1}$$

$$\boldsymbol{b}' = m_{21}\boldsymbol{a} + m_{22}\boldsymbol{b} \tag{2}$$

The surface and bulk unit cell vectors represent the periodicity which allows a translation operation to generate an infinite array of atoms in the surface or bulk structure. The coefficients m_{11}, m_{12}, m_{21}, and m_{22} define a matrix which describes the transformation of the bulk unit vectors into the surface unit vectors. For example, the simplest surface structure occurs when the surface maintains the same unit cell as the bulk. In this case the unit cell matrix would be

$$\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \tag{3}$$

and is abbreviated as (1 × 1). Thus the surface notation of a silver surface of (111) orientation [the surface plane is defined by the Miller indices (*hkl*)[11]] with a surface unit cell identical to that of the bulk would be written as Ag(111)-(1 × 1). This and other unit cells of a fcc (111) surface of larger periodicity are shown in Figure 4. When the surface unit cell is rotated with respect to that of the bulk, the notation includes the angle of rotation as in $(\sqrt{3} \times \sqrt{3})R30°$. Additional changes in the surface periodicity can arise from reconstructions of the surface and the presence of adsorbed gases, as will be discussed.

Complexities in describing the surface arise when the surface is not oriented along a principal crystallographic plane. These surface are referred to as high Miller index planes and can be described in terms of a collection of terraces separated by steps, which may also have kinks in them. This type of surface structure can be written in the general form

$$w(h_t k_t l_t) \times (h_s k_s l_s) \tag{4}$$

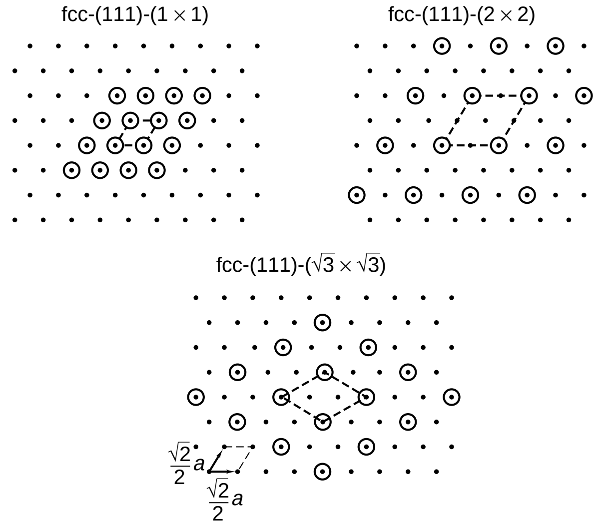

Figure 4 Commonly observed unit cells of adsorbate surface structure for a fcc (111) crystal face

where $(h_t k_t l_t)$ and $(h_s k_s l_s)$ are the respective Miller indices of the terrace and step planes and w is the width of the terrace in number of atoms. So a surface made up of terraces seven atoms wide oriented in the (111) direction separated by monoatomic steps of (310) orientation is written as $7(111) \times 1(310)$ and abbreviated as (10,8,7). This surface of platinum as well as the (111) and (755) surfaces are shown with their corresponding LEED patterns in Figure 5.

Up to this point, only the structure of surfaces in terms of the terrace step kink model has been considered. LEED

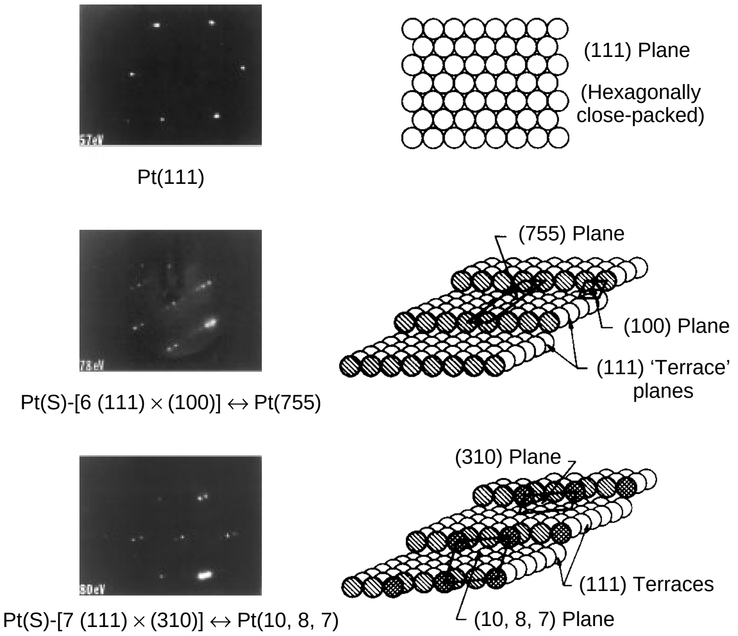

Figure 5 Surface structure of the (111), (755) and (10,8,7) crystal faces of platinum displayed with corresponding LEED images

crystallographic studies have shown that in fact surface atoms of most clean surfaces in a vacuum relax from their bulk positions.[12] These measurements typically depict the contraction of the two uppermost layers of the surface. In general, large inward contractions are observed for surfaces of lower atomic packing and density. Additional relaxations are seen to occur at steps on a surface as each atom attempts to optimize its coordination. This model of the surface represents nonrigid atom locations where motions are believed to play a significant role in much of surface chemistry.

An additional modification of the bulk structure occurs at many surfaces due to the lower coordination of surface atoms. The drastic rearrangement of surface atoms and bonding structures to compensate for the loss of nearest neighbors is referred to as surface reconstruction. While many metals display surface reconstructions, the phenomenon is most prevalent in covalently bound solids such as silicon, diamond, and gallium arsenide. At these surfaces the unsaturated dangling bonds drive a rearrangement of the surface atoms to maximize coordination, in turn affecting the bonding structure several layers into the bulk. Surface reconstruction is also observed for the polar faces of metal oxide crystals where long range electrostatic dipoles exist at the surface, terminated in only one ionic species.

3.3 Surface Structure at the Solid–Gas Interface

An additional aspect of surface structure determination involves the relationship between surface structure and reactivity. The study of adsorbates on well ordered solids constitutes much of the structural work being carried out today.[13] When an atom or molecule adsorbs on a clean substrate, its equilibrium position is determined by its interactions with the surface atoms, and its interactions with neighboring adsorbates. For physically adsorbed species, adsorbate–adsorbate interactions can equal the interaction between the adsorbate and substrate and affect the structure of the overlayer. However the adsorbate–adsorbate interactions are typically small when compared to the forces in chemical bonds formed upon adsorption and adsorbate–substrate interactions dominate in chemisorbed systems.

When considering adsorbate interactions, coverage is an important parameter affecting the structure of an adsorbed overlayer. Coverages are a measure of adsorbate surface concentration and are typically described in monolayers (ML), where one monolayer equals one adsorbed species per surface atom. Many adsorbate–metal systems exhibit a range of structures for different coverages of an adsorbate. For example, atomic oxygen forms ordered overlayers on Ni(100) at both quarter and half monolayer coverages.[14] Figure 6 presents the half monolayer structure where the appropriate surface structure notation is written as Ni(100)-$c(2 \times 2)$-O. The (2×2) unit cell refers to the location of the oxygen atoms with respect to the bulk unit cell of Ni

Ni(100)-$c(2 \times 2)$-O

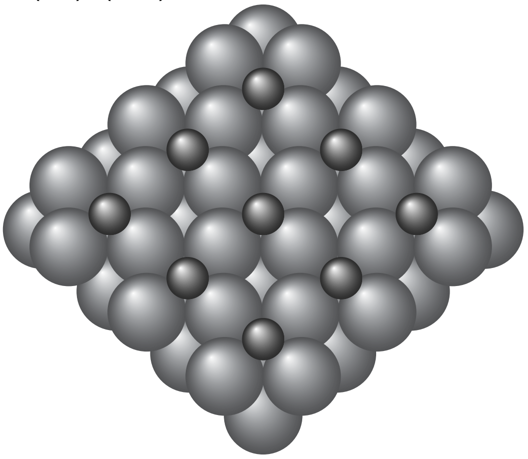

Figure 6 The half monolayer structure of atomic oxygen adsorbed on Ni(100)

(c refers to the unit cell being centered over a hollow site on the surface). For stepped surfaces where more than one adsorption site exists, coverages influence the local geometry of adsorbates as well as overlayer structure. The presence of coadsorbates and temperature can also affect the ordering and structure of adsorbed layers.

The chemisorption of atoms and molecules can also induce the restructuring of the underlying substrate. As an example, the chemical reaction of ethylene on rhodium(111) produces the chemically adsorbed species ethylidyne (C_2H_3).[15] The ethylidyne species are bound in threefold hollow sites as depicted in Figure 7. LEED structure calculations have found that the three neighboring Rh atoms expand outward from the ethylidyne forcing the nearest neighbor Rh atoms into the surface. Thus the adsorption of ethylidyne induces a corrugation in the rhodium surface. Such adsorbate-induced reconstructions are believed to be closely related to the catalytic activity of many metal surfaces.

4 THERMODYNAMIC PROPERTIES OF SURFACES

4.1 Surface Thermodynamic Parameters

As revealed by structure studies, the environment of surface atoms differs markedly from atoms in the bulk. They have fewer nearest neighbors and consequently different bonding configurations. As a result, net forces beyond those found in the bulk are exerted on the surface atoms. The existence of these forces is the basis of the thermodynamic properties of a surface. These properties can be defined separately from bulk thermodynamic parameters in the following way. The energy specific to a surface, E^S, is related to the total energy of the

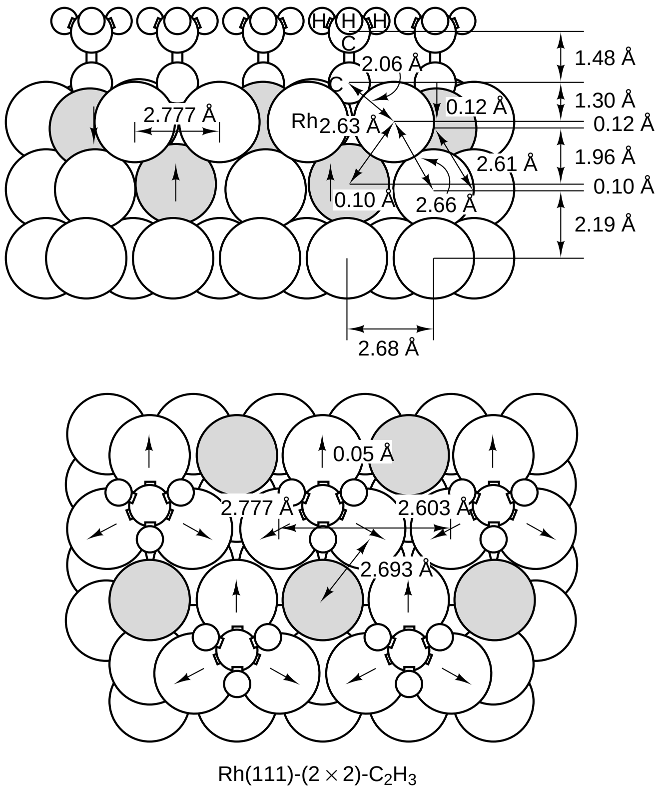

Figure 7 Surface structure of ethylidyne adsorbed on Rh(111) solved by LEED analysis. Arrows represent directions of surface reconstruction from bulk positions

system, E, by

$$E = NE^0 + AE^{\mathrm{S}} \tag{5}$$

where A is the surface area of a solid of N atoms and E^0 is the bulk energy per atom. Thus the specific surface energy, E^{S}, can be viewed as the energy excess over that of the bulk energy.

Likewise, other thermodynamic properties of the surface can be defined separately from the bulk properties. The specific free energy of the surface, G^{S}, is given by

$$G^{\mathrm{s}} = H^{\mathrm{s}} + TS^{\mathrm{s}} \tag{6}$$

where H^{S} and S^{S} are the respective surface enthalpies and entropies. The surface free energy is an important thermodynamic parameter related to the formation of a surface, which in turn describes many of the phenomena occurring at surfaces. The work required to create a surface arises from the energy involved in breaking bonds and removing nearest neighbors. The surface work, W^{S}, required to increase the surface area A by dA at constant temperature and pressure is given by

$$\partial W^{\mathrm{S}}_{T,P} = G^{\mathrm{S}}\,\mathrm{d}A \tag{7}$$

where G^{S} is assumed to be independent of surface area and dA is the change in surface area. In a one-component system, the surface free energy is equal to the surface tension, γ, and therefore

$$\gamma = G^{\mathrm{s}} = \left(\frac{\partial G}{\partial A}\right)_{T,P} \tag{8}$$

The surface tension can be viewed as the two-dimensional analog of pressure opposing the creation of a fresh surface. Since work is required to increase the surface area and thus increase the total energy of the system, the free energy of formation of a surface is always positive. The reluctance of a solid to form a new surface defines many of the phenomena associated with surfaces.

4.2 Surface Phenomena Based on Thermodynamics

From equation (8) it can be seen that solids and liquids will form equilibrium shapes in an effort to minimize their surface area and thus the free energy of the system. Indeed, crystal faces with the closest packing of surface atoms have the lowest surface area and tend to be the most stable. When one considers a two-component system, with one material on top of the other, the interaction between the two will be defined by the surface tensions. The surface tensions of some selected solids and liquids are listed in Table 2.[16–18] From these values, it can be easily predicted which materials will be capable of wetting another. In general, most liquids have lower surface tensions than clean solids and will therefore spread to cover them.

In instances where complete wetting does not occur, there will be an interface between the solid, liquid, and gas phase at the point where the solid is not covered. This situation is represented in Figure 8. The contact angle θ, typically measured by visual inspection under low magnification, is used for a quantitative measurement of wetting ability.[4] For contact angles approaching zero, liquids readily wet and cover the surface. For higher contact angles, equilibrium shapes of

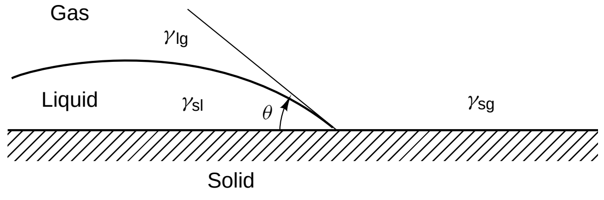

Figure 8 The contact angle between a solid and a liquid arises from differences in surface tensions and is used for a quantitative measurement of wetting ability

Table 2 Surface tension (γ) of selected solids and liquids

Material	γ (10^{-7} J cm^{-2})	Temp. (°C)
W (solid)	2900	1727

Bromine	41.5	20
Acetic acid	27.8	20
Benzaldehyde	15.5	20
Nitrobenzene	25.2	20

the liquid are formed on the surface. These shapes and the contact angle arise from the interaction of the surface tensions of the solid and liquid. Recalling that the surface tension is the two-dimensional pressure exerted along the surface, the surface free energy balance where solid and liquid are acting to minimize their surface respective surface areas, is given by

$$\cos\theta = \frac{(\gamma_{sg} - \gamma_{sl})}{\gamma_{lg}} \tag{9}$$

Here γ_{lg} is the interfacial tension at the liquid–gas interface and γ_{sg} and γ_{sl} are the interfacial tensions at the solid–gas and solid–liquid interfaces, respectively. Thus, by measuring the contact angle and liquid surface tension, γ_{lg}, the difference in the interfacial tensions ($\gamma_{sg} - \gamma_{sl}$) can be determined.

Knowledge of interfacial tensions is important in the practical problems of lubrication and adhesion. Successful lubrication occurs for a system where a lubricant completely wets a solid and maintains complete coverage under tribological conditions. The degree of adhesion of a lubricant to a solid or the strength of an adhesive can be determined by the extent to which the free energy of the system is lowered by the adsorption of the lubricant or adhesive. The energy necessary to separate the solid–liquid interface (in vacuum) is called the work of adhesion, W_A^S, and is given by

$$W_A^S = \gamma_{lo} - \gamma_{so} + \gamma_{sl} \tag{10}$$

where γ_{so} and γ_{lo} are the respective surface tension of the solid and liquid in vacuum.

A similar surface tension treatment can be made for the interface between metal oxides and metals. Native oxides typically have lower surface free energies than the bare metal, in turn driving the surface oxidation of most metals. However it is not true that all oxides have lower surface tensions than all metals or semiconductors. For the case of growth of a metal oxide film on a dissimilar metal, or a metal on a supporting metal oxide substrate, the initial phases of growth are determined by the respective surface tensions.[19] These are described by the Young–Dupré equation

$$\gamma_{MO} = \gamma_O - \gamma_M \cos\theta \tag{11}$$

where γ_{MO} is the interfacial tension between the metal and oxide, γ_O and γ_M are the respective surface tensions of the oxide and metal, and θ is the contact angle as described before. For the case of solid–solid interactions, registry, epitaxial orientation, and the possibility of interfacial reactions must be taken into account for a full treatment. The nucleation and growth properties of metals and metal oxides are critical parameters in many semiconductor and catalysis processing procedures. AES, SIMS, ISS, and various electron microscopies have been used extensively in the study of these problems.

Surface tensions can also be used to predict the behavior of multicomponent solid systems. Unlike single-component systems, the surface tension is no longer equal to the surface free energy G^S, but is related to the different component concentrations at the surface by the Gibbs equation:

$$d\gamma = -S^S\, dT - \sum \Gamma_i\, d\mu_i \tag{12}$$

Here Γ_i is the excess number of moles of compound i at the surface and μ_i is the chemical potential of the ith component. For an ideal binary solution at constant temperature, the surface composition of the solution can be estimated from the surface tensions of the two components by the equation

$$\frac{X_S^1}{X_S^2} = \frac{X_B^1}{X_B^2} \exp\left[\frac{(\gamma_2 - \gamma_1)a}{RT}\right] \tag{13}$$

In this formula, X_S^i and X_B^i refer to the respective atom fractions of the ith component at the surface and in the bulk, and a is the surface area occupied by the atoms. From this equation it can be seen that the component with the lowest surface tension will accumulate at the surface. Calculations of the segregation of silver to the surface of a Au–Ag alloy after those of William and Nason[20] are shown in Figure 9

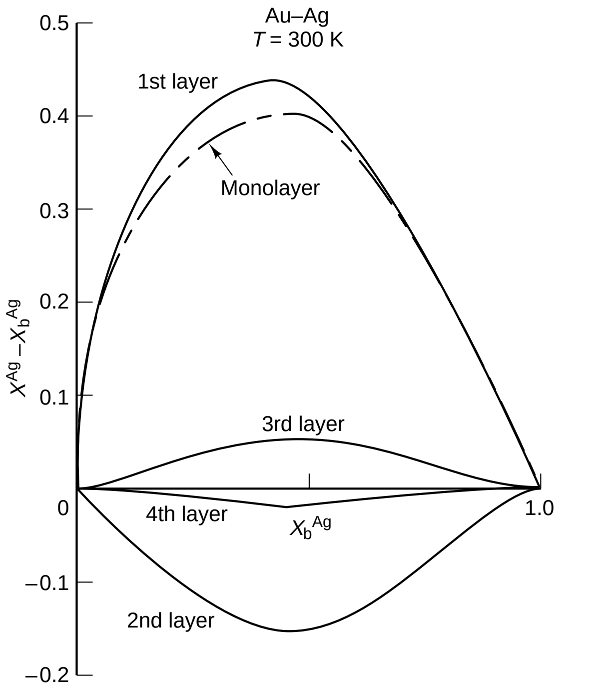

Figure 9 Preferential segregation of silver occurs at the surface of a Ag–Au alloy due to its lower surface tension

and readily demonstrate this phenomenon. The difference in surface and bulk concentrations of silver is plotted against the bulk concentration and shows a surface enrichment of silver for all compositions. A complete treatment of nonideal solutions such as the Au–Ag alloy must take into account differences in atomic diameters and the heat of mixing of the solution; however, equation (13) predicts quite well the behavior of most binary alloys. The temperature dependence of surface segregation is also predicted by equation (13), indicating a decrease in segregation with increasing temperature.

4.3 Physical and Chemical Adsorption

The thermodynamics of gas-phase species adsorbing on a surface can be separated into the classes of physical adsorption (physisorption) and chemical adsorption (chemisorption). The difference between the two classes of adsorption is related to the heat of adsorption, ΔH_{ads}. In physisorption, weak attractive forces (van der Waals) such as dipole–dipole and induced dipole interactions drive the adsorption of species from the gas phase. For chemisorbed systems, chemical bonds associated with electron transfer between adsorbate and substrate are formed upon adsorption. Each of these interactions can be described by a two-dimensional potential-energy diagram as in Figures 10 and 11.

For the case of physisorption, an incoming molecule of kinetic energy E_k can lose energy by exciting lattice phonons of the substrate. The physisorbed molecule exists in

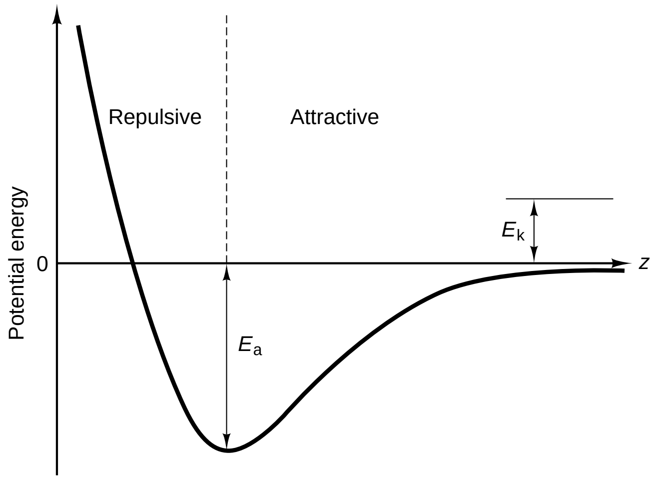

Figure 10 Potential energy diagram for the case of physisorption where adsorbates experience weak attractive forces near the surface

a potential-energy well representative of an oscillating position of equilibrium near the surface (Figure 10). The depth of this well is equal to the binding energy E_a of the molecule to the surface. For physisorbed systems, the binding energy is equal to the heat of adsorption. For a molecule to leave the surface, it must overcome the potential-energy barrier E_a; the desorption energy E_d is, therefore, also equal to E_a.

For chemisorption, molecules similarly become bound in a weakly adsorbed state near the surface as, depicted in Figure 11(a). (For atomic species, adsorption directly into the chemisorbed state is possible.) While in this precursor state, internal vibrational or electronic excitations can provide the energy necessary to cross the potential-energy barrier to the chemisorbed state. The deep potential-energy well is associated with the strong chemical bond formed between adsorbate and substrate. Again the depth of the well is associated with the energy of adsorption and equal to the heat of adsorption. In the rare case of activated chemisorption (Figure 11(b)) the heat of adsorption is equal to the difference between the desorption energy, E_d, and the activation energy of adsorption.

Heats of adsorption can be experimentally measured by calorimetry, temperature programmed desorption (TPD), and adsorption isotherms taken at different temperatures. Calorimetry involves the direct measurement of temperature rise caused by the adsorption of a known amount of gas on to a well-characterized surface. TPD is the most common method of determining the heats of adsorption. In this procedure, molecules are adsorbed on to a clean well-characterized substrate at a fixed temperature. The sample is then heated in a linear fashion while the pressure of the desorbing species is monitored with a mass spectrometer. The desorption rate $F(t)$ is given by

$$F(t) = \nu f(\sigma) \exp\left(-\frac{E_d}{RT}\right) \tag{14}$$

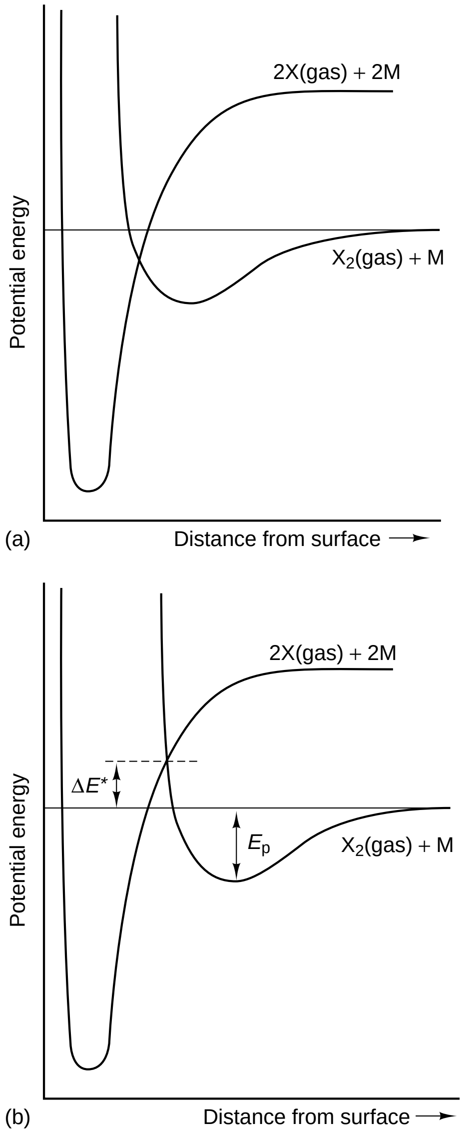

Figure 11 Potential energy diagrams for the chemisorption of a diatomic molecule: (a) the process results in the formation of a strong chemical bond and (b) in some cases may require a certain activation energy

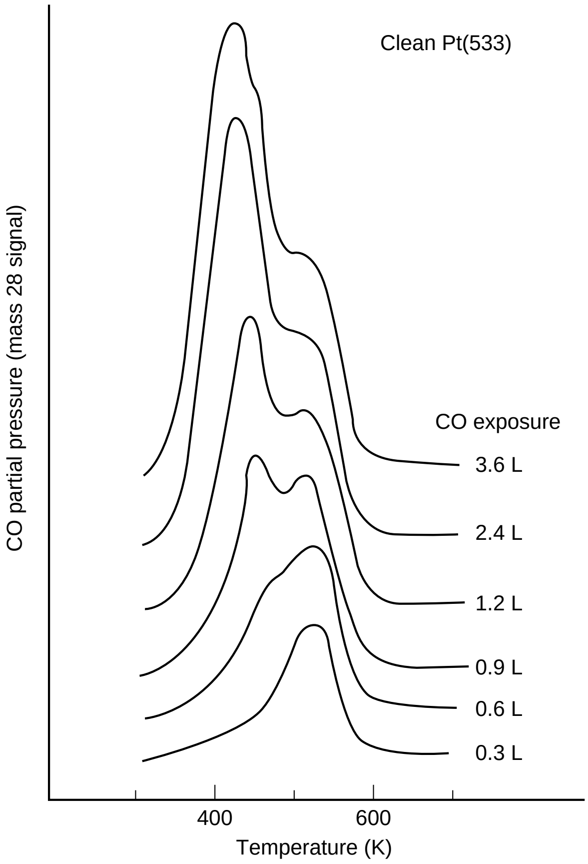

Figure 12 Temperature desorption spectrum of CO from a Pt(533) surface

where ν is the pre-exponential factor and $f(\sigma)$ is a coverage dependence factor. As an example, the plot of pressure versus temperature (desorption spectrum) for CO desorbing from a Pt(533) surface is shown in Figure 12.[21] The procedures for measuring the desorption energy and rate orders for desorption spectra are well described in the literature.[22]

The TPD spectra of CO on Pt(533) illustrate an important factor influencing the energy of desorption and hence the heat of adsorption, i.e. the local binding site. The spectra, measured as a function of coverage, depict two separate desorption peaks. The lower energy state occupied at high coverages has been associated with molecules adsorbed on the terraces of the surface, while the higher energy peak is associated with the desorption of molecules from step edges. Other factors affecting the heat of adsorption besides adsorbate–substrate interactions include coverage (as a result of adsorbate–adsorbate interactions) and temperature.

Adsorption isotherms are also used to determine heats of adsorption as well as entropy and heat capacity changes associated with adsorption. An adsorption isotherm is the relationship at constant temperature between the amount of a gas that is adsorbed on to a surface and the partial pressure of the gas. The two models most widely used to describe the adsorption process are the Langmuir isotherm[23] and the Brunauer–Emmett–Teller (BET) isotherm.[24] The Langmuir model assumes the presence of noninteracting adsorbates and a homogeneous surface, and that no adsorption occurs after the completion of a full monolayer. The possibility of multilayer formation is accounted for in the BET isotherm by introducing distinct heats of adsorption for the first and second molecular layers. The Langmuir isotherm most accurately describes systems of chemisorbed molecules, while the BET isotherm is more useful for systems involving physisorption. In practice, the heat of adsorption is obtained by measuring adsorption isotherms at two different temperatures and solving

an integrated form of the Clausius–Clapeyron equation:

$$\ln\left(\frac{P_1}{P_2}\right)_\Theta = \frac{-\Delta H_{ads}}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \quad (15)$$

where $(P_1/P_2)_\Theta$ is the ratio of pressures required to produce identical coverages at different temperatures.

5 ELECTRONIC PROPERTIES OF SURFACES

5.1 Surface Potentials

Many physical and chemical properties of surfaces can be associated with the electronic nature of the surface. This electronic character is determined largely by the concentration of mobile charge carriers (electrons, holes, and diffusing ions). Their concentration is dependent on both the inherent electronic structure of the bulk and the unique environment of the surface. Band structure theory has been used successfully to describe many electronic properties of the bulk solid. Here the discussion of electronic properties is restricted to those associated with the presence of the surface.

Electrons of a solid, in the region of a surface, experience a potential (V_S) that may be divided into three parts:

$$V_S(x) = V_{core}(x) + V_{exchange}(x) + V_{diploe}(x) \quad (16)$$

$V_{core}(x)$ is the potential associated with the interaction between valence and core electrons and $V_{exchange}(x)$ is the exchange potential between valence electrons. The exchange potential accounts for the repulsive interaction between electrons of like spin (Pauli exclusion principle) and electrons of either spin (correlation interaction). Both of these potentials are experienced in the bulk as well as at the surface. $V_{dipole}(x)$ is specific to the surface and arises from charge redistribution at the asymmetric surface.

As discussed earlier, a surface is characterized by the abrupt change in density of atoms in a given direction (boundary of the solid phase). A drastic change in electron density is associated with the change in atomic density. Electrons in a solid can be treated as electrostatically bound to a uniform density of positive charge (ion cores). This electronic picture of a solid is called the jellium model and has been used to describe many electronic properties of solids.[25] At a solid–vacuum interface, electrons are bound to the solid on only one side and can ‘spill out’ into the vacuum (Figure 13). The electrons which tunnel out of the solid at the surface leave behind a partial positive charge. This creates a space-charge region, often referred to as the electrical double layer, and leads to the associated space-charge potential $V_{dipole}(x)$.

The magnitude of the space-charge potential is closely dependent on the local structure of the surface, as will be discussed in relation to work function measurements. In the

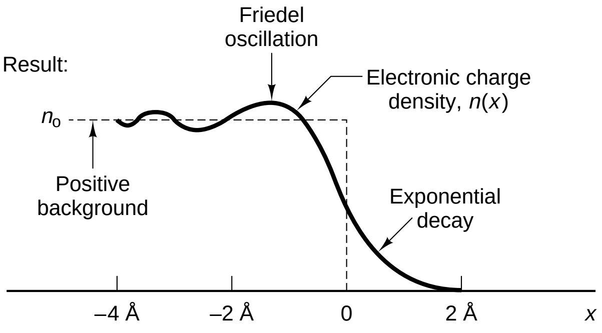

Figure 13 Plot of electronic charge density as a function of distance across a solid–vacuum interface as calculated from a jellium model

region of the surface, the height of the surface potential $V_S(x)$ and the depth of penetration into the bulk is related to the number of free carriers in the solid. It can be shown that the depth of penetration d is given by

$$d = \left(\frac{2\varepsilon\varepsilon_0 V_S}{en_e(\text{bulk})}\right)^{1/2} \quad (17)$$

where ε is the dielectric constant in the solid, ε_0 is the permittivity of free space, and n_e(bulk) is the concentration of charge carriers in the bulk. Thus the region of space charge will be much different for metals, semiconductors, and insulators; the higher the free concentration of carriers, the smaller the penetration depth of the surface potential. For metals where the range of free carriers is 10^{20}–$10^{23}\,\text{cm}^{-3}$, V_S is small and d is less than the thickness of one atomic layer. However, for semiconductors, where carrier concentrations are 10^{-10}–$10^{-16}\,\text{cm}^{-3}$, surface potentials can be large and penetration depths can extend over thousands of atomic layers into the bulk. The effect at insulating surfaces can be even more extreme.

The region of space charge and the height of the surface potential can be represented schematically by a change in the band structure of a material at the surface. By considering only the potential energy of electrons at the top of the valence band and the bottom of the conduction band, the bands can be plotted as straight lines as a function of distance through the crystal. In the region of the surface, the potential is altered by the space charge region and is represented by ‘band bending’. For the case of n-type and p-type semiconductors, the charge of the free carrier differs and thus the direction of band bending and the nature of charge accumulation at the surface differs (Figure 14). The surface region is depleted of electrons for n-type semiconductors, while the surface region becomes electron rich for p-type semiconductors.

As mentioned previously, the space-charge region can also be affected by the local structure at the surface. This is most often seen in measurements of the work function of a material. The work function (Φ) is defined as the energy required to remove an electron from the highest filled energy level to

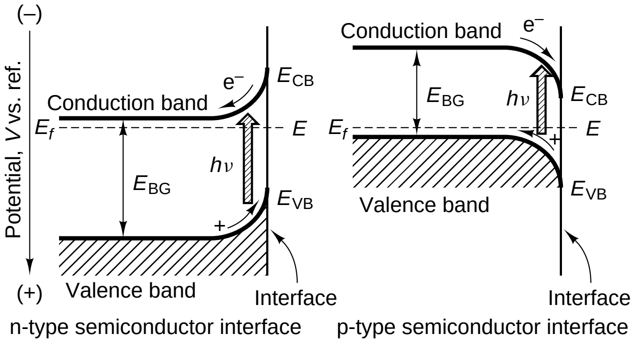

Figure 14 Electronic surface structure of n-type and p-type semiconductors depicting the effect of the space-charge region and band bending at the surface

the point of zero kinetic energy in vacuum, and is given by equation (18).

$$e\Phi = eV_{\text{exchange}} + eV_{\text{dipole}} - E_{\text{F}} \tag{18}$$

As before, V_{exchange} depends on the bulk electron density and V_{dipole} is due to the surface space charge potential that electrons must overcome in leaving the solid. The Fermi energy (E_{F}) is defined as the potential energy of an electron at the top of the valence band. Schematically, the relationship is represented in Figure 15. Equation (18) shows the direct relationship between the work function and the dipole potential. Experimentally, both the structure of the surface and the presence of adsorbates have been seen to affect work-function measurements. Table 3 lists the work function measured from several faces of tungsten, molybdenum, and tantalum crystals.[26,27] The more open and highly corrugated faces (or those containing a greater number of steps) yield a lower work function. Here, as the surface becomes more rough, the presence of ion cores of surface atoms protruding into vacuum effectively reduces the potential field at the surface (V_{dipole}) and lowers the work function.

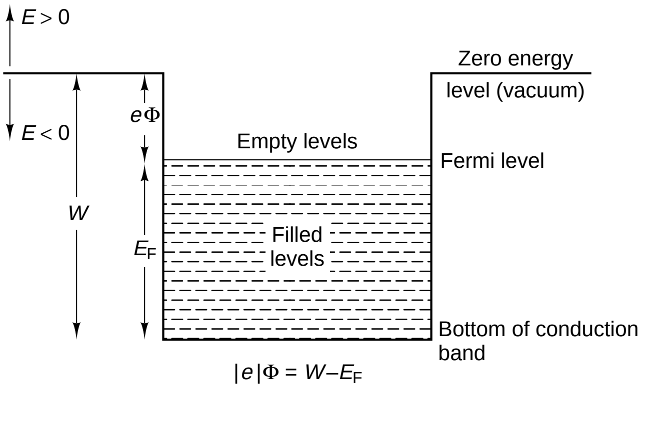

Figure 15 The work function of a solid surface is defined as the energy required to remove an electron from the highest filled energy level to the point of zero kinetic energy in a vacuum

Table 3 Work function (eV) of different crystal faces of several metals

Crystal Face	Tungsten	Molybdenum	Tantalum
(110)	4.68	5.00	4.80
(112)	4.69	4.55	–
(111)	4.39	4.10	4.00
(001)	4.56	4.40	4.15
(116)	4.39	–	–

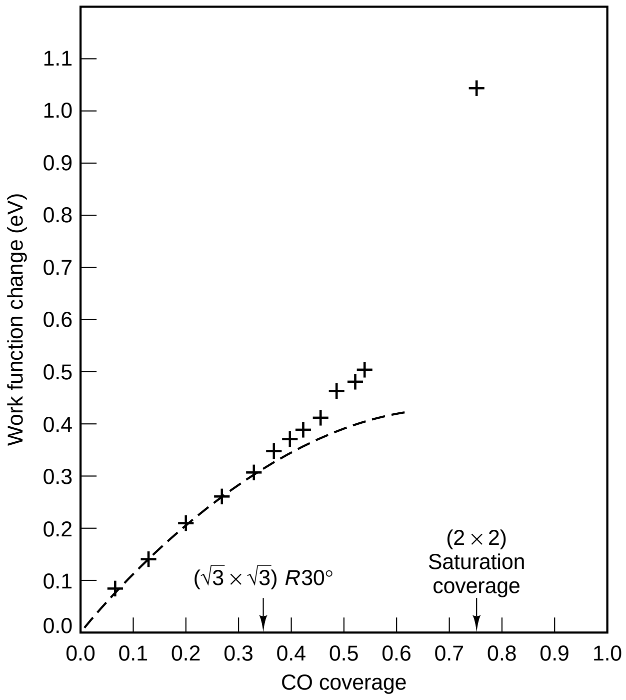

Figure 16 Work function changes induced by the adsorption of CO on Rh(111)

In a similar fashion, adsorption of atoms or molecules onto a surface can raise or lower the value of the work function. Figures 16 and 17 illustrate the affect of CO and Na adsorption on the work function of Rh(111). For the case of carbon monoxide, the presence of the double layer at the surface leads to the polarization of CO with the negative end of the induced dipole oriented away from the surface. The presence of this dipole reinforces the dipole potential and consequently increases the work function. For the case of sodium, charge transfer occurs upon adsorption leaving an electropositive element at the surface. This in turn decreases the effective magnitude of the dipole potential and lowers the work function. The data of Figure 17 also illustrate the role of adsorbate–adsorbate interactions as depolarization of the sodium occurs at near-monolayer coverage and reduces the effect. The adsorption of gas molecules on insulator

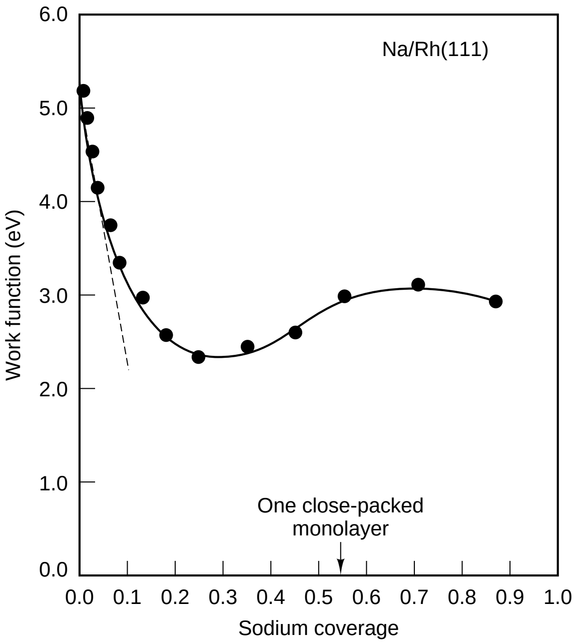

Figure 17 The work function of a Rh(111) surface is initially lowered by the adsorption of sodium atoms. The small increase at higher coverages arises from the depolarization of the sodium overlayer

and semiconductor surfaces can produce even more drastic changes in the magnitude of the dipole potential, markedly altering the electrical conductivity of these surfaces. As a result, many gas-sensor applications make use of thin films of insulators and semiconductors as detectors.

5.2 Electron Emission from Surfaces

Many of the surface characterization techniques listed in Table 1 are based on the analysis of electrons emitted from the surface region. The emission of these electrons can come as a result of temperature, applied electrical field, or the interaction of the surface species with incident photons or electrons.

As mentioned previously, the probability of emission (escape) of an electron from a solid surface is inversely proportional to the strength of interaction between the electron and the solid. In other terms, the higher the energy state of an electron in a solid, the lower the energy necessary for it to be removed from the surface. The population of these electronic energy states is proportional to temperature, and can be approximated by a Boltzmann distribution,

$$f(E) \approx \exp\left(-\frac{\Phi}{k_B T}\right) \quad (19)$$

where Φ is the work function of the metal and k_B is the Boltzmann constant. Thus, the emission of electrons from a surface can be induced by raising the temperature to the point where energies of electrons at the surface are above the work function. This process is called thermionic emission and is often used to produce electron beams from metallic filaments. Refractory metals which can be heated to the high temperatures necessary to produce a large flux of electrons are typically used. In order to increase their lifetime, metals of a lower work function can be coated onto the filament, thereby reducing the temperature required to produce a given flux.

Electron emission can also be induced by the presence of large electric fields. When a potential V is applied between a sharp metal tip and a plate, a large electric field is generated at the tip (i.e. $E \approx 10^7\,\text{V cm}^{-1}$ for a potential of 1000 V applied to a tip of $r = 10^{-4}\,\text{cm}$). This electron emission process is known as field emission. In the field emission microscope (FEM), emitted electrons are detected at a phosphor plate as a function of potential and are used to measure the work function of different crystallographic planes of the metal tip.

Finally, electrons can be emitted from a surface as a result of photon–solid or electron–solid interactions. When high energy photons or electrons are incident upon solid samples, several electronic transitions can lead to the emission of electrons. First, if the energy ($h\nu$) of an incident photon exceeds that necessary to ionize an atom of the solid, electrons not suffering inelastic collisions will be emitted from the solid with a kinetic energy (*KE*) given by

$$KE \approx h\nu - BE - \Phi \quad (20)$$

where *BE* is the binding energy of the electron in the solid and Φ is the work function of the solid. The illumination of a solid with X-rays leads to the emission of electrons from core-level energy states and provides information about elemental composition. The use of lower energy UV photons in UV photoelectron spectroscopy (UPS) leads to emission of electrons from valence energy levels and probes the character of chemical bonding at the surface. A second electron emission process can occur as a result of the core level excitation process. When core level electrons are emitted, they leave behind an electron vacancy which can be filled by the de-excitation of electrons from higher energy states. The energy released by the resulting electronic transition can be transferred to still another electron which will be emitted from the solid if its energy exceeds its binding energy (Figure 18). Electrons emitted by this process

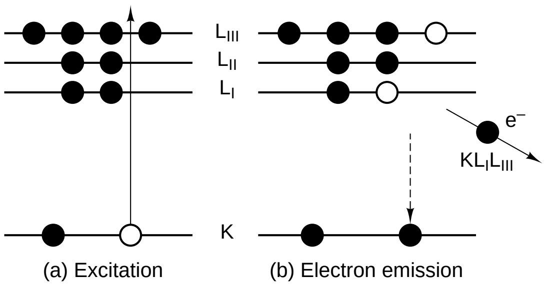

Figure 18 The Auger electron emission process is a three-electron process involving both core and valence-level electrons

are known as Auger electrons. Auger transitions are independent of the energy of the incident beam and therefore can be induced by both photon and electron excitation sources. Auger electron spectroscopy (AES) is widely used as a probe of composition and chemical state information.

The electronic transitions previously described can occur in both surface and bulk atoms of a solid. Electron spectroscopies such as XPS, UPS, and AES are capable of providing surface-specific information because of the relatively short mean free path of electrons in solids. In effect, only electrons emitted in a narrow region near the surface will escape before losing energy through inelastic scattering events. The mean free path of an electron in a solid is plotted versus electron kinetic energy in Figure 19. The data points for this plot are representative of the different kinetic energies of electrons photoemitted from a number of solids. The observed dependence of mean free path with kinetic energy is typically referred to as the 'universal curve'.[28]

5.3 Electron Tunneling at Surfaces

In the discussion of the surface space-charge region, the idea of electrons spilling out or tunneling out of the solid into vacuum was presented. While the phenomenon has been understood within the solid state physics community for many years, it has recently received a much broader exposure in the context of scanning tunneling microscopy (STM). In STM, a very sharp tip is brought within close proximity (a few angstroms) of a surface such that tunneling can occur between the tip and the sample. The direction of tunneling (electrons traveling from tip to surface or from surface to tip) is dependent on the bias potential placed on either the tip or the sample. While much of the STM work has focused on generating topographic images of the surface, there is much information to be gained from the specifics of the tunneling current. The height of the local barrier to tunneling can be measured by modulating the tip and measuring current as a function of frequency. Barrier height measurements are similar to work-function measurements; however, they differ in magnitude because of the close proximity of the tip and sample. In addition, STM offers the possibility of spatially mapping the local density of electronic states. In both techniques, a comparison to theoretical calculations is necessary to understand the tunneling current data. To date, uncertainties in tip geometry and composition, and the presence of two different surfaces (tip and sample) have precluded an exact theoretical treatment of the problem and much work remains on this topic.

6 OPTICAL PROPERTIES OF SURFACES

6.1 Photon–Surface Interactions

The interactions between light and matter at a surface include absorption, reflection, phase shift, and diffraction. The

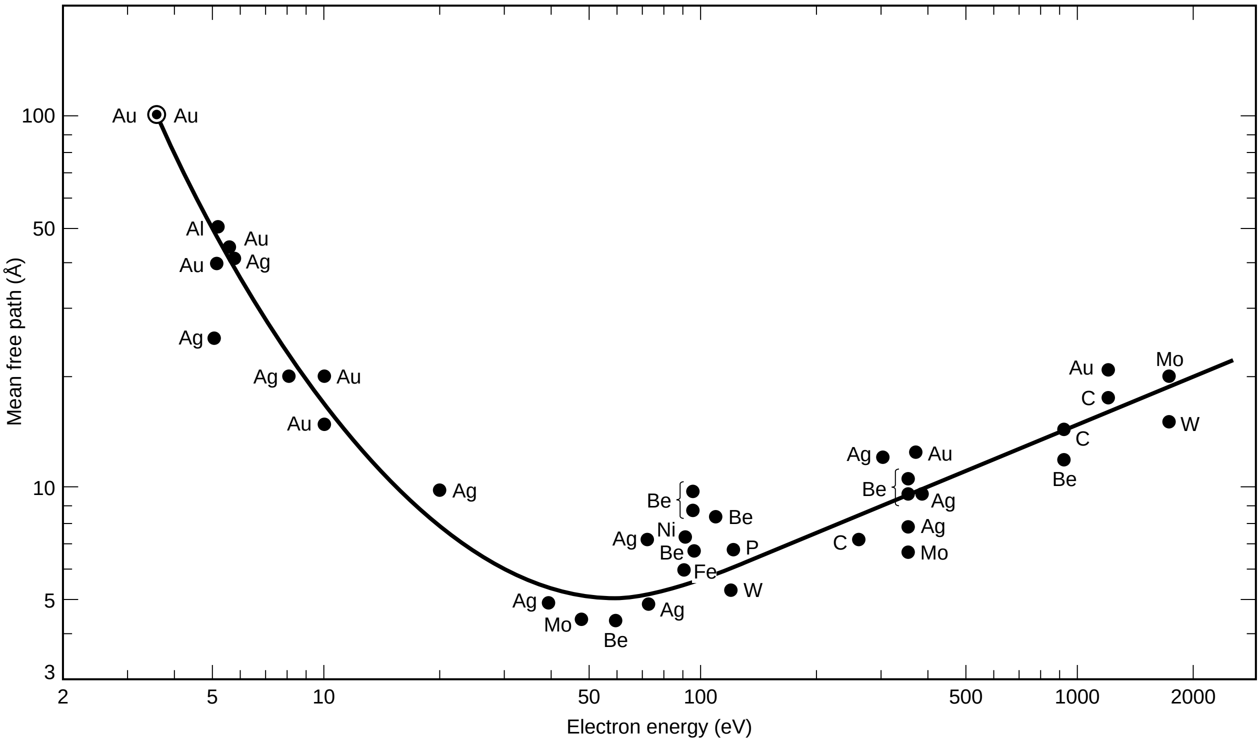

Figure 19 The 'universal curve' depicting the mean free path of different energy electrons measured in a number of materials

optical properties of surfaces, like those of the bulk, can be described in terms of two important parameters, the index of refraction η and the extinction coefficient k. The index of refraction is defined as the velocity of light propagating through a material relative to the velocity of light propagating through a vacuum. The extinction coefficient is related to the absorption or decay of radiation as it passes through matter. Often the two parameters are combined and quoted as a complex index of refraction N, given by the relation

$$N = \eta - ik \tag{21}$$

At this point it should be noted that both the index of refraction and the extinction coefficient are extremely frequency dependent. Consequently, the properties of absorption, reflection, and phase shift which depend on them will also show a frequency dependence. Value of η and k for most metals and semiconductors are tabulated in the *American Institute of Physics Handbook.*[29]

The absorption of visible light by many metals and semiconductors can be considered a surface phenomenon because much of the absorption takes place in a region very near the surface. The extent of absorption as a function of distance into a solid is given by the equation

$$I_t = I_0 \exp(-\alpha z) \tag{22}$$

where I_0 and I_t represent the incident and transmitted radiation, respectively, and α is the absorption coefficient (Figure 20). The absorption coefficient for a given wavelength λ is related to the extinction coefficient k by $\alpha = 4\pi k/\lambda$.

Another useful parameter in discussing the propagation of radiation into the surface region of a highly absorbing material is the optical skin depth. This is defined as the distance z into a material at which the ratio of transmitted intensity to incident intensity equals a value of $1/e$. Thus the optical skin depth can be defined as the reciprocal of the absorption coefficient and is useful in discussing relative penetration depths in different materials. For example, the optical skin depth of silver at an incident wavelength of 500 nm is ~150 Å while that of silicon is ~1000 Å at the same wavelength.

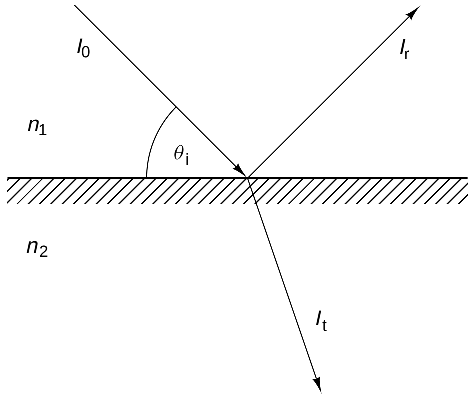

Figure 20 Schematic representation of the reflection and transmission of light at a solid surface

Closely related to the propagation of light into matter (refraction) is the reflection of light at a surface. Reflection is defined as the case of elastic scattering of radiation where the scattered angle is equal to the angle of incidence θ_i (Figure 20). For the case of normal incidence, the intensity of reflected light at the interface between two homogeneous media is given by

$$R = \frac{(\eta_0 - \eta_1)^2 + k_1{}^2}{(\eta_0 + \eta_1)^2 + k_2{}^2} \tag{23}$$

Here η_0 is the refractive index of the medium of incidence (approximately 1 for air and vacuum environments) and η_1 and k_1 are the index of refraction and extinction coefficients of the absorbing material. A complete treatment of the intensity of reflected light from a surface at angles other than normal incidence can made using Fresnel's equation.[30] Values of R at visible wavelengths for a transition metal surface typically fall within the range of 65–95%. Obviously, for many metal oxides which are transparent in the visible, the value of R will be very low.

A phase change ρ of the radiation will be associated with the reflection and is given by the equation

$$\rho = \tan^{-1} \frac{2\eta_0 k_1}{\eta_0{}^2 - \eta_1{}^2 - k_1{}^2} \tag{24}$$

It should be pointed out that the index of refraction and the extinction coefficient are quantities experimentally derived from reflectivity measurements. Variations in the chemical and mechanical properties of a surface are known to produce drastic changes in the values of these parameters. Therefore, the use of clean (by vacuum standards) and atomically flat surfaces is highly desirable for such measurements.

Finally, the incidence of radiation on to a surface can lead to diffraction. Diffraction arises from the interaction of a propagating wave, light in this case, with a periodic array of scattering sites. From the condition for diffraction,

$$n\lambda = 2d \sin\theta \tag{25}$$

where λ is the incident wavelength, n is the order of diffraction, d is the separation of scattering sites and θ is the angle of incidence, it is easily seen that the periodicity of scattering sites must be on the order of the incident wavelength. Thus, diffraction of visible light is only observed from surface structures with periodicity of hundreds of nanometers (i.e. gratings). Diffraction at an atomic scale is possible with the use of X-rays ($\lambda \approx \mathring{A}$'s); however, as most material is partially transparent at these wavelengths, X-ray diffraction typically arises from periodicity of the bulk lattice and surface symmetry is lost. Yet, with the high flux of X-rays available from synchrotron sources and the use of a glancing angle of incidence, X-ray diffraction has recently provided important structural information in studies of thin film growth.

6.2 Optical Measurements at Surfaces

The specific interactions of light and matter at a surface are an inherent part of optically based surface characterization techniques. While Fourier transform infrared (FTIR) spectroscopy and Raman spectroscopy are traditionally employed in analyzing bulk structural properties, careful consideration of surface properties has led to their development as surface techniques. Both of these spectroscopies have been used to measure the vibrational spectra of molecular adsorbates on a wide variety of surfaces.[31,32] Vibrational information is derived from the interaction of light with the dipole oscillation (IR) and polarizability (Raman) of the molecules. In both instances the intensity of the interaction is proportional to the electric field that the molecule experiences. This fact that is the basis of the widely studied phenomenon of surface-enhanced Raman scattering (SERS),[33] where a 10^4 enhancement of the electrical field strength is observed in the region of some roughened metal surfaces. Electric field strengths at the surfaces of conductors show a drastic dependence on angle of incidence and polarization as well as on the index of refraction and extinction coefficient of the solid. As a result, stringent requirements are placed on the experimental layout of the techniques. In addition, screening and the creation of image charges at the surface influence the selection rules of these spectroscopies.

The techniques of second-harmonic generation and sum-frequency generation derive their sensitivity to surfaces from the asymmetry of the surface region.[34] In second-harmonic generation (SHG), attention is focused on an induced-dipole component at twice the frequency of the incident radiation. The strength of this component is proportional to the nonlinear susceptibility of the material which is only active in regions that lack inversion symmetry. The physical origin of the surface nonlinearity can arise from both structural discontinuity, as in the dangling bonds of semiconductor surfaces and electric field discontinuities. SHG studies have addressed the processes of molecular adsorption and desorption as well as surface diffusion of molecular adsorbates. Sum-frequency generation (SFG) relies on the combination of two incident frequencies (one infrared) to produce a third frequency ($\omega_1 + \omega_2 = \omega_3$). Again, the process is dependent on nonlinear susceptibility and takes advantage of resonant enhancements of this effect at frequencies of molecular excitation or vibration. In this way, by tuning the infrared frequency, the vibrational spectrum of adsorbates can be obtained.

Alternatively, the technique of laser-induced desorption takes advantage of the adsorption properties of surfaces. As previously discussed, the optical skin depth of most metals is on the order of 50 Å for IR frequencies. As a result, local heating can occur (up to $10^{10}\,\mathrm{K\,s^{-1}}$) when incident radiation is focused to a small spot on a surface. By analogy to temperature programmed desorption (TPD), molecular species present in this region can be thermally desorbed and detected with a mass spectrometer. The rapid local heating of the surface induced by adsorption typically leads to the desorption of 'intact' species and thus allows the concentration of surface adsorbates to be probed as a function of time.

7 DYNAMIC PROPERTIES OF SURFACES

7.1 Surface Atomic Vibrations

Much of the previous discussion of surface properties has treated the surface as the termination of a rigid periodic lattice. In reality, at temperatures above 0 K, surface atoms are vibrating about their equilibrium position. A useful model of this process is the one-dimensional harmonic oscillator. In this model, atoms are treated as a mass attached through a spring to a fixed surface. As depicted in Figure 21, restoring forces are exerted on the atom as it moves from its equilibrium position r. This force is linearly proportional to the displacement x and a proportionality constant k, called the force constant. The force is given by the equation

$$f = m\frac{d^2x}{dt^2} = -kx \tag{26}$$

where m is the mass of the atoms and t is time. The potential energy change (dV) of such a system with respect to displacement (vibration) of the atom is given by $dV/dx = kx$. Thus the potential energy of a vibrating surface atom can be

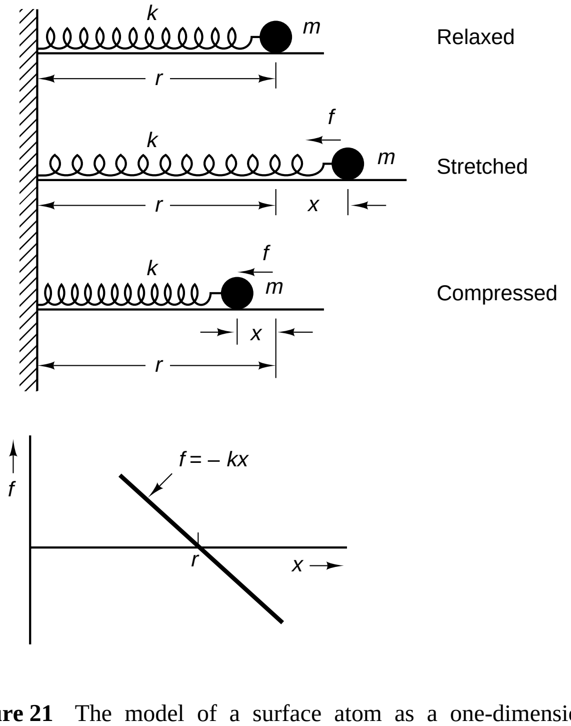

Figure 21 The model of a surface atom as a one-dimensional harmonic oscillator

modeled as

$$V = \frac{1}{2}kx^2 \qquad (27)$$

Such a potential energy function gives rise to the familiar parabolic curve (Figure 22) where the curvature of the function is related to the force constant. The success of this simple harmonic model in treating surface atom vibrations lies in the relatively small displacement of surface atoms during a period of vibration. For some crystal properties, such as thermal expansion at elevated temperature, anharmonic contributions to the potential must be included for an accurate description.

The surface of a solid can be viewed as a collection of many harmonic oscillators, each coupled to its nearest neighbor. The surface vibrational modes of such a collection can be obtained by considering the propagation of waves in a semi-infinite isotropic elastic medium. For a stress-free surface, it is found that long wavelength modes of propagation exist parallel to the surface and decay exponentially into the bulk. The vibrational spectrum of atoms at solid surfaces has been measured by inelastic helium scattering and high resolution electron energy-loss spectroscopy (HREELS). Studies of this type have detected vibrational modes related to specific sites. They find that the inward relaxation of surface atoms at step sites is larger than that of terrace atoms and thus gives rise to a higher vibrational frequency. Surface vibrational modes (phonons) are typically low in energy (<70 meV) and are found in the 10–500 cm^{-1} region of the spectrum.

The effect of surface atom vibrations is seen clearly in low energy electron diffraction (LEED). Experimentally, an exponential decrease in the intensity of scattered beams and an increase in background intensity are observed with increasing temperature. This arises as a result of the increased vibrational amplitude of the surface atoms that occurs at elevated temperatures. Atoms displaced from their equilibrium position during the scattering process will scatter out of phase, reducing the number of electrons in the diffracted beam. A similar temperature dependence is observed in X-ray diffraction from bulk lattices. In both instances, the phenomenon can be described by the Debye–Waller factor which includes the material-dependent Debye temperature. By measuring the temperature dependence of diffracted beam intensities, the Debye temperature can be calculated and taken as a measure of surface vibrational amplitude perpendicular to the surface. For most metals, the rms vibrational amplitude of surface atoms normal to the surface is 1.4 to 2.5 times larger than the bulk atom displacements.

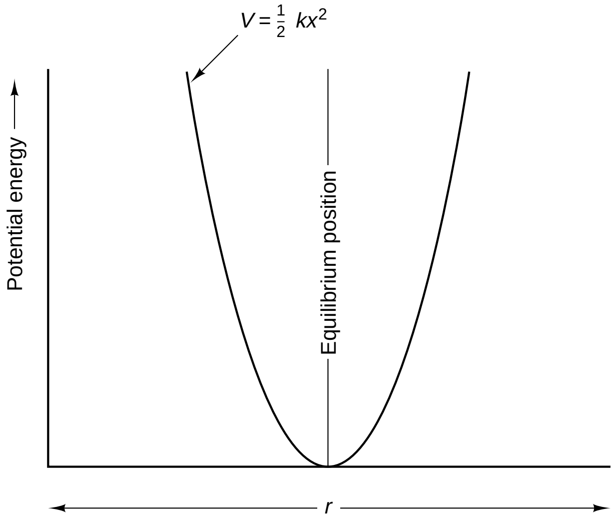

Figure 22 Potential energy of the one-dimensional harmonic oscillator as function of interatomic displacement *r*

Atoms and molecules adsorbed on a surface will also have a characteristic vibrational spectrum. For the case of physisorbed molecules, ‘surface allowed’ vibrations will closely resemble those of the gas-phase molecule. However, new modes associated with local adsorption geometries and the formation of new chemical bonds arise for chemisorbed molecules. Reflection-absorption infrared spectroscopy (RAIRS), SFG, Raman, and HREELS are all useful techniques for studying the vibrational spectra of adsorbed species; however, there are limitations to each approach and careful consideration of the system to be analyzed must be made. As an example, the vibrational spectrum of CO adsorbed on Rh(111)[37] is shown as a function of coverage in Figure 23. At low coverages, CO occupies only atop sites and two bands characteristic of the carbon–oxygen stretch and the metal–carbon stretch are observed. At higher coverages, repulsive interactions between the adsorbates force CO to occupy sites of lower symmetry. As a result of the repulsion, the bonding of the molecules in bridging sites is weakened and additional bands lower in the vibrational spectrum are observed.

7.2 Surface Diffusion

The motion of atoms both in and on the surface can also occur through surface diffusion. The concept of atom transport along the surface plane is important in equilibrium surface structure, nucleation and growth of thin films, and surface reactivity.

As discussed in relation to surface structure, surfaces can possess many defects on the atomic scale. The equilibrium distribution of these sites is reached through surface diffusion. This can be considered as a multistep process where atoms break away from their local position and migrate across the surface to a new equilibrium site. As each surface site (step, kink, terrace) will have a different binding energy, diffusion from lower binding energy defect sites is most common. The frequency ν with which an atom can escape from a site is exponentially proportional to the height of the potential energy barrier ΔE^* associated with leaving the site. The frequency is

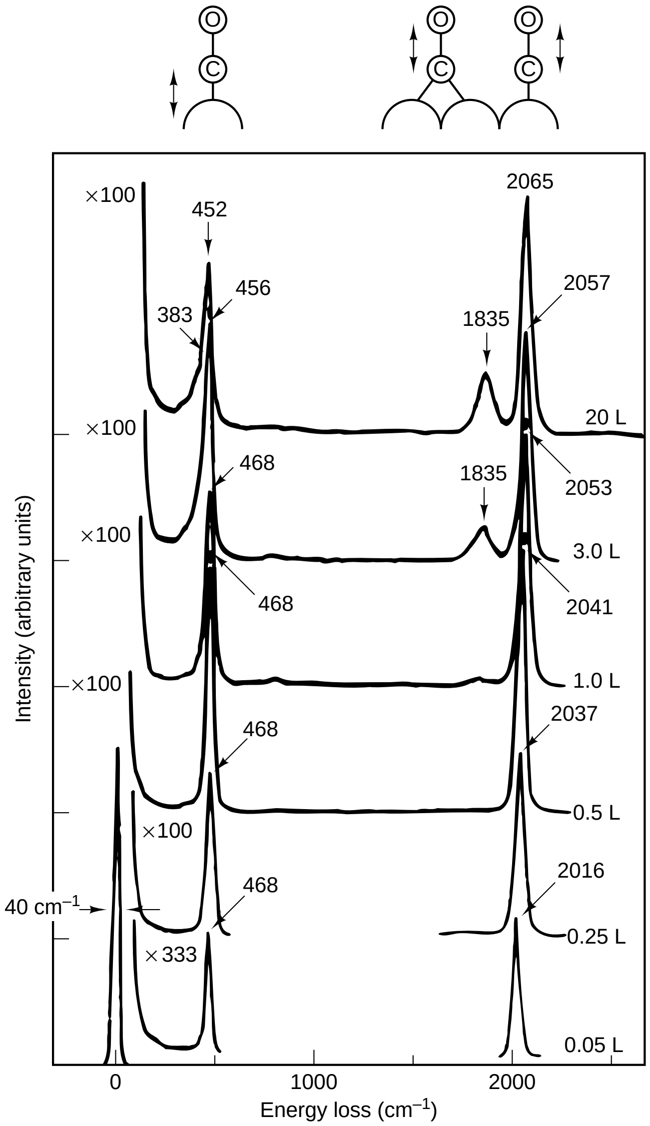

Figure 23 High-resolution electron energy-loss spectrum of CO adsorbed at different coverages on Rh(111)

given by the equation

$$\nu = z\nu_0 \exp\left(\frac{-\Delta E^*}{k_B T}\right) \qquad (28)$$

where z is the number of nearest neighbors and ν_0 is the vibrational frequency of the escaping atom. Assuming a vibrational frequency of $10^{12}\,s^{-1}$ and a barrier height of $20\,kcal\,mol^{-1}$, surface atoms with six nearest neighbors are estimated to 'jump' once every 50 s at room temperature. However, the same atom at 1000 K is estimated to move from a site once in every 10^{-8} s!

While high diffusion *rates* can be induced by temperature, a more important parameter is the distance across the surface that the diffusing atom can travel. The rms diffusion distance is defined in terms of a diffusion coefficient which can be derived from experimental measurements. In most surface-diffusion experiments, a coverage gradient is evaluated by measuring the concentration of diffusing atoms as a function of distance along the surface. Optical reflection techniques, laser-induced desorption and scanning Auger electron spectroscopy have been used for such measurements. Field ion microscopy can also be used to monitor the diffusion of individual atoms at the surface of a very sharp metal tip.

7.3 Gas–Surface Interactions

The discussion to this point has only considered the dynamics of atoms of the surface plane and adsorbates at this plane. The dynamics of molecules arriving at the surface from the gas phase are important in determining the properties of physical and chemical adsorption (see also Section 4). The interaction of gas-phase atoms or molecules with a surface is a multistep process that begins with collision at the surface. The result of the collision can range from energetically elastic scattering back into the gas phase to chemical reaction and accommodation at the surface (sticking). The type of interaction is determined by the energy of the gaseous molecule, temperature, and the local structure of the surface.

Figure 24 represents the collision of a diatomic molecule with incident energy E_i with a surface of energy E_i'. The total energy of the incident molecule is the sum of its translational, vibrational, rotational, and electronic energies. During the collision process, the molecule can exchange energy with the

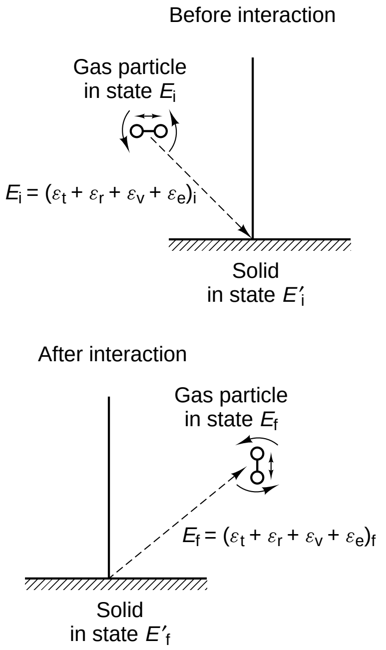

Figure 24 Scheme of energy transfer in gas–surface interactions which involve translational, vibrational, rotational, and electronic energy states

surface through several channels. These include the transfer of energy between the translational, vibrational, and rotational states of the incident molecule and the vibrational energy states of the surface. Detection of the scattered molecule in a state-specific fashion provides a detailed picture of the dynamic collision process.

The most important technique for studying dynamic gas–surface interactions has been molecular beam surface scattering (MBS). In these experiments, a collimated beam of atoms or molecules of known energy (thermal, vibrational, and rotational) is impinged on a well-characterized, clean surface of known temperature. The scattered molecules are detected by a mass spectrometer with the angular spread in scattering measured by rotating the detector about the scattering plane. Velocity distributions are determined by chopping the incident beam and measuring the scattered molecules or atoms in a time-of-flight manner. Rotational and vibrational distributions have been measured by optically probing the scattered molecules (i.e. two-photon ionization).

The amount of incident energy of the molecule (E_{incident}) that is transferred to the surface can be represented by an energy accommodation coefficient γ^{E}:

$$\gamma^{\mathrm{E}} = \frac{E_{\mathrm{incident}} - E_{\mathrm{scattered}}}{E_{\mathrm{incident}} - E_{\mathrm{surface}}} \tag{29}$$

Here E_{surface} is defined as the thermal energy of the solid. A plot of the component accommodation coefficients for NO molecules scattered from a Pt(111) surface as a function of crystal temperature is shown in Figure 25. Referring to equation (29), when the energy of the scattered molecule equals the thermal energy of the solid, the accommodation coefficient will be equal to 1. This can occur when incident molecules come to equilibrium with the surface atoms during the collision process. For the case of NO scattering from Pt(111), the thermal and vibrational energies are well accommodated at the surface over a wide range of temperature. The decrease in the rotation accommodation coefficient with temperature indicates that there is a barrier to free rotation of the molecule on the surface, most likely associated with the direction of the N–O bond.

The accommodation of energy at the surface suggests a finite residence time of the molecule or atom on the surface during the collision process. The residence of a molecule on the surface can arise from an attractive potential at the surface. The angular distribution of scattered species is representative of the strength of the attraction and thus the degree of interaction during the collision. The limiting cases of angular spread are shown in Figure 26. A peaked distribution in the specular direction (45° from surface normal in this case) is representative of short residence times and little interaction. Conversely, a cosine distribution is characteristic of long residence times where molecules have become strongly coupled to the energy states of the surface. This is the same angular distribution that is observed from physically adsorbed molecules desorbing with an energy equal to the surface energy (temperature).

Molecular beam scattering is also a powerful tool for probing the structure-sensitive nature of reactive (dissociative) scattering events.[35] In Figure 27 the production of HD from the surface reaction of a mixed H_2–D_2 molecular beam is plotted versus incident angle for two crystal faces of platinum. The close-packed Pt(111) surface shows a low reaction probability

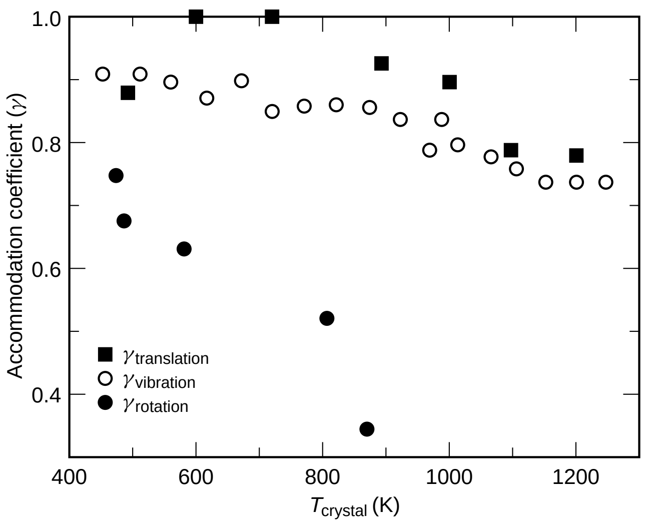

Figure 25 Translational, vibrational, and rotational accommodation coefficients for NO molecules scattered from a Pt(111) surface at different surface temperatures

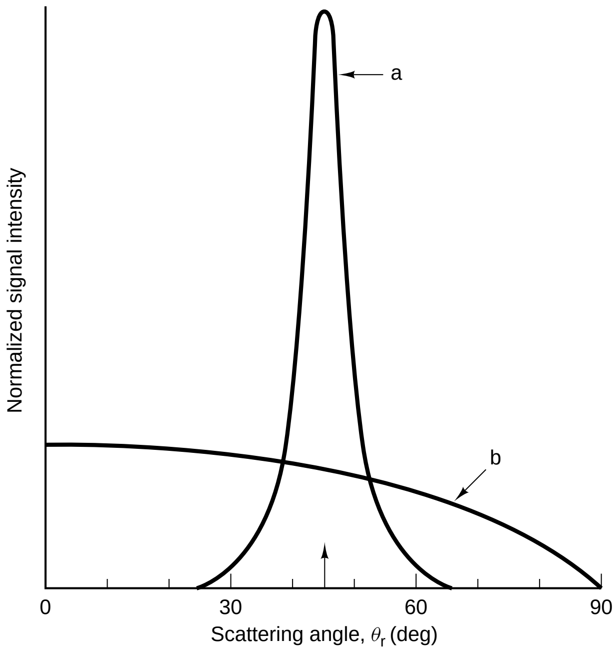

Figure 26 The limiting cases of angular distribution of species scattered from a solid surface: (a) specular scattering characteristics of short residence time, (b) cosine distribution characteristic of long residence times

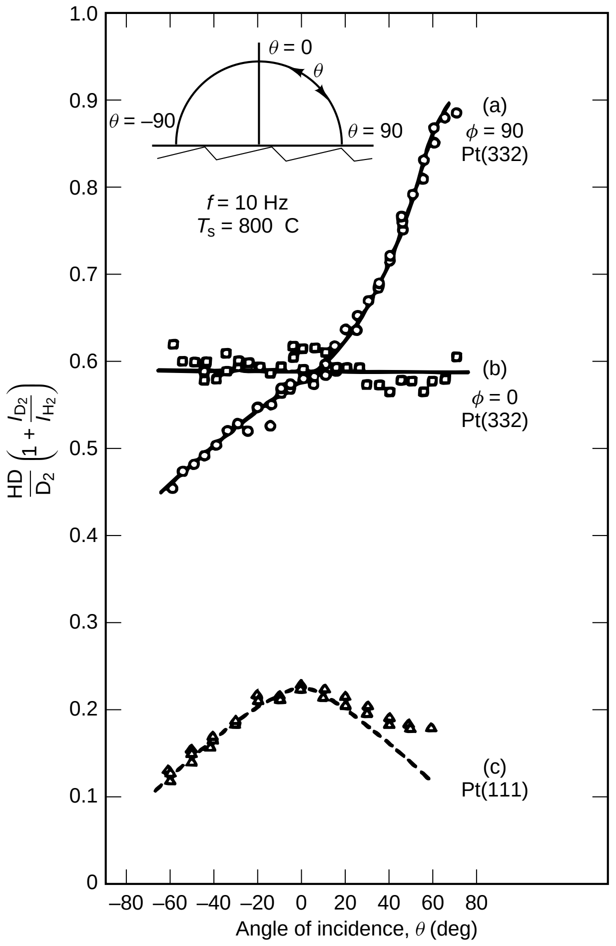

Figure 27 Reactive scattering cross-sections of the $H_2 + D_2$ reaction as a function of angle of incidence shown for three crystal faces of platinum

for the H_2–D_2 exchange. The Pt(332) surface contains a high concentration of steps (defects) and shows a much higher reactivity towards the dissociation of the incident H_2 and D_2 molecules. Furthermore, measurements as a function of azimuthal angle in the surface plane show that the greatest probability for reaction occurs for glancing angles of incidence normal to the step edge direction. This result illustrates the high reactivity of step sites for the dissociation of H_2 and D_2.

As mentioned earlier, the ultimate accommodation of incident energy occurs when the molecule becomes trapped by the attractive surface potential. The process can occur molecularly or dissociatively, leading to a new chemical species and is discussed in detail in Section 4.3.

8 SURFACE REACTIONS

The study of surface chemical reactions comprises much of the work being carried out on surfaces today and spans a number of disciplines (chemistry, materials science, and chemical and electrical engineering). A complete discussion of chemical reactions at surfaces is well beyond the scope of this discussion (*see* ***Heterogeneous Catalysis by Metals***). Here, only a classification of surface reactions will be presented. In general, surface reactions can be divided into four categories as follows.

8.1 Catalytic Reactions

A fundamental definition of a catalyst is a substance that increases the rate of a chemical reaction without being changed or consumed by the reaction. In surface-catalyzed reactions, the surface acts as a catalyst by providing a site for the reaction. During the course of the reaction, molecules adsorb from the gas or liquid phase, diffuse to the active site, undergo chemical reaction, and ultimately desorb, regenerating the active site. In addition to enhancing the rate of reaction, a surface can act as a catalyst by inducing selective channels of reactivity. Heterogeneous catalysis of this type is used in almost all chemical technologies and throughout many other industries. Understanding the role of surfaces as a catalyst on an atomic scale involves identifying active sites and potential poisons of the catalytic reaction and is one of the major focuses of fundamental surface science.

8.2 Crystal Growth Reactions

Alternatively, chemical reactions at a surface can lead to the deposition of material and the extension of the solid phase. Such reactions are involved in crystal growth, thin film deposition and the formation of novel heterostructures. In these reactions, the material being deposited can be the same as the substrate (crystal growth), or different as in the case of many coatings technologies. Atoms or molecules may be used as reactants and can be delivered by vaporization, molecular beam techniques, or diffusion through solution. Growth reactions are found in the common processes of chemical vapor deposition (CVD), molecular beam epitaxy (MBE) and electroplating.

8.3 Corrosion Reactions

Like growth reactions, corrosion at surfaces involves a change in surface composition: however, it is typically associated with a deleterious change. Corrosion reactions can be separated into two classes: those involving the removal of material from the solid and those involving the formation of a surface reaction layer. In the first type of reaction, gas- or solution-phase species react with the surface to produce volatile or soluble products as in the etching of silicon by hydrofluoric acid. The second type of reaction involves the reaction of surface atoms to form a new compound which remains on the surface. The oxidation of many metals is considered a corrosion reaction of this type.

8.4 Photochemical Surface Reactions

The illumination of solid surfaces can lead to unique photochemical reactions by one of two means. First, incident radiation can be absorbed directly by surface adsorbates thereby exciting certain electronic or vibrational modes of the adsorbate. This process allows these molecules to further react at the surface via energy pathways normally absent. Second, radiation can be absorbed by the solid, producing charge carriers in the surface region. These charge carriers, upon migrating to the surface, can drive the oxidation or reduction of adsorbates. The photoelectrochemical dissociation of water at the surface of TiO_2 is a classic example of this type of reaction. In both absorption processes, the wavelength of the incident radiation is directly related to the excitation probability and is thus an important parameter in these reactions.

1 INTRODUCTION

The concept of symmetry is important in many structural and spectroscopic aspects of inorganic chemistry. The symmetry of a compound can be described by its point group, which is a mathematical group consisting of the symmetry operations of the molecule. This article summarizes some of the fundamental ideas of point group symmetry and the use of group theory to study various aspects of symmetry. For background information or further details the reader is referred to standard texts on chemical applications of group theory.[1]

2 SYMMETRY OPERATIONS

A symmetry operation is a movement of an object such that, after completion of the movement, every point of the body coincides with an equivalent point or the same point of the object in its original orientation. The position and orientation of an object before and after carrying out a symmetry operation are indistinguishable. Thus a symmetry operation takes an object into an equivalent configuration.

The symmetry operations for objects in ordinary three-dimensional space can be classified into four fundamental types, each of which is defined by a symmetry element around which the symmetry operation takes place. The four fundamental types of symmetry operations and their corresponding symmetry elements are listed in Table 1.

The identity operation, designated as E, leaves the object unchanged. Although this operation may seem trivial, it is mathematically necessary in order to convey the mathematical properties of a group on the set of all the symmetry operations applicable to a given object. This point will be clarified later in this article. The reflection operation, designated as σ, involves reflection of the object through a plane, known as a reflection plane. For example, in a reflection through the xy-plane (conveniently designated as σ_{xy}) the coordinates of a point (x, y, z) change to $(x, y, -z)$. A reflection operation thus can result in the change of only a single coordinate. A rotation operation, designated as C_n, consists of a $360°/n$ rotation around a line, known as a rotation axis. For example, a C_2 rotation around the z-axis changes the coordinates of a point (x, y, z) to $(-x, -y, z)$; a rotation operation thus can result in a change of only two coordinates. An improper rotation, designated as S_n, consists of a $360°/n$ rotation around a line followed by a reflection in a plane perpendicular to the rotation axis. An S_2 operation is called an inversion and is designated by i. The intersection of the C_2 axis and the perpendicular reflection plane is called an inversion center. Inversion through the origin changes the coordinates of a point (x, y, z) to $(-x, -y, -z)$. An S_n operation thus must change the signs of all three coordinates. An S_1 improper rotation in which the C_1 proper rotation component is equivalent to the identity E corresponds to a reflection operation σ. Thus the reflection operation σ is a special type of improper rotation, namely S_1.

3 MATHEMATICAL GROUPS

A set of elements forming a mathematical group (e.g. symmetry operations) must satisfy the following four conditions.

1. The product of any two elements in the group and the square of each element must be an element of the group. In order to apply this condition the concept of a product of elements must be defined. In this connection a product of two group elements is obtained by applying them successively. A square of a group element is obtained by applying the same operation twice. This definition can be extended to higher powers of group elements. Forming a product of two group elements is called multiplication by analogy to arithmetic. The multiplication of two group elements is said to be commutative if the order of multiplication is immaterial, i.e. if $AB = BA$. In such a case, A is said to commute with B. The multiplication of two group elements is not necessarily commutative.
2. One element in the group must commute with all others and leave them unchanged. This element is conventionally called the identity. In this case of symmetry point groups the identity element consists of 'doing nothing' and is conventionally designated as E (Table 1). This is why the 'trivial' identity operation E must be considered when treating symmetry point groups. This condition may be concisely stated as $EX = XE = X$.
3. The associative law of multiplication must hold. This condition may be expressed concisely as $A(BC) =$

Table 1 The four fundamental types of symmetry operations

Symmetry operation	Designation	Corresponding symmetry element	Dimensions
Identity (no change)	E	The entire object	3
Reflection	σ	Reflection plane	2
Rotation	C_n	Rotation axis	1
Improper rotation	S_n	Improper rotation axis (= point of intersection of a proper rotation axis and a perpendicular reflection plane)	0

$(AB)C$, i.e. the result must be the same if C is multiplied by B to give BC followed by multiplication of BC by A to give $A(BC)$ or if B is multiplied by A to give AB followed by multiplication of AB by C to give $(AB)C$.

4. Every element must have a reciprocal, which is also an element in the group. The element Z is the reciprocal of the operation A if $AZ = ZA = E$. The reciprocal of an element A is frequently designated by A^{-1}. Note that multiplication of an element by its reciprocal is always commutative.

These defining characteristics of a group have been summarized concisely[2] by defining a group as '... a mathematical system consisting of elements with inverses which can be combined in some operation without going outside the system'.

The elements in a group can be characterized by their periods. In this context the period of an element is the minimum number of times it must be multiplied by itself before the identity E is obtained. In the case of symmetry operations (Table 1) the period of the identity operation E is, of course, 1; the periods of the reflections σ are always 2; the periods of the proper rotations C_n are n; the periods of the even improper rotations S_{2n} are $2n$; and the periods of the odd improper rotations S_{2n+1} are $4n + 2$.

The number of elements in a group is sometimes called the order of the group. Within a given group it may be possible to select various smaller sets of elements, each set including the identity element E, which are themselves groups. Such smaller sets are called subgroups. A subgroup of a group G is thus defined as a subset H of the group G which is itself a group under the multiplication of G. The fact that H is a subgroup of G may be written $H \subset G$. The order of a subgroup must be an integral factor of the order of the group. Thus if H is a subgroup of G and $|H|$ and $|G|$ are the orders of H and G, respectively, then the quotient $|G|/|H|$ must be an integer; this quotient is called the index of the subgroup H in G.

Let A and X be two elements in a group. Then $X^{-1}AX = B$ will be equal to some element in the group. The element B is called the similarity transform of A by X and A and B may be said to be conjugate. Conjugate group elements have the following properties:

1. Every element is conjugate with itself. Thus for any particular group element A there must be at least one element X such that $A = X^{-1}AX$.
2. If A is conjugate with B, then B is conjugate with A. Thus if $A = X^{-1}BX$, then there must be some element, Y, in the group such that $B = Y^{-1}AY$.
3. If A is conjugate with B and C, then B and C are conjugate with each other.

A complete set of elements of a group which are conjugate to one another is called a class (or more specifically a conjugacy class) of the group. The number of elements in a conjugacy class is called its order; the orders of all conjugacy classes must be integral factors of the order of the group.

A group in which every element commutes with every other element is called a commutative group or an Abelian group after the famous Norwegian mathematician, Abel (1802–1829). In an Abelian group every element is in a conjugacy class by itself, i.e. all conjugacy classes are of order one. A normal subgroup N of G, written $N \lhd G$, is a subgroup which consists only of entire conjugacy classes of G.[3] A normal chain of a group G is a sequence of normal subgroups $C_1 \lhd N_{a_1} \lhd N_{a_2} \lhd N_{a_3} \lhd \cdots \lhd N_{as} \lhd G$, in which s is the number of normal subgroups (besides C_1 and G) in the normal chain. If such a chain starts with the identity group C_1 and leads to G and if all of the quotient groups $N_{a_1}/C_1 = C_{a_1}$, $N_{a_2}/N_{a_1} = C_{a_2}$, ..., $G/N_{a_s} = C_{a_{s+1}}$ are cyclic, then G is a composite or soluble group. Otherwise G is a simple group. Simple groups are particularly important in the theory of finite groups.[4] A soluble group can be expressed as a direct product of the factor groups $C_{a_1} \times C_{a_2} \times \cdots \times C_{a_{s+1}}$.

4 SYMMETRY POINT GROUPS

When any set of complete symmetry operations for an object satisfies the above four conditions for a mathematical group, such a group is called a symmetry point group. Such symmetry point groups have a standard designation, called the Schoenflies symbol, based on either a conspicuous operation in the point group (such as the highest order rotation axis) or a common case of occurrence of the symmetry point group (such as describing the symmetry of a well-known polyhedron like the tetrahedron, octahedron, or icosahedron).

There is a systematic way to classify objects by their symmetry point groups based on the following sequence of questions:

1. Is the object linear (i.e. only 'one-dimensional')?
   Linear objects are the only objects having infinite rather than finite symmetry point groups since the linear axis corresponds to an infinite order rotation axis, namely C_∞. If there is a reflection plane perpendicular to the infinite order rotation axis (dividing the object into two equivalent halves), then the symmetry point group is D_∞; if not, the symmetry point group is C_∞.
2. Does the object have multiple 'higher-order' rotation axes (i.e. $C_{>2}$ axes)?
   Multiple axes in this question refer to noncollinear $C_{>2}$ axes. Such nonlinear objects have the symmetries of well-known regular polyhedra and are generally readily recognizable in containing the regular polyhedra in some manner. Such groups are sometimes called the polyhedral point groups. Thus the tetrahedral groups T, T_h, and T_d with 12, 24, and 24 operations, respectively, have four non-collinear C_3 axes and are distinguished by the presence or absence of horizontal (σ_h) or diagonal (σ_d) reflection planes. The octahedral groups O and O_h with 24 and 48 operations, respectively, have not only four noncollinear C_3 axes but also six noncollinear C_4 axes and are distinguished by the presence or absence of reflection planes. The icosahedral groups I and I_h having 60 and 120 operations, respectively, require ten noncollinear C_3 axes and six noncollinear C_5 axes and are also distinguished by the presence or absence of reflection planes.
3. If the object does not belong to either a linear group or a polyhedral group, then does it have proper or improper axes of rotation (i.e. C_n or S_n)?
   If no axes of either type are found, the group is either C_s, C_i, or C_1 with 2, 2, and 1 operations, respectively, depending whether the object has a plane of symmetry (σ), an inversion center (i), or neither. The C_1 designation corresponds to an object with no symmetry at all and therefore to a symmetry point group containing only one element, namely the identity element E.
4. Does the object has an even-order improper rotation axis S_{2n} but no planes of symmetry or any proper rotation axis other than one collinear with the improper rotation axis?
   The presence of an improper rotation axis of even order S_{2n} without any noncollinear proper rotation axes or any reflection planes indicates the symmetry point group S_{2n} with $2n$ operations.
5. If the object does not belong to the linear point groups, the polyhedral point groups, or the point groups C_s, C_n, C_1 or S_{2n}, then look for the highest order rotation axis. Call the highest order rotation axis C_n.
6. Are there nC_2 axes lying in a plane perpendicular to the C_n axis? If there are nC_2 axes lying in a plane perpendicular to the C_n axis, then the object belongs to one of the symmetry point groups D_n, D_{nh}, or D_{nd} with $2n$, $4n$, and $4n$ operations, respectively, depending on whether there are no planes of symmetry, a horizontal plane of symmetry (σ_h), or n vertical planes of symmetry (σ_v), respectively. If there are no C_2 axes lying in a plane perpendicular to the C_n axis, then the object belongs to one of the symmetry point groups C_n, C_{nv}, C_{nh}, with n, $2n$, and $2n$ operations, respectively, depending upon whether there are no planes of symmetry, n vertical planes of symmetry (σ_v), or a horizontal plane of symmetry (σ_h), respectively. If there are only C_2 axes then a unique C_2 axis is chosen as the 'reference axis' if there is any ambiguity as to which C_2 axis to choose.

Some of these ideas are illustrated using the trigonal bipyramid depicted in Figure 1 with the locations of the C_3 and three C_2 axes indicated by a solid arrow and three dotted arrows, respectively.

The symmetry point group of the trigonal bipyramid is D_{3h} of order 12 with the conjugacy classes $E + 2C_3 + 3C_2 + \sigma_h + 2S_3 + 3\sigma_v$. Note the following concerning these conjugacy classes:

1. The identity operation E is in a class by itself.
2. The two operations in the C_3 class correspond to 120° (C_3) and 240° (C_3^2) rotations around the single C_3 axis. Note that the C_3^2 rotation is the inverse of the C_3 rotation, i.e. $C_3^{-1} = C_3^2$.
3. The C_2 rotations around each of the three C_2 axes form the class $3C_2$ of order 3.
4. Reflection in the plane of the equatorial vertices (σ_h) is in a class by itself.
5. The two operations in the S_3 class correspond to 120° and 240° rotations around the C_3 axis followed by reflection in the σ_h plane. Thus $S_3 = (\sigma_h)(C_3)$ and $S_3^2 = (\sigma_h)(C_3^2)$ are two examples of multiplication operations in the D_{3h} point group.
6. The three types of reflections in the planes containing both axial vertices and one of the three equatorial vertices (σ_v) form the class $3\sigma_v$ of order 3.

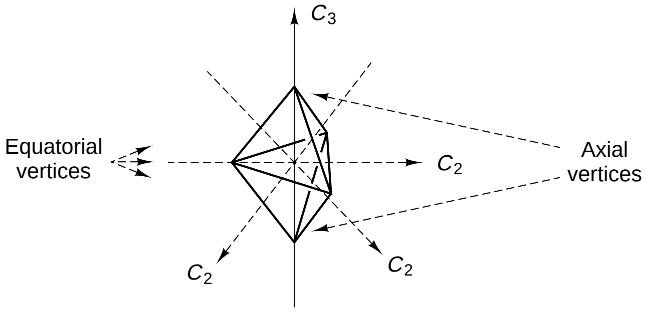

Figure 1 The rotation axes in a trigonal bipyramid

1 INTRODUCTION – THE ELEMENTS

Tc and Re are Mendeleev's eka-manganese and dvi-manganese, which he recognized as blank spaces in his periodic table. Both elements are rare, and Tc is also radioactive. Selected properties: At. no. 43 (Tc), 75 (Re); At. wt. 98.906 (^{99}Tc), 186.207 (Re); Density (20 °C) 11.5 (Tc), 21.0 (Re); Mp (°C) 2200 (Tc), 3180 (Re); Bp (°C) 4567 (Tc); Electronegativity (Pauling) 1.9 (Tc, Re); Metallic radius (Å) 1.36 (Tc), 1.37 (Re); Covalent radius (Å) 1.31 (Tc); Tc for superconductivity (K) 7.7 (Tc); Principal isotopes (half-life, y) 97 (2.6×10^6) (Tc), 98 (1.5×10^6) (Tc), 99 (2.12×10^5) (Tc), 185 (37.4%, stable) (Re), 187 (62.6%, 5×10^{10}) (Re); Reduction potentials (V) for $M^{n+}(aq) + ne^- \rightarrow M(s)$ 0.4 ($n = 2$, Tc), 0.3 ($n = 3$, Re), for $MO_4^-(aq) + 5e^- \rightarrow M^{2+}(aq)$ 0.5 (Tc), 0.42 (Re); Common ox. states (geometries): +1 (oct.), +3 (sq. pyr., oct.), +5 (oct.), +7 (tet., oct.).

Rhenium was first detected (1925), from its X-ray emission, by Noddack, who later isolated it on a macroscopic scale from Mo ores. Re is not normally found alone in minerals but only in association with other metals, such as Mo, Cu, Pd, Zn, Pt, or Nb. Typical Re concentrations in molybdenite ores are 0.6–21 g t^{-1}, where Re can replace Mo in an isomorphous fashion. Re is often produced commercially as a by-product in Mo refining and so it is readily available even though its abundance in the Earth's crust is low (7 ppb). The element is usually isolated as the sparingly soluble potassium perrhenate, which is also a common synthetic precursor for Re chemistry. Re is extremely high melting (3180 °C). The extraction methods depend on the source.[1] It has relatively few uses but it forms part of several heterogeneous bimetallic catalysts, notably Pt–Re for petroleum reforming. Homogeneous catalysis constitutes a fruitful area in current expansion.

^{185}Re and ^{187}Re are the naturally occurring isotopes, the former being stable and the latter weakly radioactive (β-emission) with a very long half-life (5×10^{10} y). The ^{187}Re/^{187}Os isotope system is used in geology and cosmology to determine the age of minerals and meteorites. The radioactive ^{186}Re and ^{188}Re isotopes have nuclear properties suitable for therapeutic applications (Section 4.2); being β-emitting radionuclides (half-lives of 3.78 d and 17.0 h, 1.07 MeV β or 2.12 MeV β, respectively) and the beta particles having a large penetrability, with a low % of γ emission [137 keV γ (9%) or 155 keV γ (15%)]. ^{188}Re is readily obtained from a generator based on the decay of $[^{188}WO_4]^{2-}$ on a stationary phase where it disintegrates to form perrhenate or perrhenic acid. These can be eluted and provide the starting material for radiopharmaceutical preparations.

Tc was the first element to be synthesized artificially, hence its name. It was first detected in 1937 by Perrier and Segré in the products of deuteron bombardment of Mo. All the isotopes of Tc are radioactive but ^{99}Tc, with a half-life of 2.1×10^5 y, is a sufficiently long-lived β-emitter that it can be handled in standard laboratory equipment with appropriate precautions. It is recovered from fission reactors by solvent extraction and ion-exchange methods. It makes up ca. 6% of fission products from ^{235}U and so is available in kilogram amounts for macroscopic chemical study. Hot acid solutions

of $[TcO_4]^-$ lose Tc_2O_7, which allows the element to be separated from Re, in which the oxide becomes volatile only on distillation from hot concentrated sulfuric acid. The ^{99m}Tc isotope required for nuclear medical applications (Section 4.1) is formed in 10^{-6}–10^{-9} M concentrations from $[^{99}MoO_4]^{2-}$ (66 h half-life) loaded in a generator column. The ^{99m}Tc nucleus ($t_{1/2} = 6.02$ h) is a nuclear excited state (hence the m for metastable) that decays by γ-ray emission at 141 keV; the detection of this emission allows imaging of organs. Tc is one of the most important elements in nuclear medicine, being used in the form of its ^{99m}Tc isotope. This has stimulated much work on the element. Ammonium pertechnetate is an effective corrosion inhibitor.

The elements are gray, chemically relatively unreactive powders both having an hcp lattice, and both can be obtained by hydrogen reduction of the ammonium permetallates or by heating $NH_4[MCl_6]$. As powders, both elements burn in oxygen at >400 °C to give the volatile heptaoxides. The metals are insoluble in nonoxidizing mineral acids but do dissolve in concentrated nitric or sulfuric acids or aqueous Br_2. Both elements form compounds with an unusually wide range of oxidation states from −3 to +7, although most M^I and lower compounds are organometallic (*see* ***Technetium: Organometallic Chemistry*** and ***Rhenium: Organometallic Chemistry***).

2 BINARY COMPOUNDS

2.1 Oxides and Sulfides[2]

The yellow heptaoxides (mps, 119.5 °C (Tc); 300 °C (Re)), formed by burning the metals in O_2, are $O_3M–O–MO_3$ (with tetrahedral metal coordinations) in the vapor but are polymeric in the solid with, in the case of Re, alternating corner-sharing ReO_4 and ReO_6. Both dissolve in water to give colorless perrhenic or pertechnetic acids, both strong acids with the structure $O_3M–O–MO_3(OH_2)_2$ in the crystalline form. Both the M_2O_7 oxides and these acids are relevant starting materials for coordination synthesis (see below).

Red ReO_3, which can be obtained by CO reduction of the heptaoxide at 175–280 °C, is a good electrical conductor with a metal-like temperature dependence; the d^1 electron is clearly delocalized. It has octahedral Re^{VI} and easily forms nonstoichiometric bronzes in which an alkali metal donates an electron to the metal–oxo lattice and enters the structure as a cation. Supported ReO_3 is important in alkene metathesis catalysis. No Tc analog is known. Blue Re_2O_5, brown ReO_2, and black Re_2O_3 are also known. For Tc, the only lower oxide is TcO_2.

The sulfides M_2S_7 and MS_2 are known, the first from the permetallate and either H_2S or thiosulfate and 2N HCl, and the latter by reducing the heptasulfide with sulfur or from the elements at 400 °C. The Re materials have catalytic activity for the hydrogenation of unsaturated species and are much less sensitive to poisons, especially S-based poisons, than the platinum group metal catalysts. Both diselenides and both ditellurides are formed from the elements on heating. Ternary chalcogenides, such as $M'_4M_6Q_{12}$ (M' = alkali metal; Q = S, Se), $M'_4M_6Q_{13}$, and $M'_{10}M_6S_{14}$, contain $[M_6Q_8]$ clusters with an octahedron of six metals.

2.2 Halides[2]

Re has the only heptavalent halide of these elements, ReF_7, a yellow, low-melting species, from fluorination of the element at high temperature and pressure. Fluorination at 120 °C and 1 atm gives the hexafluoride (mp 19 °C), which can be reduced with H_2 to the green-yellow, low-melting pentafluoride, or with Re to the blue ReF_4. For Tc, only the hexa- and pentafluorides are known. ReF_7 and ReX_6 have probably pentagonal bipyramidal and octahedral geometries respectively. Most of the penta- to hepta-halides can be obtained directly from the elements at appropriate temperatures and pressures.

$ReCl_6$ (mp 29 °C) is a greenish-red species. Chlorination of the element at ca. 600 °C gives dark red Re_2Cl_{10}, rhenium 'pentachloride', the dimer $[Cl_4Re(\mu\text{-}Cl)_2ReCl_4]$ with octahedral coordination that, after $KReO_4$, is the most common starting material for Re chemistry. The Re^{III} halides are obtained by thermal decomposition of higher halides, and heating Re_2Cl_{10} gives the important cluster halide Re_3Cl_9, which has a metal–metal double-bonded triangle of Re, with each Re–Re bond (d(Re–Re) = 2.48 Å) bridged by a Cl; no Tc analog is known. This unit persists in much of the chemistry of the compound, such as in the reaction with pyridine to give $[Re_3Cl_9(py)_3]$. Heating Re_3Cl_9 with Re_2Cl_{10} is a good route to $ReCl_4$, which is made of $ReCl_6$ octahedra with shared faces and corners, and has also metal–metal bonds, although not so extensive as in Re^{III} halides. Tc forms $TcCl_6$ and $TcCl_4$, the latter from chlorination of the element or from CCl_4 and the heptaoxide; unlike the Re analog, Tc–Tc bonding is not present.

The brown pentabromide is formed by bromination of Re at high temperature. The dark red tetrabromide is obtained from $HReO_4$ and HBr. Pyrolysis of the pentabromide gives reddish-brown Re_3Br_9, which resembles the analogous chloride. The highest iodide is black ReI_4, obtained from $HReO_4$ and HI; on heating it gives the black triiodide and diiodide. The latter probably contains Re–Re bonds.

Oxohalides are common: ReO_2F_3, $ReOF_5$, ReO_3X, $ReOX_4$, and $ReOX_3$ (X = F, Cl, Br), as well as TcO_3X, $TcOX_4$ (X = Cl, F), and $TcOCl_3$, are known. The oxohalides can be prepared by treatment of the halides with oxygen or of the oxides with halogens. Both the halides and the oxohalides with the oxidation states +5 and +6 readily hydrolyze with disproportionation to $[MO_4]^-$ and MO_2.

2.3 Other Binary Compounds

Several refractory borides, such as ReB_2 and $Re_{23}B_6$, can be prepared from heating the elements at ca. 1200 °C. $ReSi_2$ is a semiconductor. The nitride Re_3N is formed from ammonia and ammonium perrhenate, but Re does not form a nitride with N_2. MP_3, prepared from the elements in the presence of iodine, contain M^{III} and have both P–P and M–M bonds.[3] Re_2P, Re_3Q_7, and ReP are also known (Q = P or As).[4] Carbon dissolves in Re up to 5 mol%.

3 COMPLEXES

Several recent reviews on the coordination chemistry of Tc[5–7] and Re[8,9] are available.

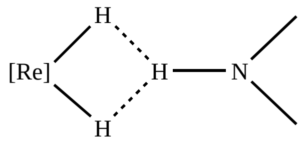
3.1 Hydrides

Rhenium forms one of the most extensive series of polyhydrides.[8,10,11] The most remarkable is the homoleptic $K_2[ReH_9]$, with a tricapped trigonal prism (TTP) geometry. The Tc analog is also known. The Re compound may be substituted with a variety of phosphines (=L) to give $K[LReH_8]$. Treatment of $[ReOCl_3L_2]$ with hydride reducing agents under various conditions gives the polyhydrides $[ReH_7L_2]$ and $[ReH_5L_3]$. On heating, $[ReH_7(PPh_3)_2]$ converts to the unusual dimeric hydride $[H_2(PPh_3)_2Re(\mu\text{-}H)_4ReH_2(PPh_3)_2]$ with the $M(\mu\text{-}H)_4M$ system. Where L_2 is dppe, a neutron diffraction study of $[ReH_7L_2]$ shows a TTP structure, but where L is $P(p\text{-tolyl})_3$, a similar study shows the first example of a stretched dihydrogen complex, the H–H distance being 1.357 Å.[12] The coordination polyhedron is no longer TTP but dodecahedral, as appropriate for the formulation $[Re(H_2)H_5L_2]$.

Although a short ^1H NMR T_1 relaxation time (which can be related with the H···H distance) is usually diagnostic for a nonclassical $\eta^2\text{-}H_2$ ligand, T_1 measurements can be inconclusive for some Re polyhydrides. Nevertheless, in the series $[ReH_7\{P(C_6H_4X\text{-}4)_3\}_2]$ (X = OMe, Me, H, F, CF_3), with isosteric phosphines, T_1 decreases with the electron-withdrawing character of X as measured by the Hammett's σ_p constant, and the complexes are believed to display an elongated $\eta^2\text{-}H_2$ ligand with a H···H distance that shortens with the increase of that character.[13] In accord, the type of Re–H bond for $[ReH_2L_5]^+$ is dependent on the other ligands: a π-acid L, like CO or $CNBu^t$, favors the Re^I dihydrogen formulation, whereas a more basic L, for example, PMe_3, promotes the Re^{III} dihydride structure.[14] Neutral low oxidation state Re (or Tc)–H complexes are also known, as the dinitrogen complex *trans*-$[ReH(N_2)(dppe)_2]$ (obtained on treatment of $K_2[ReH_9]$ with dppe under N_2)[15] or the dihydrogen complexes $[ReCl(\eta^2\text{-}H_2)(PR_3)_4]$, which (e.g. $2PR_3$ = dppe, dppee) can display long H–H bonds,[16] and $[TcCl(\eta^2\text{-}H_2)(dppe)_2]$ derived from H_2 addition to $[TcCl(dppe)_2]$.[17]

Multinuclear Re hydrides, in particular CO/phosphine complexes, with the hydride bridging two or three metals and compounds with H atoms bridging Re and other metals, for example, obtained from the reactions of Re polyhydrides with metal salts,[8] have been reported. The coordination chemistry of hydrido/phosphine complexes has been extended, in a number of cases, to related phosphite, phosphonite, or arsine complexes.[8]

The H ligands can form interesting intermolecular Re–H···H–N 'dihydrogen bonds' with a suitable H-donor like the indole or imidazole of crystallization in $[ReH_5(PPh_3)_3]\cdot indole\cdot C_6H_6$ and $[ReH_5(PPh_3)_2(imidazole)]\cdot 0.5imidazole\cdot 1.5C_6H_6$, respectively, the latter obtained by treatment of $[ReH_7(PPh_3)_2]$ with imidazole in benzene.[18,19] The N–H moiety of the base is close to two of the Re hydrides forming a three-centre dihydrogen bond (**1**).



(**1**)

Protonation of a polyhydride can occur at the metal, increasing the number of hydride ligands or leading to a $\eta^2\text{-}H_2$ ligand, which can liberate as H_2. In spite of the low kinetic and thermodynamic (pK_a = 25.5 in acetonitrile) acidity of $[ReH_4(PMe_2Ph)_4]^+$, deprotonation occurs by a base like potassium phenolate.[20] Replacement of one phosphine by CO enhances the acidity of the complex by at least 7 orders of magnitude ($pK_a < 18.5$).[20]

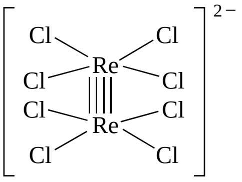
Other common hydride reactions include its abstraction and replacement, for example, by a halide or a neutral ligand as in $[ReH_5L_3]$ [$L_3 = (PPh_3)_3$,[21] triphosphine, that is, Cyttp[22]] that, on treatment with the hydride abstractor $[C_7H_7]A$ (A = PF_6, BF_4) in the presence of a nitrile or an isocyanide (L′), lead to the corresponding $[ReH_4(L')L_3]A$. Insertion of an unsaturated molecule into a Re–H bond has also been reported, for example, in the reactions of $[ReH_5(Cyttp)]$ with heterocumulenes X=C=S [X = S, $p\text{-}O_2NC_6H_4N$, EtOC(O)N] to afford $[ReH_4(SCH{=}X)(Cyttp)]$.[22]

On heating in alkane in the presence of a hydrogen acceptor like $t\text{-}BuCH{=}CH_2$, $[ReH_7L_2]$ (L = PPh_3) gives dehydrogenation of alkanes, such as of cyclooctane to cyclooctene; enhanced reactivity is displayed by the chelating bis(silyl) complexes $[ReH_5(disil)(PPh_3)_2]$, with a stretched $\eta^2\text{-}H_2$ ligand, formed by reaction of $[ReH_7(PPh_3)_2]$ with 1,2-bis(dimethylsilyl)benzene or 1,2-bis(dimethylsilyl)ethane.[23] $[ReH_5(triphos)]$ also catalyzes alkane dehydrogenation driven by continuous removal of H_2 upon reflux of substrate or of cosolvent or by inert gas flow.

Scorpionate hydride complexes are also documented. [$TpReOCl_2$] reacts with $LiAlH_4$ to give [$TpReH_6$], which has a classical structure with all-terminal hydrides and was the first N-donor stabilized polyhydride; a related and classical species, [$\{CH_2(pz)_2\}ReH_7$], is also known.[24] The oxo-hydrides [Tp*ReO(H)Cl], [Tp^*ReOH_2] and [TpReO(H)Cl] are obtained by reactions of [Tp*ReO(OMe)Cl], [$Tp^*ReO(OMe)_2$], or [TpReO(OEt)Cl] with $BH_3{\cdot}THF$ at low temperature, whereas [Tp^*ReH_6] is formed upon prolonged reaction of [$Tp^*ReO(OR)_2$] with excess $BH_3{\cdot}THF$.[25] Insertion into a Re–H bond can occur and [Tp*ReO(X)(OTf)] (X = OEt, Et, Pr) are formed by reacting [Tp*ReO(OH)(OTf)] (derived from reaction of [Tp*ReO(H)Cl] with AgOTf) with acetaldehyde, ethylene, or propylene, respectively.[25] The heteroscorpionate hydride complexes [$ReH_2\{\eta^3\text{-}B(OR)_2(pz)_2\}(PPh_3)_2$] and [$ReH_4\{\eta^3\text{-}BH(OR)(pz^*)_2\}(PPh_3)$] are prepared on reaction of [$ReOCl_3(PPh_3)_2$] with NaBp or NaBp*, respectively, in ROH as solvent.[26]

3.2 Metal–metal Bonded Species

$[Re_2Cl_8]^{2-}$ (**2**) was the first compound shown to contain a quadruple bond. It can be formed from [Bu_4N][ReO_4] and PhCOCl. Apart from a σ and two π bonds from overlap of d_{z^2} orbitals (σ) (z is the M–M axis) and of d_{xz} and d_{yz} (π) orbitals on each metal, the δ-bond comes from overlap of d_{xy} orbitals, implying that the two $ReCl_4$ units are eclipsed, the sterically least favorable arrangement.[2,27] The absorption in the visible (700 nm) assigned to a $\delta \rightarrow \delta^*$ transition is responsible for the royal blue color of the ion. One-electron oxidation and reduction of (**2**) and of its Tc analog is possible electrochemically.



In the Cs salt:
Re–Re 2.237 Å
Re–Re–Cl 104°
Cl–Re–Cl 87°

(**2**)

$[Re_2X_8]^{2-}$ (X = Cl, Br) are usual starting materials for dirhenium(II) compounds. (**2**) reacts with carboxylic acids to give [$Re_2Cl_2(RCO_2)_4$], quadruply bonded species in which the carboxylates bridge the two metals and the halides bind along the M–M axis. Phosphine (=L) substitution occurs with reduction and gives [$Re_2Cl_4L_4$], a species in which the δ^* is filled and so the bond order drops to three. $NaBH_4$ reacts with (**2**) to give [$H_2L_2Re(\mu\text{-}H)_4ReH_2L_2$]. (**2**) reacts with dppm to give a triply M–M bonded species of the [$Re_2Cl_4L_4$] type. With the dppm (L_2) bridges to hold the dirhenium system together more tightly, it is possible to effect sequential oxidation and chloride addition ($-e^- + Cl^-$) two times, with concomitant M–M bond order decrease to 2.5 and 2.0. Other bridging groups have been used, such as Ph_2P(2-pyridyl) (=L), which gives [$Re_2Cl_4L_3$].

Dinuclear complexes with bridging both hydrides and diphosphines, prepared from multiply bonded Re species like [$Re_2Cl_4(\mu\text{-dppm})_2$] or [$Re_2Cl_4(\mu\text{-dmpm})_3$], exhibit a degree of Re–Re bonding that increases with the number (n) of the bridging hydrides,[28] for example, short Re–Re contacts of 2.5–2.6 Å occur for compounds with $n = 3$ or 4 like $[Re_2H_2(\mu\text{-}H)_3(\mu\text{-dppe})(dppe)_2]^+$, whereas no Re–Re bond is observed for $n = 1$, for example, in [$Re_2H_4(\mu\text{-}H)(\mu\text{-dmpm})_3$].

The Tc analogue of (**2**), $[Tc_2Cl_8]^{2-}$, is known but is less stable and has a longer M–M bond (2.147 Å) than expected; paramagnetic $[Tc_2Cl_8]^{3-}$ is easier to obtain by Zn reduction of $[TcCl_6]^{2-}$.

3.3 Complexes with Group 14 Elements

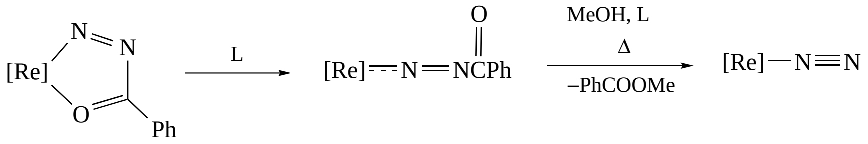
Re has an extensive organometallic chemistry, for example, the oxo-alkyls [$MeReO_3$], [Me_3ReO_2], and [Me_4ReO] (*see* ***Rhenium: Organometallic Chemistry***) but does not have many significant complexes with the other Group 14 elements. [ReH_7L_2] (L = PPh_3) reacts with R_3EH (E = Si or Sn) to give adducts [$Re(ER_3)H_6L_2$] in which the TTP structure of [ReH_7L_2] is retained but in which neutron diffraction shows that two short Si···H distances are present. For a chelating disilane such as $(Me_2SiH)_2O$, the disilyl derivative [$Re\{(Me_2Si)_2O\}H_5L_2$] can be made (see Section 3.1 for other examples).

3.4 Complexes with Group 15 Elements

Re is one of the few elements in which series of N_2 complexes can be obtained,[29,30] normally from organohydrazines, which display a relevant role in the coordination chemistry of this metal, constituting also sources of a variety of other N-ligands like diazenides, hydrazides, and diazenes, whose formal bond description[31] can follow different conventions. The N_2 complexes, usually with a +1 metal oxidation state, can be formed by reaction of [$ReOCl_3(PPh_3)_2$] with benzoylhydrazine to give the cyclic hydrazide of Scheme 1, which is reduced with phosphine, phosphite, or phosphonite (=L) in refluxing MeOH to give *trans*-[$ReCl(N_2)L_4$] (**3**)[32,33] or related products. Mixed amine/phosphine and amine/phosphite N_2 complexes, which can be chiral,[34] can be prepared in similar ways, involving also ligand replacement by the appropriate amine.

The isolation of the hydrazide or derived diazenide species on the way to the N_2 complex is not always required and [$Re(N_2)_2L_4$][BPh_4] [L = $P(OMe)_3$, $P(OEt)_3$] can be prepared in a single-pot synthesis from reaction of [$ReOCl_3(AsPh_3)_2$] with L and Bu^tNHNH_2 in THF/ROH (R = Me, Et).[35]

The chloro-Re^I-N_2 complexes (**3**), typically (**3a**) (L_2 = dppe) and (**3b**) (L = PMe_2Ph), are particularly stable and the coordinated N_2 survives Cl^- replacement by NCS^-,



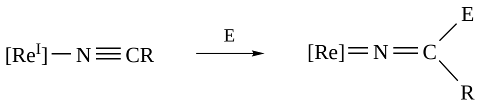
Scheme 1

NCO^-, or N_3^-,[36] phosphine or phosphite replacement by CNR[37] (which can compete with N_2 for the π-electron release from Re), or even one-electron oxidation of the complex. The ν (N≡N) stretching frequencies in the IR spectra are very low for terminally bound N_2, for example, 1923 cm^{-1} in (**3b**). The N–N distance at 1.06 Å is only slightly elongated relative to free N_2. The coordinated dinitrogen is very basic and linear Re–N–N–M′ adducts are formed with Lewis acids,[29,30] such as *trans*-[ReCl(N=N–$AlMe_3$)L_4], *trans*-[ClL_4Re–N≡N–Fe(porph)]$^+$,[38] or [{ClL_4Re=N=N=}$_2$Mo Cl_4]$^+$. The N–N distance in the latter is long, 1.285 Å, and ν (N=N) stretching is low, 1660 cm^{-1}, showing that N_2 has been reduced toward the diimine level. Other N_2-bridged bimetallic complexes are known, for example, the pyrazolylborate [{Tp′M(CO)$_2$}$_2$(μ-N_2)] (M = Tc, Tp′ = Tp*;[39] M = Re, Tp′ = Tp[40]) with the strong CO competitor for π-electron backbonding. PhCOCl reacts with (**3b**) to give *trans*-[ReCl_2(N=N–COPh)L_3],[30] an unusual case of C–N bond formation from an N_2 complex.

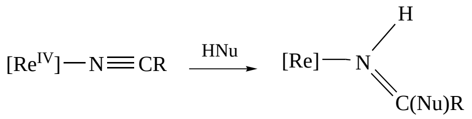
trans-[ReCl(N_2)(dppe)$_2$] (**3a**) is a good precursor for a variety of other N- or P-ligated species, for example, *trans*- or *cis*-[ReCl(NCR)(dppe)$_2$] (**4**) (R = alkyl, aryl); *trans*- or *cis*-[Re(NCR)$_2$(dppe)$_2$]$^+$ on reactions with NCR;[41–43] *trans*-[Re(OH)(N=CR′$_2$)(dppe)$_2$] in which the azavinylidene (or methyleneamide) is derived from oxidative addition of an oxime, HON=CR′$_2$, with N–O bond cleavage;[44] *trans*-[Re(NO)$_2$(dppe)$_2$]$^+$ (a formal 20-electron Re^{-I} complex)[45] and *trans*-[ReCl(NO)(dppe)$_2$][NO_3]$_2$[46] on reaction with NO that in the latter case is oxidized to nitrate; and *trans*-[ReCl(P≡CBu^t)(dppe)$_2$] in which the phosphaalkyne undergoes spontaneous hydrolysis to give the phosphinidine oxide *trans*-[ReCl{P(O)CH_2Bu^t}(dppe)$_2$].[47] The mixed phosphirene-, cyanamide-, or cyanoguanidine-N_2 complexes *mer*-[ReCl(N_2)L′L_3] [L′ = PPhCPh=CPh,[48] NCNR_2 (R = Me, Et, H);[49] L = PMePh_2, PMe_2Ph] are obtained from reaction of the appropriate (**3**) and L′. The cyanamide complexes can also be obtained,[49] in a more direct way, by refluxing a methanol solution of NCNR_2 and the benzodiazenido complex [ReCl_2(NNCOPh)L_3], which is a precursor for (**3**) (Scheme 1). The isocyanide[50,51] and alkyne-derived[47] vinylidene and allene complexes *trans*-[ReCl(L′)(dppe)$_2$] (**5**) (L′ = CNR, C=CHR, η^2-CH_2=C=CHPh), related to the nitrile compounds (**4**), are also obtained from (**3a**).

As a result of the strong π-electron-donating ability of the Re^I center in (**3a**) and (**5**), the nitrile and the other unsaturated L′ ligands are activated toward β-electrophilic attack (typically protonation) to afford the corresponding azavinylidene (reaction 1, E = H^+),[52] aminocarbyne,[50] carbyne,[47] or η^2-vinyl[47] products, that is, *trans*- or *cis*-[ReCl(N=CHR)(dppe)$_2$]$^+$ or *trans*-[ReCl(L′H)(dppe)$_2$]$^+$ (**6**) (L′H = CNHR, CCH_2R, η^2-CH_2CCH_2Ph), respectively. The azavinylidene ligand is essentially linear[52] thus acting as a 3e-donor, as the other L′H ligands.

However, when bound to a higher metal oxidation state center, with a limited π-electron donor ability, the nitriles display ν (N≡C) higher than in the free state and can be activated toward nucleophilic attack,[42,43] as observed for the reactions of *cis*-[ReCl_4(NCMe)$_2$] (formed by spontaneous reduction of ReCl_5 in NCMe) with oximes, HON=CRR′, amino-alkylated adenines, or alcohols, which behave as protic nucleophiles (reaction 2) to yield, for example, in the first case, the imine complexes *cis*-[ReCl_4{NH=C(Me)ON=CRR′}$_2$].



(1)



(2)

Isocyanides, when bound to weak π-donor metal centers, can also undergo addition of protic nucleophiles (HNu) to form aminocarbene M=C(Nu)NHR species.[53] Hence, a parallelism of behavior is observed for nitriles and isocyanides. In both ligands, either the electrophilic or the nucleophilic addition occurs at the unsaturated atom at the β-position that exhibits a higher reactivity than the metal coordinated terminal atom.

Nitriles are activated to hydrolysis by Re^{III} in di- and tri-nuclear cores with multiple metal–metal bonds like [NBu$^t_4$]$_2$[Re_2Cl_8] and [Re_3(μ-Cl)$_3$$Cl_6$], to form amidate species as [NBu$^t_4$][Re_2Cl_6(μ-PhCONH)] and [NBu$^t_4$][Re_2Cl_5 (μ-MeCONH)(μ-MeC(OH)N)]. The reactions are proposed to involve intramolecular nucleophilic attack of a hydroxide ligand to an NCR ligating an adjacent Re atom.[54]

Redox potential-electronic structure relationships in 18- and 17-electron mononitrile complexes of Re have been established.[55] It was possible to estimate, for the nitrile and related ligands, for example, in complexes (**3–6**), the values of the electrochemical P_L ligand parameter, a measure of the net electron donor minus π-acceptor character of a ligand. The

order of this character is as follows: vinylidenes > NCR > CNR > N_2 ≥ CO ≥ aminocarbynes > carbynes.[56]

The relative stability of the geometrical isomers of $[ReCl(NCR)(dppe)_2]$ (**4**) and $[Re(NCR)_2(dppe)_2]^+$ is markedly dependent on the metal oxidation state, oxidation promoting cis → trans isomerization.[57] The kinetics was investigated by digital simulation of cyclic voltammetry, according to double-square schemes. A high thermodynamic gain toward the trans isomer results from the first electron-transfer, but kinetic reasons hamper the isomerization, which, in order to readily occur, requires a second oxidation step to Re^{III}. The isomeric equilibrium constants and the rate constant for the isomerization respond to electronic and steric effects.[57] The related carbonyl complex *cis*-$[ReCl(CO)(dppe)_2]$ also undergoes an oxidative cis → trans isomeric conversion, which follows an electron-transfer chain (ETC) catalytic process.[57]

Nitrosyl complexes are rather numerous and $[Re(NO)X_5]^{2-}$ is known for all the halides (= X); addition of phen or bipy (= L–L) gives $[Re(NO)X_3(L–L)]$ or of pyridine, alcohols, DMSO, or MeCN (= solv) gives $[Re(NO)X_4(solv)]^-$; PPh_3 in EtOH followed by $NaBH_4$ gives the nitrosyl hydride $[ReH_2(NO)(PPh_3)_3]$.[58] Other nitrosyl complexes include $[Re(NO)Cl_2(OMe)(PPh_3)_2]$ and $[Tc(NO)Br_4]^-$ and the low-valent complexes indicated above.

Polypyridyl ligands can also stabilize low metal oxidation states since they can accept electron density from the metal. Among conventional N-donors, the $[M(bipy)_3]^+$ cations are known,[59] as are $[MOX_3(bipy)]$ (X = Cl or Br). Na/Hg reduction of $[ReCl_4(THF)_2]$ in the presence of phen or bipy (= L–L) give formally Re^0 species $[Re(L–L)_3]$, but the complex is probably better described as having reduced ligands. The coordination chemistry of Re (and, to a lesser extent, Tc) with pyrazolylborate ligands, that is, of scorpionate oxo-complexes, is being quite developed (Section 3.5).

Many tertiary phosphine complexes are known (see above), especially in oxidation states from +1 to +5: (**3–6**), $[MH(N_2)(dppe)_2]$, $[ReCl_3(PR_3)_3]$, $[TcBr_2(dppe)_2]^+$, and $[ReOCl_3(PR_3)_2]$ are typical. *cis*-$[ReCl_4(NCMe)_2]$, mentioned above, reacts with monodentate phosphines, L, to give *trans*-$[ReCl_4L_2]$; bidentate phosphines also react but the products are very dependent on conditions.[60]

Trigonal bipyramidal $[ReCl(dppe)_2]$, formed by photolytic displacement of N_2 from (**2a**),[61] is a rare example of 16-electron Re^I. It is also formed by cathodically induced Re–Cl bond cleavage in *trans*-$[ReCl_2(dppe)_2]^n$ (n = 0, 1).[62] The analogous $[TcCl(dppe)_2]$, obtained by reduction of $[TcCl_4(PPh_3)_2]$ with Zn in the presence of dppe, adds dinitrogen to form $[TcCl(N_2)(dppe)_2]$.[63] Both $[MCl(dppe)_2]$ add H_2 to give $[MCl(\eta^2\text{-}H_2)(dppe)_2]$.

Phosphites, in comparison with phosphines, tend to give lower oxidation state complexes: $[Re_2\{P(OR)_3\}_{10}]$, $[ReH\{P(OR)_3\}_5]$, and $[ReH_3\{P(OR)_3\}_4]$.[64] Much of the chemistry of Re^I involves carbonyl complexes (*see* ***Rhenium: Organometallic Chemistry***).

The multiple bonded π-electron donor nitride (N^{3-}) and imide (NR^{2-}) ligands are isoelectronic with the oxo (O^{2-}) ligand and also able to stabilize both Tc and Re (which can easily form multiple bonds to those electronegative elements) in the highest oxidation states (typically from +7 to +5). The +5 oxidation state provides the largest number of structurally characterized complexes and the strong trans influence of those ligands can lead to square-pyramidal five-coordinate compounds or to six-coordinate complexes with a pronounced tetragonal distortion.[58] The imido $\{M{=}NR\}^{3+}$ core is rarer, in particular for Tc. The nitride complexes $[ReNCl_4]^-$, $[ReNCl_2L_2]$ (L = PPh_3), and $[ReNCl_2L_3]$ (L = $PMePh_2$) are typical in having Re–N distances of 1.6–1.7 Å and, in the latter case, long M–X distances trans to ReN.[65] $[ReNCl_4]$ has Re≡N–Re chains in the structure.[66] $[ReNF_4]$ is also known from the reaction of Me_3SiN_3 with ReF_6. Since the first Tc≡N complex, $[TcN(dtc)_2]$ (1981; d(Tc–N) = 1.604(6) Å), a number have been made[5] and the corresponding ^{99m}Tc complexes can find radiopharmaceutical application (Section 4.1). These species are also basic at N and form adducts with Lewis acids, which can be applied to the synthesis of imido complexes.

Imido complexes are also readily formed from reactions of amines or isocyanates with oxides.[8] For example, $[Re({=}NR)Cl_3(PPh_3)_2]$ is obtained from primary amines and $[ReOCl_3(PPh_3)_2]$, and $[XRe({=}NR)_3]$ (**7**) (X = $OSiR'_3$, Cl; R = Bu^t), which are good starting materials for other Re^{VII} imido complexes, are prepared by reactions of amines or isocyanates with $[Me_3SiOReO_3]$ (X = $OSiR'_3$) or R_2O_7 (X = Cl).

Imido ligands are stronger electron-donors than the oxo ligand leading, for example, to Re^{VII} complexes harder to reduce (X in (**7**) can thus be a readily oxidizable species like H^- or PR_2^-) and reactive toward Lewis acids and proton. Hence, protonation of $[XRe({=}NR)_3]$ with HCl affords the di(imido) complexes $[ReCl_3({=}NR)_2]$. The tunable steric bulkiness of the =NR ligands can stabilize otherwise inaccessible low-coordination species like the trigonal-planar $[Re(NAr)_3]^-$.[67] Haloimido complexes may also have synthetic value.[68]

3.5 Complexes of Group 16 Elements

Perrhenates are important oxo-complexes and the perrhenate $[ReO_4]^-$ group can act as a ligand in metal complexes.[69] The Tl^+ and K^+ salts are sparingly soluble, the Ba^{2+} and NH_4^+ salts are moderately soluble, while the Na^+, Mg^{2+}, and Ca^{2+} salts are very soluble (1.6, ca. 10, 53.2, 62.3, 1000, 1679, and 1776 g L^{-1}, respectively, at 20 °C). The purple color of permanganate is a result of ligand-to-metal charge transfer (LMCT). The corresponding LMCT bands for the colorless pertechnetate and perrhenate ions are found in the UV because the central metals are more difficult to reduce. Salts of the rhenate ion, such as $Ba[ReO_4]$, are unstable to air and to water. Aqueous Re^V easily disproportionates into Re^{VII} and Re^{IV}, as

shown by the hydrolysis of $ReCl_5$ to $HReO_4$ and ReO_2, driven in part by the insolubility of the dioxide.

Some of the early work in Re chemistry was in error because it was not realized how easily an oxo atom can be incorporated into a complex. The strong IR Re=O stretch at 950–1000 cm^{-1} should always be searched. A problem with X-ray methods is the ease with which oxo-complexes can disorder and cocrystallize with halides.[70]

Oxo-complexes are very important for Re and Tc and dominate the aqueous chemistry. For both Re and Tc, the +5 oxidation state is the most studied one. This reflects the relevance of this oxidation state in ^{99m}Tc complexes applied in nuclear medicine and the use of Re complexes as nonradioactive models.[5,8] The complexes often exhibit the oxo $\{M{=}O\}^{3+}$ or the nitrido $\{M{\equiv}N\}^{2+}$ core (Section 3.4).

The coordination chemistries of these metals often are comparable, but the stronger oxidizing character of the Tc centers can result in considerable differences.

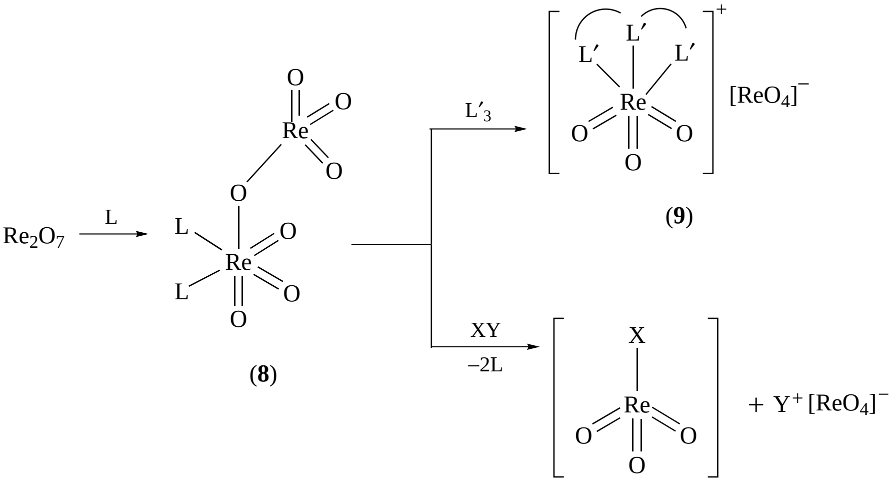
The permetallates $[MO_4]^-$ are the most common starting materials in this area, the Tc compound being somewhat more easily reduced. Air sensitive dianions are formed in aqueous solution by electrochemical reduction. Perrhenate reacts with phosphines in alcohol solutions containing HCl to give the very stable green oxo-complexes $[ReOCl_3L_2]$; the PPh_3 complex is a standard synthetic precursor in Re chemistry. In contrast, $[TcO_4]^-$ loses the oxo groups much more readily and is reduced by the phosphine to $[TcCl_4L_2]$ or $[TcCl_3L_3]$ under similar conditions. The Cl trans to the oxo group in $[ReOCl_3L_2]$ is labilized by the trans effect and is readily replaceable; for example, EtOH gives $[ReO(OEt)Cl_2L_2]$, which in turn reacts with acidic en (= L_2) or pyridine (=L) solutions to form the dioxo complexes *trans*-$[ReO_2L_4]^+$. The *trans*-Re^VO_2 group is a common one, as well as *trans*-O=Re–O–Re=O, for example, in $[Re_2O_3py_4Cl_4]$ formed from $[ReOCl_3(PPh_3)_2]$ with pyridine. Oxo groups can undergo protonation/deprotonation equilibria.

Tc^V oxo-complexes are often either of the square-pyramidal $[TcOL_4]$ type with a vacancy opposite the oxo group, or of the *trans*-$[TcO_2L_4]^+$ type. Examples used for organ imaging are given in Section 4.1. A number of THF complexes, such as $[Re_3Cl_9(THF)_3]$ and $[ReCl_4(THF)_2]$, are known. The homoleptic alkoxide $[Re(OMe)_6]$ is formed from ReF_6 and $Si(OMe)_4$.

Re^{VII} oxo-complexes are particularly interesting and their inorganic and organometallic chemistries, as well as those of related imido and amido complexes, have been reviewed.[71] The Re^{VII} trioxo complexes are much more common than the dioxo or monoxo ones, the latter being normally derived from Re^{VII} oxyfluorides or present catecholate ligands.[8]

Re_2O_7 is a key starting material. Its solid-state polymeric structure is broken by solvolysis, upon dissolution, to form the solvent adducts $Re_2O_7{\cdot}L_2$ (**8**) (L = H_2O, NCMe, THF, DMF, etc., the Re–O–Re unit being essentially linear for L = H_2O but bent in other cases) with the octahedral center bearing both solvent ligands (Scheme 2). Similar structures are usually obtained by reacting Re_2O_7 in THF or NCMe with bidentate ligands (e.g. $L_2 = 2,2'$-bipyridine), but tridentate N or S donors (e.g. L'_3 = $HC(pz)_3$, 1,4,7-triazacyclononane or 1,4,7-trithiacyclononane) lead to the heterolytic cleavage of the μ-O bridge to give the ionic $[L'_3ReO_3][ReO_4]$ products (**9**).[71] Hence, Re_2O_7 can be regarded as a type $[XReO_3]$ (X = ReO_4) species with a $ReO_4{}^-$ leaving group that can be replaced by various nucleophiles like halides or pseudohalides to yield (Scheme 2) the trioxo complexes $[XReO_3]$ (**10**) (X = F, Cl, Br, CN, SCN), isolated as their bipy adducts.[71]

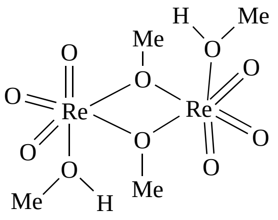
Alkoxide analogues like $[(R_3EO)ReO_3]$ (E = Si, Ge, Sn, Pb) can be obtained by related methods on reaction of Re_2O_7 with $(Me_3Si)_2O$ or Ph_3SiOH, Me_3Ge, Me_4Sn, or



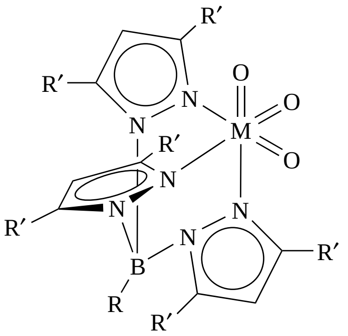
(**8**) (**9**) (**10**)

Scheme 2

Ph_4Pb respectively.[71] The siloxy derivative $[(Me_3SiO)ReO_3]$, known since long, can be used for the preparation of alkoxides $[(RO)ReO_3]$ on reaction with Me_3SiOR and as a starting material for organometallic Re oxides. The alkoxides can also be prepared by reaction of $[ClReO_3]$ with Me_3SiOR. They are unstable at room temperature, but are stabilized by adduct formation to give hexacoordinate species, for example *fac*-$[(RO)ReO_3(tmeda)]$ (R = Me, Bu^t); by dimerization, for example, in the case of $[\{ReO_3(MeOH)\}_2(\mu\text{-}OMe)_2]$ (**11**) (which, upon MeOH evolution, polymerizes to $[(MeO)ReO_3]_n$); or by intramolecular arrangements.[71]



(**11**)



(**12**)

M = Re, Tc
R = H, pz, Ph
R′ = H, Me

Scorpionate Re^{VII} or Tc^{VII} trioxides $[Tp'MO_3]$ (**12**) (M = Re, Tc) with tridentate hydrotris- and tetrakis(pyrazolyl)-borates and related ligands [Tp′ = Tp, Tp*, $B(pz)_4$ (pzTp) or $(Ph)B(pz)_3$ (PhTp)] are obtained by reaction of M_2O_7 with the appropriate Na^+ or K^+ scorpionate salt (XY, Scheme 2); $Na[MO_4]$ or $K[MO_4]$ is the other product.[71–73] They exhibit a distorted octahedral coordination and their chemistry, as well as of the other (much less studied) Re or Tc oxidation state scorpionate complexes, has been reviewed.[72,73]

Like the related η^5-cyclopentadienyl $[C_pMO_3]$ species, $[TpMO_3]$ adds ethylene to give the glycolate $[TpMO(OCH_2CH_2O)]$, which is stable for Tc but reverts to the trioxide for Re. $[Tp'ReO_3]$ can undergo reductive deoxygenation with PPh_3 to give the Re^V dimers $[Tp'ReO(\mu\text{-}O)]_2$ (**13**) (Tp′ = Tp, pzTp) or, in the presence of L (pyridine, imidazole, 1/2 diphosphine), the dioxo complexes *trans*-$[(\kappa^2\text{-}Tp')ReO_2L_2]$ (Tp′ = Tp, pzTp, PhTp) with a bidentate pyrazolylborate and, in the presence of $ClSiMe_3$, the monoxo species $[Tp'ReOCl_2]$ (**14**) (Tp′ = Tp, pzTp, Tp*), which can be further deoxygenated to Re^{III} paramagnetic products.[72,73]

These oxo Re^V complexes can furnish various derivatives, for example, with N-, O-, S-, or C- ligands, that is, Re^V oxo-amido, -imido, -alkoxide, -phenoxide, -diolate, -thiolate, -alkyl, or – aryl complexes, on reactions of (**13**) or (**14**) with amines, alcohols, phenoxides, diols, thiols, organozinc, or Grignard reagents, respectively.[72,73]

The nucleophilicity of the oxo ligands at some of the alkoxide and diolate Re^V complexes was shown by addition of the strong Lewis acid $B(C_6F_5)_3$ to form the corresponding $OB(C_6F_5)_3$ complex adducts.[74] $[ClReO_3]$ also acts as a Lewis base, forming the adducts $[ClO_2ReO{\rightarrow}MX_n]$ with various Lewis acids MX_n, for example, $AlCl_3$, $NbCl_3$, $SbCl_5$, or $ReOCl_4$.[71]

In contrast, the cationic dioxo-phenyl Re^{VII} complex $[TpReO_2(Ph)]^+$, derived from the reaction of $[TpReO(Ph)(OTf)]$ (formed by phenylation of (**14**) (Tp′ = Tp) with PhLi followed by a reaction with I_2 and AgOTf) with O-atom donors, for example, PyO or Me_2SO, undergoes facile phenyl-to-oxo migration, at ambient temperature, to give a phenoxide product. This is the first well-established example of thermal migration of a ligand from a metal center to an oxo ligand, a step that is believed to be promoted by the high electrophilicity of the oxo ligand at the cationic Re^{VII} center.[75] A related, but photochemical, migration occurs in the photolysis of the Re^V complexes $[TpReO(R)Cl]$ (**15**) (R = aryl, ethyl) to form the Re^{III} alkoxides $[TpRe(OR)ClL]$ (L = py, NCMe, Me_3PO). Complexes (**15**) (R = aryl) were obtained by C-H activation of aromatic hydrocarbons (RH) on photolysis of solutions with $[TpReO(Cl)I]$. The photochemistry of the oxo-oxalate complex $[TpReO(C_2O_4)]$ was also investigated and shown to proceed via releasing of carbon dioxide and monoxide to form the transient {TpReO} that can be trapped with species like O_2 to give $[TpReO_3]$ as the final product, $CDCl_3$ to yield $[TpReOCl_2]$, or 9,10-phenanthrenequinone (L) to form $[TpReO(L)]$.[76]

Complexes with S donors are much less common. $[Et_4N][ReS_4]$, which is derived from heating $[ReO_4]^-$ in a methanolic ammonium polysulfide solution, can lead to sulfido-bridge polynuclear complexes, for example, with the tetrahedral $[ReS_4]^-$ ligand. $[ReO_4]^-$ and H_2S give $[ReO_3S]^-$, which is most conveniently isolated as the Tl^+ salt. $[ReS_4]^-$ is a useful synthon for S-rich Re complexes, yielding sulfido and thiolato Re^V, Re^{IV}, or Re^{III} complexes upon reactions with unsaturated species like alkenes, alkynes, or isocyanides.[8]

Other interesting all-sulfur examples are the square-pyramidal $[ReS(S_4)_2]^-$ (obtained from the reactions of polysulfides with Re_2O_7, $[ReO_4]^-$, $ReCl_5$, or $[Re_2Cl_8]^{2-}$) and $[ReS(SCH_2CH_2S)_2]$ (formed by a reaction of $[ReCl_6]^{2-}$ with 1,2-ethanedithiol), and the trigonal prismatic dithiolenes $[Re(S_2C_2R_2)_3]$.[8] The first complex with a Tc=S bond is $[TpTcSCl_2]$, obtained from $[TpTcOCl_2]$ and B_2S; the Re analog is similar.[77]

Oxo-complexes with S-donor ligands are well documented, mainly for Re,[8] for example, by the five-coordinate trigonal bipyramidal $[ReO(SR)_4]^-$ (SR = bulky thiolate) complexes (prepared by a ligand replacement from $[ReOCl_3(PPh_3)_2]$ or $[ReCl_6]^-$), the square-pyramidal dithiolate or dithiolene $[ReO(S^\cap S)_2]^-$ compounds, the tumor targeting $[ReO(DMSA)_2]^-$ mercaptosuccinate complex (Section 4.2), the thioether $[ReOX_3(RSC_6H_4SR)]$ (X =

halide) compounds, and the complexes [ReO(L)(SR)] with the tridentate $^{-}SCH_2CH_2YCH_2CH_2S^{-}$ (Y = S, O) ligands (prepared from a reaction of $[ReOCl_4]^-$ with H_2L and RSH). Chelating mixed-donor N,S ligands (e.g. aminothiolates, amidothiolates, *N*-heterocyclic thiolates (like pyridine-2-thiolate, pyrimidine-2-thiolate, thiazoline-2-thiolate), S-containing aminoacid derivatives) and P,O donors (e.g. $R_2PC_6H_4X$-2 (X = O^-, COO^-)) combining a harder (N or O) with a softer (S or P) coordinating atom can meet the electronic requirements of the $\{Re^VO\}^{3+}$ core (also of the related $\{ReN\}^{2+}$ or $\{Re(NR)\}^{3+}$ ones). Quite a good number of such types of oxo-complexes is known, also for Tc, in particular with possible medical use (Section 4). Those ligands are also adequate for Re^{III}, whose stabilization is favored by ligands that present good electron donor and π-acceptor character (PR_3 and CO are also favorable). Complexes with other chelating mixed ligands like P,S donors (e.g. phosphinothiolates) and P,N donors (as amino- and amido-phosphines) are also well represented.

3.6 Complexes with Group 17 Elements

Representative examples have been given in Sections 2.2 and 3.2. Others are as follows.[2,78] KF and ReF_6 give the square prismatic $K_2[ReF_8]$. The species $K_2[MX_6]$ are also known for both metals and all the halides. They are obtained by a mild reduction of the permetallate in HX solutions. The reaction of ReF_6 with $Re_2(CO)_{10}$ in HF gives $[Re(CO)_6][F_5Re(\mu\text{-}F)ReF_5]\cdot[Re_3Cl_{12}]^{3-}$ has the trirhenium cluster core of $[Re_3Cl_9]$ (Section 2.2). The phase changes in the hexahalogenorhenates have been rationalized on the basis of radius ratio effects. Reduction of acidic (HCl) perrhenate solutions with iodide gives the dimeric linear oxo-bridged species $[Cl_5ReOReCl_5]^{4-}$; spin pairing is almost complete and the ion is only weakly paramagnetic. In solution, the magnetism increases due to hydrolysis to give $[(HO)ReCl_5]^{2-}$. $[ReOX_4]^-$ is also known for Cl, Br, and I; these ions take up a variety of donors in the vacant site trans to the oxo group to give $[ReOX_4(L)]^-$ (L = py, MeCN, H_2O).

4 RADIOPHARMACEUTICALS

Tc and, in fewer cases, Re compounds have found applications in medicinal inorganic chemistry as radiopharmaceuticals for clinical diagnosis (^{99m}Tc for scintigraphic and emission tomographic imaging)[79–88] or even therapy (^{186}Re e.g. for the palliation of severe bone cancer pain).[79,83,88,89]

4.1 ^{99m}Tc

Most of the radiopharmaceuticals used in clinics are labeled with ^{99m}Tc, a γ-ray emitter with favorable nuclear properties toward an effective detection of the emitted γ-rays and a low radiation exposure of the patient, together with a relative ready availability and low cost (Section 1). $[^{99m}TcO_4]^-$ is available in very low concentration in the eluate from its generator column and thus the syntheses of the derived ^{99m}Tc radiopharmaceuticals take place in very dilute aqueous solutions and the common methods of characterization used for macroscopic amounts of compounds cannot be applied. Hence, in order to isolate and fully characterize technetium compounds, one has to work with the ^{99}Tc isotope that is a very long-lived weak β-emitter that can be handled safely under adequate precautions. Once characterized a ^{99}Tc compound, the confirmation of the identical ^{99m}Tc structure can be done by high performance liquid chromatography (HPLC) (UV and β-detection), electrophoresis, or mass spectrometry.

Although $Na[^{99m}TcO_4]$ can be applied as such for thyroid and brain imaging, most of the ^{99m}Tc radiopharmaceuticals are obtained upon the reduction of $[^{99m}TcO_4]^-$ (e.g. by Sn^{II}, $S_2O_6{}^{2-}$, H_3PO_4, $SO_3{}^{2-}$, or $S_2O_4{}^{2-}$) in the presence of a suitable coordinating species such as an amine oxime, a cysteine ester, an iminodiacetic acid derivative, a polyamino-polycarboxylic acid, a mercaptoacetyltriglycerine, a mercaptosuccinic acid, an alkyldiphosphonate, or an isocyanide.

The ^{99m}Tc complexes are conveniently prepared shortly before use, by addition of the ^{99m}Tc generator eluate to the contents of commercially available kits that contain the coordinating species to be labeled and often the reducing agent (usually Sn^{II}).

Examples of approved ^{99m}Tc radiopharmaceuticals are as follows: [TcO(D,L-HM-PAO)] (Ceretec) (**16**), [TcO(L,L-ECD)] (Neurolite) (**17**), and [TcCl{(DMG)$_3$2MP}] (**18**), which can penetrate the intact blood-brain barrier in view of their neutral and lipophilic character, used for cerebral imaging; $[TcO(MAG_3)]^-$ (TechneScan) (**19**) for renal function imaging; $[TcO_2(R_2PCH_2CH_2PR_2)_2]^+$ (Tc−tetrofosmin, Myoview) (**20**) (R = $CH_2CH_2OCH_2CH_2$), $[Tc(\text{Schiff base})(PR_3)_2]^+$ (Tc−furifosmin, TechneScan Q12) (**21**) (Schiff base = *trans*-(1,2-bis(dehydro-2,2,5,5-tetramethyl-3-furanone-4-methylene-amino)ethane), and $[Tc(CNR)_6]^+$ (Tc-sestamibi, Tc-hexamibi, Cardiolite) (**22**) (R = CH_2CMe_2OMe), for myocardial perfusion imaging (complex (**22**) also for breast cancer imaging); and $[Tc(HIDA)]^-$ (**23**) for liver and gall bladder imaging.[79,84,87,88]

Many of the Tc complexes (**16, 17, 19**) present the oxo $\{Tc^V{=}O\}^{3+}$ core and are pentacoordinate (square pyramid), but other metal oxidation states and coordination numbers are possible, for instance, in (**20**) (hexacoordinate with the dioxo $\{Tc^VO_2\}^+$ core), in (**18**) (heptacoordinate Tc^{III}), in (**21**) or (**23**) (hexacoordinate Tc^{III}), or in (**22**) (hexacoordinate Tc^I). In Tc-diphosphonate radiopharmaceuticals, used as bone imaging agents, the metal is believed to be in the +4 oxidation states.[81] The +1 oxidation state in the homoleptic isocyanide complex (**22**) is expected to be advantageous in terms of the kinetic inertness associated to its low-spin d^6 configuration,

and the syntheses of various promising complexes with the organometallic $\{^{99m}Tc(CO)_3\}^+$ core has been achieved by displacement reactions of $[TcX_3(CO)_3]^{2-}$ ($X = Cl^-$, Br^-) or $[Tc(H_2O)_3(CO)_3]^+$ conveniently prepared from $[TcO_4]^-$ and CO (1 atm).[90] A similar $\{^{188}Re(CO)_3\}^+$-based chemistry has also been developed.[90]

The Tc-nitrido $\{Tc^V{\equiv}N\}^{2+}$ core, with the strong π-electron donor nitride ligand, which effectively stabilizes the Tc^V oxidation state, is isoelectronic with $\{Tc^V{=}O\}^{3+}$ and is known to form complexes with a variety of chelating ligands,[85] and $[^{99m}TcN(noet)_2]$ (**24**) constitutes a new myocardial imaging agent.[82] The preparation of the $^{99m}Tc{\equiv}N$ synthon can be conveniently achieved directly from $[^{99m}TcO_4]^-$ upon reaction with N-methyl, S-methyl dithiocarbazate, H_2N-NMeC(=S)SMe (which acts as the donor of the nitride N-atom), in the presence of reducing agents such as Sn^{2+} and tris(*m*-sulfophenyl)phosphine.[84]

The above ^{99m}Tc radiopharmaceuticals fall in the ‘technetium essential’ class of drugs (the Tc is an integral part without which the molecule would not be delivered to its target), but noticeable and rapid progresses are being achieved toward the development of ‘technetium tagged’ drugs, for which the targeting species (such as a peptide, an antibody, or a hormone) has been labeled with ^{99m}Tc (directly or by a bifunctional chelate) that is delivered to the target side as a passenger. Recent developments have been made in the field of ^{99m}Tc-based receptor (or target)-specific radiopharmaceuticals (whose ultimate distribution is determined by their receptor binding (or other biological) interactions.[81,82] In particular, the ^{99m}Tc-labeled P280 peptide (an oligopeptide with two identical 13 aminoacid monomers, each monomer containing a cysteine-glycine-cysteine sequence capable of S-binding to the $\{Tc{=}O\}^{3+}$ core) has been approved as a commercial product (Acutec) for thrombus imaging.[82]

4.2 ^{186}Re or ^{188}Re

The coordination chemistry of rhenium is better known and easier to handle than that of technetium and, in view of their expected analogies, the former metal can be used for nonradioactive model studies for technetium. In addition, ^{186}Re and ^{188}Re display attractive properties (Section 1) for nuclear medicine.[88,89] The biolocalizations of analogous Re and Tc compounds can also be similar. Hence, the ^{99m}Tc and the ^{186}Re (or ^{188}Re) radionuclides constitute a potential ‘matched pair’ for diagnosis and therapy.[85]

However, in spite of the similarity of the physical properties (like size, charge, and lipophilicity, which can determine the biodistribution) expected for analogous complexes of Re and Tc, on account of, for example, the ‘lanthanide contraction’, the former are usually easier to oxidize (harder to reduce) and less kinetically labile than the latter. The easier oxidation in vivo of the Re complexes to $[ReO_4]^-$ can be advantageous in terms of excretion from the body (via the kidneys) of the radionuclide.

The preparations of Re radiopharmaceuticals start from perrhenate with the radionuclide (Section 1) and involve metal reduction and complexation reactions, an overall procedure similar to that used for Tc.

As observed for diphosphonic acid derivatives (like HEDP) labeled with ^{99m}Tc that are used as bone imaging agents, related ^{186}Re-labeled diphosphonates, like ^{186}Re-HEDP formed on reaction of $[^{186}ReO_4]^-$ with HEDP in the presence of $SnCl_2$ as reductant, also accumulate at bone cancer sites and act as a ‘rhenium essential’ drug for palliation of metastatic bone cancer pain.[83,89] The Re-HEDP species appears to be polymeric (with a metal–metal multiple bond), as the analogous Tc agent. ^{99m}Tc complexes with dimercaptosuccinate (DMSA) have been applied for diagnoses of renal diseases and for imaging of medullary thyroid carcinoma. The related ^{186}Re complex, with a square-pyramidal structure and the apical Re^V-oxo group $[ReO(DMSA)_2]^-$ (**25**), which exists as a pH-dependent mixture of isomers (depending on the orientations of the carboxylic groups), also undergoes selective uptake in the carcinoma and is expected to be of a therapeutic value.[83,89]

The Re radionuclides have been applied not only in ‘rhenium essential’ drugs, as shown above, but also recently, and following strategies similar to those used for technetium, for labeling biomolecules like antibodies, steroids, and peptides, which thus become potential targeting agents for therapeutic uses of Re radionuclides. In particular, both Re and Tc square-pyramidal oxo-complexes with tetradentate bifunctional chelators (i.e. of the N_xS_{4-x} classes, see e.g. (**17**) and (**19**) for Tc) are adequate for such couplings.[81–83,89] The rhenium radiopharmaceutical chemistry for therapy, although yet little explored, is already a promising and developing field of research.

5 CATALYSIS

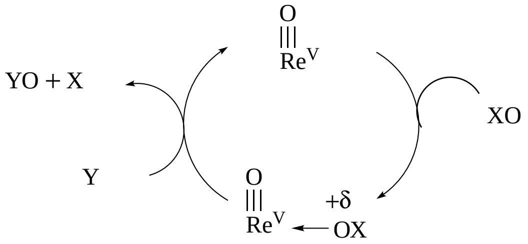
The use of rhenium complexes in catalysis has developed mainly during the last few years and constitutes a current and promising area of Re chemistry. Oxo-rhenium complexes can be active typically in oxidation catalysis, that is, OAT and related reactions. They can also catalyze other synthetically important reactions like isomerization or etherification of allylic or propargylic alcohols, the Beckmann rearrangement of oximes, the dehydration of primary amides and aldoximes, and, unconventionally, reduction of aldehydes and ketones. Other reactions like CO_2 reduction, dehydrogenation of alkanes, and H/D exchange have been catalyzed by some (nonoxo) rhenium catalysts. Examples are given below, but organometallic systems, mainly involving the extensively studied [$MeReO_3$] and related organorhenium oxides, have been reviewed elsewhere.[91–93] (*see also* ***Rhenium: Organometallic Chemistry***)

5.1 Oxygen Atom Transfer (OAT) and Other Oxidation Reactions

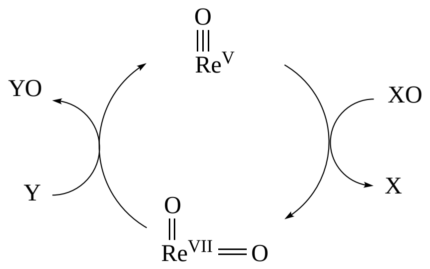
Oxo-rhenium complexes can catalyze various OAT reactions between suitable oxo-donors (XO = sulfoxides (R_2SO); tertiary amine *N*-oxides (R_3NO); pyridine *N*-oxide (C_5H_5NO, PyO); triphenyl-phosphine, -arsine, or -stilbene oxide (R_3AO) (A = P, As, Sb); peroxides (Bu^tOOH, H_2O_2); perchlorate (ClO_4^-); epoxides (R_2C–O–CR_2)) and oxo-acceptors (Y = sulfoxides (R_2SO); sulfides or thioethers (R_2S); disulfides (RS-SR); thiols (RSH); phosphines (PR_3); phosphites ($P(OR)_3$); and olefins ($R_2C{=}CR_2$)). The reactions comprise both oxidation of Y and reduction of XO but the oxidative viewpoint is that which is normally enhanced. Recent reviews focusing on rhenium oxazoline,[94] thiazoline,[94] and dithiolate[95] complexes are available.

Two overall mechanisms have been considered[94] for such reactions: one (Scheme 3) occurs via an electrophilically activated oxo-donor (XO) toward the oxo-acceptor (Y), upon coordination to a Lewis acid {ReO} center; and the other one (Scheme 4) involves a metal-centered oxygen transfer via a {Re^VO}/{$Re^{VII}O_2$} couple that parallels that of Mo oxotransferases (via the isoelectronic Mo^{IV}/Mo^{VI} couple).

Examples of catalytic systems include the following ones. [$ReOCl_3(PPh_3)_2$] catalyzes the oxidation (with sulfoxides) of thiols to disulfides,[96,97] of sulfides to sulfoxides,[98] of acyclic disulfides to thiosulfonates (RSO_2SR),[97] of cyclic disulfides to thiosulfites [S–S$(CH)_2)_3CH_2$ to O=S–S$(CH)_2)_3CH_2$],[97]

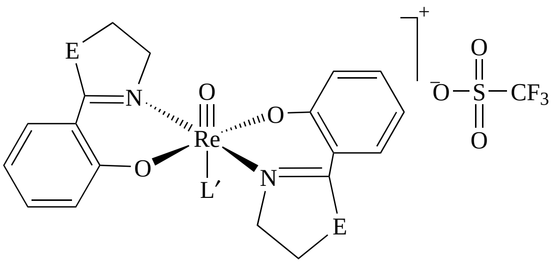


Scheme 3



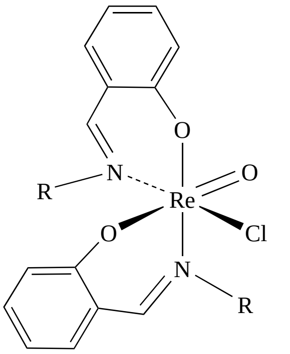
Scheme 4

and of PPh_3 to $OPPh_3$,[99] and some of the reactions are indicated to occur via the mechanism of Scheme 3. That of Scheme 4 is followed by the Re^V phenoxy-oxazoline and phenoxy-thiazoline (L) complexes $[ReOL_2(L')]OTf$ (**26**) and (**27**) ($L' = H_2O$, NCMe) obtained from the reaction of $[ReOCl_3(PPh_3)_2]$ or $[ReOCl_3(OPPh_3)(SMe_2)]$ with HL (**26**) or by using $[NBu_4][ReOCl_4]$ as the precursor (**27**), followed by chloride ligand replacement by L′ in the presence of AgOTf.[94] (**26**) and (**27**) are highly active in catalytic OAT from O-donors like perchlorate, sulfoxides, or pyridine *N*-oxide to O-acceptors like sulfoxides, thioethers, or $P(MeO)_2Ph$. The reduction of perchlorate by pure oxo-transfer is rather difficult to achieve and (**26**) and (**27**) catalyze the overall cycle more effectively than $[MeReO_3]$.[94]

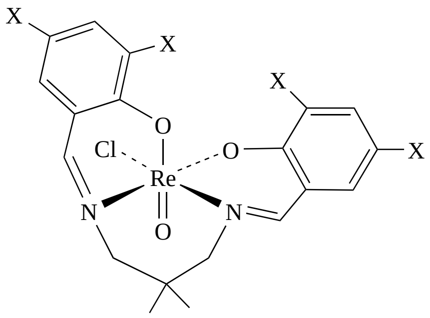


(**26**) E = O
(**27**) E = S; L′ = H_2O, NCMe

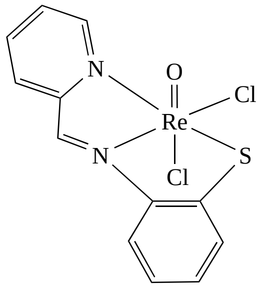
Re^V chloro oxo-complexes, with bi-, tri-, or tetra-dentate Schiff bases (L), like [ReOCl(L)] or $[ReOCl_2(L)]$, prepared from reaction of $[NBu_4][ReOCl_4]$ with the appropriate HL or H_2L, are also known catalysts for OAT reactions. Hence, (**28**) and (**29**) are catalysts for olefin epoxidation with Bu^tOOH (**28**, with two bidentate *N*,*O*-ligands, are better catalysts than (**29**) with a tetradentate *N*,*N*,*O*,*O*- one),[100,101] whereas (**30**) (with *N*,*N*,*S*-tridentate pyridylbenzothiazoline ligand) catalyzes the OAT from PyO to tris(*p*-methylphenyl)phosphine (however, the pentacoordinate oxo-methyl complexes (**31**) and (**32**), with the related *N*,*N*,*S*- or *O*,*N*,*S*-tiazoline derivatives, obtained from $[MeReO_3]$, are more active catalysts).[102]



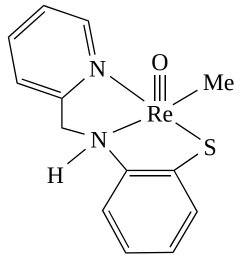
(**28**) (R = C_6H_5, C_6H_{11})



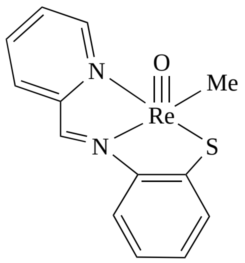
(**29**) (X = Cl, H, Bu^t)



(**30**)



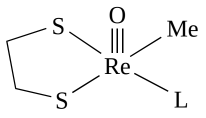
(**31**)



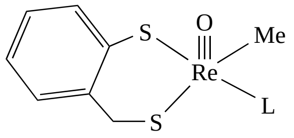
(**32**)

Other square-pyramid oxo-methyl Re^V complexes with dithiolate ligands like [MeReO(dithiolate)L] (e.g. (**33**) and (**34**), L = phosphine) or $[MeReO(dithiolate)]_2$ (derived from reaction of $[MeReO_3]$ with the appropriate dithiol, in the presence or in the absence of L, respectively) are also active, for example, for the OAT from PyO to PR_3, to R_2S, or to R_2SO; from R_2SO to R_2S; and from Bu^tOOH to PR_3, to R_2S, or to R_2SO.[95] Kinetic studies suggest a mechanism via a dioxorhenium(VII) intermediate (Scheme 4) for the $PyO/PR_3/(\mathbf{33})$ system, or a mechanism according to Scheme 3 for the $Bu^tOOH/PR_3/(\mathbf{34})$ case.[95] Interestingly, the dinuclear complex $[\{ReO\}_2(mtp)_3]$ (**35**), without any methyl ligand, prepared from the reaction of Re_2O_7 with H_2mtp, catalyzes the OAT from molecular oxygen to PR_3, via a postulated peroxo intermediate, apart from the more usual oxidation of PR_3 by Me_2SO and PyO.[95] The diimido complexes $[MeRe^V(NAr)_2(PR_3)_2]$ also catalyze the oxidation of phosphines by O_2, via the oxo-Re^{VII} intermediate

$[MeReO(NAr)_2]$.[95] The dioxotris(pyrazolyl)borate Re^V complex $[Tp^*ReO_2]$, obtained by in situ reduction of $[Tp^*ReO_3]$ by PPh_3 or $P(OEt)_3$, catalyzes the OAT from epoxides to those P reductants, whose kinetics have also been studied.[103]

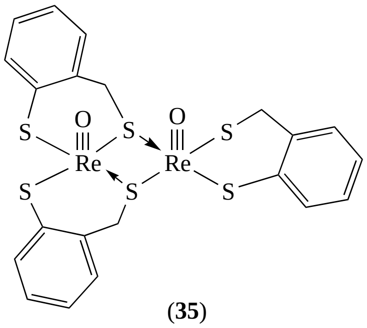


(33)



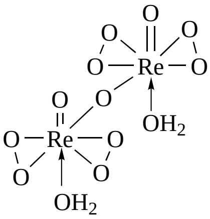
(34)

(L = phosphine)

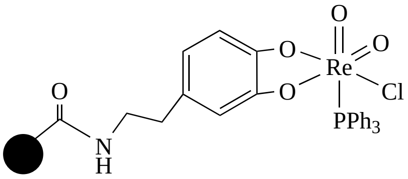


(35)

The ‘peroxo perhenic acid’ (**36**) (the molecular structures of the diglyme adduct was determined by X-rays) is believed to be the active species in the catalytic oxidation of olefins and aromatics by Re_2O_7/H_2O_2 or ReO_3/H_2O_2.[104] However, (**36**) is not so active a catalyst as the related peroxo methylrhenium(VII) $[MeReO(O_2)_2]\cdot H_2O$ (**37**) (the active species of the known $[MeReO_3]/H_2O_2$ system in a wide variety of oxidations) since the hydrolysis product (perhenic acid) of (**36**) is inactive whereas those from (**37**), that is, $[MeReO_3]$ and $[MeReO(O_2)_2]\cdot H_2O$, regenerate the catalyst (**37**) on reaction with H_2O_2.



(36)



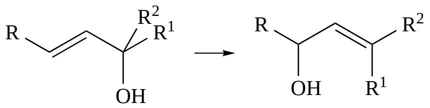
(38)

Supported oxo-rhenium catalysts in heterogeneous systems have also been reported, for example, the polystyrene-supported (catecholato)oxo-rhenium(VII) complexes (**38**), obtained from the reaction of polystyrene-supported catechol with $[ReOCl_3(PPh_3)_2]$, which catalyze alcohol oxidation to ketones or aldehydes with dimethylsulfoxide and epoxide reductions to alkenes with PPh_3, following the proposed mechanism of Scheme 4.[105]

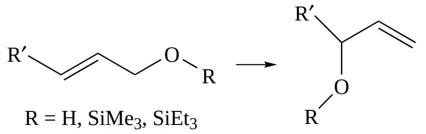
The use of technetium compounds in catalysis is a much less studied field. An example, investigated kinetically, is the oxidation of hydrazine (to NH_4^+, N_2 and other nitrogeneous products) by oxo-anions (nitrate or perchlorate) catalyzed by pertechnetate in aqueous acidic medium, which was proved to proceed via a chain process.[106] The hydrazine is oxidized by high oxidation state (+7, +6 or +5) Tc species and the reduced states of Tc are reoxidized by nitrate (or perchlorate) to regenerate the high Tc oxidation state. The reaction has significance in the technological reprocessing of nuclear fuel.

5.2 Isomerization or Etherification of Allylic or Propargylic Alcohols

The Re^{VII} trioxo compounds $[ReO_3X]$ (X = $OSiMe_3$, $OSiPh_3$, $OReO_3$) act as catalysts, at room temperature, for the isomerization of allylic alcohols and allylic ethers (reactions 3 and 4), by 1,3-shift of a hydroxy or a trialkylsiloxy group, which is proposed to involve the initial replacement at Re of X by the allylic alkoxide (to form a perrhenic ester) followed by formation of a postulated allyl-dioxorhenium intermediate.[107] The isomerization of allylic and propargylic alcohols is also catalyzed by $[NBu_4][ReO_4]$ and *p*-toluenesulfonic acid, via $HReO_4$.[108]



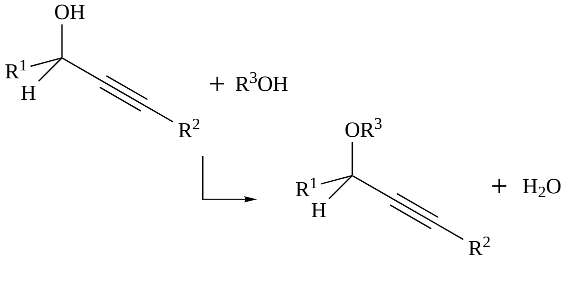
(3)



R = H, $SiMe_3$, $SiEt_3$

(4)

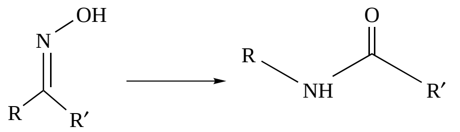
Single-pot etherification of propargyl alcohols by alcohols (reaction 5) has been achieved by the rhenium(V)-oxo complex $[ReOCl_3(dppm)]$ bearing a diphosphine ligand, in NCMe, via a postulated allenolate intermediate $R^1CH{=}C{=}C(R^2)$-O-[Re]=O, which would undergo a nucleophilic addition of R^3OH at the R^1CH carbon.[109]



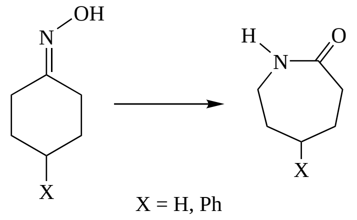
(5)

5.3 Beckman Rearrangement of Oximes to Amides and Lactams

The conversion of oximes into amides or lactams (reactions 6 or 7), in particular, ε-caprolactam from cyclohexanone oxime (X = H), is catalyzed by $[NBu_4][ReO_4]$ and CF_3SO_3H in refluxing nitromethane, via a postulated perrhenic ester of oxime $[RR'C{=}N\text{-}O\text{-}ReO_3]$.[110]



(6)

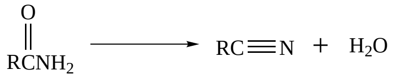


(7)

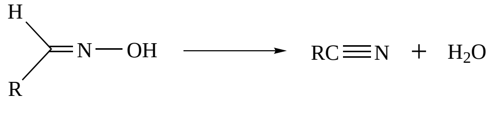
Since oximes are obtained from condensation reactions of ketones with hydroxylamine, the single-pot preparation of amides and lactams directly from ketones and $H_2NOH.HCl$ was achieved via in situ generated oximes, by using the above catalyst in nitromethane under azeotropic conditions.[110]

5.4 Dehydration of Primary Amides and Aldoximes to Nitriles

Nitriles can be prepared by dehydration of primary amides (reaction 8) or of aldoximes (reaction 9), catalyzed by the Re^{VII} trioxo compounds $[ReO_3X]$ (X = $OSiMe_3$, $OReO_3$, OH) in azeotropic (e.g. toluene/water or mesitylene/water) reflux.[111] Aqueous perrhenic acid (X = OH) is the most convenient catalyst in view of the moisture sensitivity of the others. The oxophilicity of the Re(VII) oxo-complexes is believed to play a determining role in the reactions, which are proposed to involve six-membered cyclic transition states formed upon preferential *O*-coordination, relative to *N*-coordination, of the amide or oxime.[111]



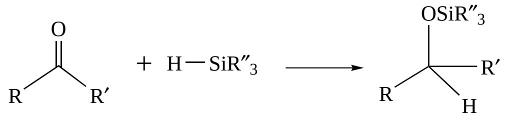
(8)



(9)

5.5 Reductive Hydrosilylation of Aldehydes and Ketones

In contrast with the common activity of oxo-rhenium compounds in oxidation catalysis (see above), the Re^V-dioxo-complex $[ReO_2I(PPh_3)_2]$ catalyzes the reductive hydrosilylation of aldehydes and ketones to give silyl ethers (reaction 10), which can provide a single-pot reduction-protection of carboxyl groups.[112] This silyl etherification conceivably proceeds via a [2 + 2]-type addition of the Si–H bond of the silane to the Re=O π-bond to yield a siloxy-substituted metal hydride that acts as a reductant of the aldehyde or ketone. The second oxo ligand appears to provide a spectator oxo effect favorable to the reaction.



(10)

5.6 Photo- and Electrocatalysis

Re^I diimine complexes act as photocatalysts and/or electrocatalysts for CO_2 reduction to CO. Examples include the tricarbonyl complexes *fac*-$[Re(\alpha\text{-diimine})(CO)_3L]^n$ [$n = 0$, L = halide; $n = 1$, L = NCMe, $P(OR)_3$; α-diimine = 1,4-disubstituted 1,4-diazabuta-1,3-dienes or bpy and related chelating N-heterocycles],[113,114] for example, *fac*-$[Re(dmb)(CO)_3(NCMe)]^+$,[115] $[Re(dmb)(CO)_3]_2$[115] and *fac*-$[Re(bpy)(CO)_3\{P(OPr^i)_3\}]^+$.[116] Electron-transfer from an amine electron donor (e.g. triethanolamine or triethylamine) to the excited state complex is usually considered as the initiation of the photocatalysis, and metallocarboxylates and metallocarboxylic acids have been proposed as intermediates in the formation of CO.[115] The electrocatalytic process is triggered by a 1-electron or a 2-electron cathodically induced chloride (X) or L ligand dissociation to form the catalytic species.[117]

$[ReCl_6]^{2-}$ is photooxidized by electron acceptors, for example, 2,3,5,6-tetrachloro-1,4-benzoquinone (chloranil) and DDQ, to $[ReCl_6]^-$, which is an intermediate in the oxidation of Cl^- to Cl_2 and of toluene to benzaldehyde.[118]

5.7 Other Reactions

$[ReO_2I(PPh_3)_2]$, with an alkyl iodide as an initiator, in the presence of a metal alkoxide like $Al(OPr^i)_3$, catalyzes the living radical polymerization of styrene and para-substituted styrenes.[119]

In $[ReH(SH)_2(PMe_3)_4]$, unexpectedly obtained via S-atom transfer from $[ReS_4]^-$ to PMe_3 in a reaction with H_2S, the protic (SH) and hydridic (ReH) sites undergo intramolecular proton exchange and the SH proton exchanges with protic reagents like CH_3OD. The complex undergoes isotopic H/D exchange at both SH and ReH with D_2, and catalyzes the conversion of H_2 and D_2 into HD and the isotopic exchange between D_2 and H_2S to give HD and DHS.[120]

cis-$[ReH(N_2)L_4]$ (L = PMe_2Ph) catalyzes aldol-type reactions, for example, of ethyl cyanoacetate $NCCH_2CO_2Et$ or of $NCCH_2CN$ with benzaldehyde to yield the corresponding (*E*)-α-cyanocinnanamate derivatives, $NC(EtO_2C)C{=}CHPh$ or $NC(NC)C{=}CHPh$. The reaction

proceeds via active Re^{I} enolate intermediates, $[Re(NCCRCO_2R')(NCCHRCO_2R')L_4]$ (R = H, Me; R′ = alkyl) and the derived $[Re(NCCHCO_2Et)\{NC(EtO_2C)C{=}CHPh\}L_4]$, which are also catalysts for olefin metathesis.[121]

Various polyhydride Re phosphine complexes catalyze alkane dehydrogenation, as described in Section 3.1.

Supported mono and bimetallic (M-Tc, with M = group 8–10 metal) technetium catalysts, in a number of cases similar to Re/supported (alumina, silica or MgO) ones, have shown activity in various reactions[122–124] like dehydrogenation of alkanes and hydrogenation of acetone (to isopropyl alcohol and propane), of aromatic hydrocarbons, of CO and of CO_2 (to methane). Re complexes with N,O-ligands catalyse (liquid biphasic catalysis) the peroxidative oxidation of alkanes under mild conditions.[125]

Glossary

Diagnostic imaging: the use of an isotope which emits readily detectable radiation and which is present in a compound that is absorbed by a healthy target organ, in order to produce an image of soft tissue using a radiation source from within the organ; the procedure generally provides much better information than standard X-ray photographs
Nuclear medicine: the use of isotopes in any capacity to aid the practice of medicine

1 INTRODUCTION

Technetium belongs to group 7 of the second row transition metals and its chemistry is quite different from the two other elements of the same group, manganese and rhenium. The chemistry of technetium is not developed as much as the one of the relatively rare and expensive element rhenium and also much less than for the more common manganese. The reason for the difference is due to its natural absence in nature. Technetium is unique among the d-block elements since it has no stable isotope (*see Isotopes & Isotope Labeling*). As discussed elsewhere (*see* ***Technetium & Rhenium: Inorganic & Coordination Chemistry***), element 43 does not exist in nature in any significant quantity. All the isotopes are radioactive and among the approximately 20 known technetium isotopes (^{91}Tc–^{110}Tc), ^{99}Tc has the longest half-life (212 000 years, *see Radioactive Decay*). Since the earth is much older, most traces have already disintegrated since the 'big bang'. There might be ultratraces produced as the product of the natural fission of uranium, particularly in the natural reactor of Oklo in Gabon. However, technetium-99 constitutes about 5% of the fission by-products (*see Fission Product*) of nuclear reactors. It can be fairly readily isolated from these wastes and its abundance today has been estimated to exceed that of several naturally occurring elements. The price of solid $NH_4[^{99}TcO_4]$ is very low, but handling and packaging is expensive. It is available from Oak Ridge Laboratories (Batch No Tc-99-P-48 containing 51.6% Tc-99 by weight) for about 93.US$ per gram, but the technical services charges ($2765.) and radioisotope packing ($1200) are expensive. It has been said that rather large amounts are available in the former Soviet Union, so perhaps this supply will reach the commercial market in the near future.

The chemistry of technetium is quite complex especially because of its numerous oxidation states (+7 to −1). In the higher oxidations states (Tc(IV) to Tc(VII)), the metal behaves as a hard Lewis acid and its chemistry is dominated by multiple-bonded oxo ligands. The lower oxidation states ions can be classified as soft metals and will form stable compounds with ligands containing the following donor atoms: P, As, S, Se, X^- (except F^-), N, and π-acceptors such as CO, NO, and isonitriles.

The importance of the chemistry of technetium has greatly increased since the discovery that the element could be useful as a radiotracer in medicine. The ^{99m}Tc isotope which exists in a metastable nuclear excited state is now widely used in nuclear medicine as a diagnostic agent. It was first used in 1961 for diagnosis of thyroid disease. The compound $[^{99m}TcO_4]^-$ seemed to behave like the iodide ion, known to be taken up by the thyroid. Ten years later, a significant milestone was made with the development of a ^{99m}Tc-polyphosphonate preparation, since it provided the most sensitive method to study skeletal abnormality by imaging. Since the initial work in the field was performed by clinical diagnosticians, most of the earlier preparations were not fully characterized. But for the last 25 years, coordination chemists have clarified the structures and the chemistry of several of these radiopharmaceuticals, develop new methods and design many new imaging agents. Several of these are organometallic Tc compounds. Today, ^{99m}Tc is used in more than 85% of all the diagnostic scans done in hospitals. The nuclear properties of ^{99m}Tc are ideal for nuclear imaging. It emits a 140 KeV γ-ray with a half-life of 6 hours with negligible radiation dose to the patients.

No macroscopic chemistry, such as NMR or IR spectroscopy is possible with the ^{99m}Tc compounds. The decay product of ^{99m}Tc is the long-lived ^{99}Tc which emits weak β^- particles (292 KeV). This makes ^{99}Tc suitable for macroscopic studies. When present in significant quantity, a fair amount of bremsstrahlung radiation (fairly low energy) is produced

from the absorption of the β particles in the glass or other container material, but it is possible to work fairly safely with small quantities of ^{99}Tc using normal glassware and prudent isolation conditions. Both Davidson[1] and the authors of Gmelin[2] give some helpful recommendations concerning the handling of this mildly radioactive material. Monitored hoods, gloves, aprons, and isolation are obvious precautions. The handling of ^{99}Tc on a small scale (<20 mg) does not present a danger to health provided some elementary precautions are taken. However, there are numerous examples of work, both in the current and in the older literature, in which the quantities far exceed these fairly conservative recommendations. This is particularly true when starting materials are prepared, or when the commercial source (usually bought in larger quantities) is handled.

The valuable tracer ^{99m}Tc used in nuclear medicine can be obtained as the pertechnetate ion using a ^{99}Mo–^{99m}Tc generator (*see Radioisotope Generators*), which takes advantage of the equilibrium between the parent radionuclide ^{99}Mo and the daughter radionuclide ^{99m}Tc. The separation between the two radionuclides is done on an alumina column by the selective elution of $[^{99m}TcO_4]^-$ with a saline solution.

$$^{99}\text{Mo} \xrightarrow{66\,\text{h}} {}^{99m}\text{Tc} \xrightarrow{6\,\text{h}} {}^{99}\text{Tc} \xrightarrow{212\,000\,\text{yrs}} {}^{99}\text{Ru(stable)} \qquad (1)$$

Optimum isolation of ^{99m}Tc is achieved with minimal ^{99}Tc accumulation every 24 h, which is ideal for hospital use. A new generator is purchased every week and elution of $[^{99m}TcO_4]^-$ is done everyday for preparing the radiopharmaceuticals. The development of this generator has allowed the radionuclide to become routinely available in hospitals at a reasonably low price.

The radiopharmaceuticals are prepared by reacting the ^{99m}Tc(VII) starting material $[^{99m}TcO_4]^-$ with an excess of ligand usually in the presence of a reducing agent. The ^{99m}Tc radiopharmaceuticals can be roughly classified in two classes. The first class contains compounds which are called 'technetium essential'. They are small molecules in which the ^{99m}Tc core plays a very important role in the biodistribution, which depends on the geometry of the radioactive compound, the nature of the ligands, the oxidation state of Tc, and the charge on the complex. The product will be absorbed in different organs of the body. The radioactivity of ^{99m}Tc in the organ can be used to trace or map its functionality, using gamma cameras found in most hospitals. The second class of radiopharmaceuticals are larger molecules called 'technetium tagged'. These compounds are biomolecules like peptides, hormones, antibodies, which have been labeled with ^{99m}Tc in order to target more specifically a given organ. Sometimes, a chelating ligand (*see Chelating Ligands*) is attached to the molecule before the reaction with ^{99m}Tc. In this type of radiopharmaceuticals, the presence of Tc is hidden in a larger molecule in order to prevent a change in the biodistribution of the biomolecule.

Macroscopic chemistry with the long-lived ^{99}Tc isotope is usually conducted to determine the chemical nature of the species produced at the tracer level, especially for the 'technetium essential' molecules or models for the larger ones. These studies have revealed a considerable amount of technetium chemistry. In the past, many studies have been done on rhenium compounds instead of the ^{99}Tc complexes, especially since rhenium is not radioactive. But we believe that the chemistry of rhenium is too different from the one of technetium to be a good model. Rhenium is much more difficult to reduce than technetium. Many ligands (like phosphines) will easily reduce technetium in the absence of any other reducing agent, while it is much more difficult to change the oxidation state of rhenium. Therefore rhenium models for technetium chemistry should be used with caution.

Much of the technetium chemistry directed toward nuclear medicine deals with coordination compounds having oxygen, nitrogen, and other noncarbon atoms bonded to the metal, thereby removing them from the field of organometallic chemistry. This chemistry is discussed in considerable depth in the preceding article (*see* ***Technetium & Rhenium: Inorganic & Coordination Chemistry***). However, a number of recently prepared Tc compounds are classified as organometallic and are considered below. Classical organometallic compounds are very rare in biological systems. The vitamin B coenzyme adenosyl cobalamine is one of the rare natural organometallic compound known. But recently, bioorganometallic science has become an important emerging field and many new compounds containing Tc organometallic cores are under consideration for medical use. A good review was recently published on the current use and future potential of organometallic radiopharmaceuticals.[3]

Organometallic complexes of technetium-99 can be studied by the traditional physical tools used in chemistry. Techniques like infrared, multinuclear magnetic resonance, and mass spectroscopies, as well as magnetic susceptibility (to determine the number of unpaired electrons and thus the oxidation state) and X-ray crystallography are the main methods to study these complexes. X-ray diffraction methods are particularly important since only one small crystal is needed to determine the complete structure of the compound.

^{99}Tc NMR is a method that is worthy of special mention. Technetium is the fifth most sensitive nucleus for NMR work. The sensitivity per nucleus is less than that of hydrogen and fluorine but greater than that of phosphorus and particularly of carbon and other commonly studied nuclei. Its nuclear spin of 9/2 presents a potential problem owing to the possibility of quadrupolar broadening. Sharp NMR lines theoretically require highly symmetrical structures of the diamagnetic compounds. The pertechnetate ion (Tc(VII), d^0) can be detected with particular ease. The ^{99}Tc NMR signal of a dilute aqueous solution of ammonium pertechnetate can be seen with a good signal:noise ratio, with only a few pulses at concentrations so low that a typical survey meter will not detect the radioactivity of ^{99}Tc. A publication compiling a few NMR data was published by O'Connell *et al.*[4] Surprisingly, $Tc_2(CO)_{10}$ (Tc(0), d^7 with a metal–metal bond) gives also a

sharp NMR spectrum. It is not yet clear whether the sharp line is fortuitious or has significance for other technetium organometallic complexes. When PF_3 is substituted for CO in $Tc_2(CO)_{10}$ to produce the monophosphine complex, the technetium signal broadens considerably, in spite of the fact that PF_3 is very similar to CO. More recently, a ^{99}Tc NMR investigation of complexes containing the moiety *fac*-$[Tc(CO)_3]^+$ with macrocyclic thioethers of various ring sizes has shown that this technique is becoming more common.[5]

The first phase of technetium organometallic chemistry concerns the hot-atom chemistry or recoil chemistry. A second phase deals with the early macroscopic chemistry, particularly the excellent, independent, pioneering work of Kaesz[6] and Fischer.[7] A third period concerns the work of more recent years, which were preceded by a number of years in which very little work on organometallic chemistry was published. The second and third phases are discussed together in the major part of this article.

2 HOT-ATOM CHEMISTRY

Technetium hot-atom chemistry can be considered almost as a by-product of other studies.[8] When a compound like $Mo(CO)_6$ or other organometallic compound is bombarded by thermal (low energy) neutrons, an (n, γ) nuclear reaction occurs on the ^{98}Mo isotope to produce the ^{99}Mo isotope (half-life of three days). The sum of the masses of the neutron and the ^{98}Mo atom exceeds the mass of the ^{99}Mo nuclide. The extra mass/energy is about 5 MeV and is rapidly lost. The bulk of this energy is carried off by γ-rays, but the ^{99}Mo still recoils with several hundred eV of energy. That energy is more than enough to break all the metal–carbonyl bonds in the hexacarbonyl. The bulk of such hot-atom studies have been designed to determine what happens to the molybdenum atom during the 98–99 transformation. A remarkable amount of the ^{99}Mo from such neutron bombardment ends up in the chemical form of an organometallic compound like the hexacarbonyl. The mechanism by which this process occurs is the subject of controversy.

Given a method of preparing ^{99}Mo organometallic compounds, the β decay transformation of ^{99}Mo to ^{99m}Tc could be studied. The β decay of ^{99}Mo to ^{99m}Tc yields a nuclide with much lower recoil energy than that formed in the molybdenum (n, γ) process. However, this decay produces a cascade of Auger electrons (*see Auger Spectroscopy*) which can cause bond disruption. These studies are difficult, because the technetium-99m product is produced at radiochemical tracer levels. Macroscopic quantities of products are not available for spectroscopic characterization.

It may be assumed that a Tc species that has undergone significant manipulations during various physical separations must be an 18-electron compound, since 17- or 19-electron species are not stable enough to survive such operations. Therefore ionic species such as $[Tc(CO)_6]^+$ or $[Tc(CO)_5]^-$ would be expected to form from the decay of $^{99}Mo(CO)_6$.

Two other examples of the preparation of organometallic compounds by a hot-atom route have been postulated. The β decay of the ^{99}Mo atoms in $Mo(CO)_6$ could yield the $\cdot Tc(CO)_5$ radical as an intermediate, which might be trapped as a stable compound using the $\cdot Mn(CO)_5$ radical, which could come from any of several manganese carbonyls. De Jong and Wiles[9] isolated a ^{99m}Tc material, which they assigned to a mixed manganese–technetium decacarbonyl. Another technetium compound is obtained during the ^{99}Mo decay in the dimer $[C_5H_5Mo(CO)_3]_2$. This compound could form a stable 18-electron species $C_5H_5Tc(CO)_3$ through the conversion of the dimer to a monomer, without breaking either carbonyl or cyclopentadienyl (*see Cyclopentadienyl*) bonds. The compound $C_5H_5Tc(CO)_3$ is known to be a stable species.

Many excellent and detailed radiochemical tracer experiments have been utilized to support these compound assignments. However, it should be emphasized that further confirmation by spectroscopic or other macroscopic means has not been possible, owing to the trace concentrations of these product species.

3 STARTING MATERIALS

The ultimate starting material for ^{99}Tc or ^{99m}Tc chemistry is always $NH_4[TcO_4]$. When the ^{99}Tc material is purchased, it must be purified by recrystallization from 30% hydrogen peroxide or from nitric acid (caution: $NH_4[TcO_4]$ in acid medium will produce some radioactive volatile compounds). All manipulations must be performed in a laboratory monitored for radioactive material according to the country's national regulations. For the ^{99m}Tc preparations, the ^{99}Mo–^{99m}Tc generator will be the source of the anion $[^{99m}TcO_4]^-$.

Several intermediate materials can be used for preparative work of Tc compounds in a lower oxidation state. The square-pyramidal complex $[TcOCl_4]^-$ has been commonly used as starting material for several potent $[Tc{=}O]^{3+}$ core radiopharmaceuticals. The oxo ligand is located in the apical position and these compounds exhibit relatively short Tc–O bond distances, indicating some partial triple bonding involving the dπ orbitals of Tc. Nitrido complexes containing the Tc≡N core can be prepared by reduction of $[TcO_4]^-$ with hydrazine in the presence of dilute HCl. The strong π-accepting properties of the nitride ligand seems to promote the coordination of relatively soft ligands. Reaction of compounds like $TcCl_4$ with NaC_5H_5 in ether is a common synthetic method to synthesize cyclopentadienyl technetium complexes. Tc compounds with phosphine ligands are also interesting intermediates for preparing lower oxidation states compounds, especially those with phosphine and isonitrile ligands. The reaction of $[TcO_4]^-$ with phosphines in the

presence of HCl will produce either $Tc^{IV}(PR_3)_2Cl_4$ or $Tc^{III}(PR_3)_3Cl_3$ depending on the conditions and the bulkiness of the phosphine. More recently, the ionic compounds $[Tc^{III}(PR_3)_4Cl_2]^+$ were reported with small phosphines, from the reaction of $[TcO_4]^-$ with the phosphine in methanol in the presence of a chloride salt. When using phosphine ligands, no other reducing agent is needed since phosphines are good reducing agents being oxidized to the phosphine oxide. The reactions of these phosphine complexes with another ligand like isonitrile will produce the mixed-ligand Tc complexes.[10]

The compound $Na[Tc_3(CO)_9(OMe)_4]$ prepared by the incomplete carbonylation of sodium pertechnetate in methanol shows promises as an important reagent for the future.[11] It has been used to prepare $LTc(CO)_3$, $Tc_2(CO)_{10}$, and various arene and cyclopentadienyl complexes (*see Arene Complexes* and *Cyclopentadienyl*). The reaction conditions for these syntheses are moderately mild.

More recently, the Tc(I) compound $[Tc(CO)_3(H_2O)_3]^+$ has become an important starting material for labeling organometallic pharmaceuticals. The compound can be prepared in water and at normal pressure. The use of the toxic gaseous CO was a problem, but a kit has recently been developed using solid nontoxic potassium boranocarbonate, which releases CO when hydrolyzed and which can reduce Tc(VII) to Tc(I).[12] Therefore this kit should increase drastically the use of the precursor $[Tc(CO)_3(H_2O)_3]^+$ for ^{99}Tc and ^{99m}Tc studies. The chemistry of this molecule will be discussed in more details in a later section.

4 BINARY CARBONYL COMPOUNDS

In organometallic chemistry, the most important π-accepting ligand (*see π-Acid Ligand*) is CO. The bond between the metal and CO is through the C atom. The nature of the linear terminal metal–CO bond is multiple. The σ bond is formed from the dative overlap of the filled CO σ orbital with an empty σ-type orbital on Tc. The back-donating (*see Back Bonding*) π bond is formed from the overlap of the filled dπ orbital of the metal with an empty π^* orbital on CO. This bonding mechanism is synergic (*see Synergic Bonding*) and the effects of σ-bond formation strengthen the π bonding and vice versa. Therefore the M–CO bond is quite strong. This type of π-accepting ligand is classified as a soft ligand and will interact with soft metal ions. Therefore in its compounds with technetium, the oxidation state of Tc is usually low (≤ 3).

The multiple nature of the M–CO bond increases the strength of the M–C bond and reduces the one of the C≡O bond, which can be observed in the vibrational spectrum of the metallic compound. The CO molecule has a stretching ν(C–O) frequency of 2143 cm^{-1}. When coordinated to a metal, the frequency is reduced to about 1900–2125 cm^{-1} for terminal CO groups, showing a reduction in the CO bond order. Moreover, when changes are made to increase the extent of back-bonding, the CO frequencies are shifted to even lower values. IR spectroscopy is also very useful to suggest the structure of metal carbonyl compounds. Bridging CO groups absorb between 1750 and 1850 cm^{-1}, while terminal groups absorb at higher frequencies (1850–2125 cm^{-1}).

For binary metal carbonyl compounds, the 18-electron rule is a very useful concept. Stable metal complexes will be formed when the metal has 18 electrons in its valence shell (metal valence electrons + 2 electrons from each CO ligand). Since Tc(0) has 7 valence electrons, the neutral monomeric species $Tc(CO)_x$ cannot be stable, but ions like $[Tc(CO)_6]^+$ or $[Tc(CO)_5]^-$ attain a total of 18 electrons. In the neutral molecule, it will dimerize to $Tc_2(CO)_{10}$ in order to obey the 18-electron rule. The formation of a Tc–Tc bond adds an electron on each Tc atom. This 18-electron rule is quite useful to predict the structures of the metal binary carbonyl compounds.

The initial synthesis of $Tc_2(CO)_{10}$ was quite difficult to perform and it became a significant barrier to future work. The high-pressure syntheses that were used for many years could not be performed in standard high-pressure equipment.[13] The synthetic situation has improved noticeably in the subsequent years. A preparation which is a refinement of the one reported earlier has been reported in 1991.[14] In this procedure, 0.5 g of $NH_4[TcO_4]$ is placed in a 450 mL autoclave with a small amount of THF as solvent and 2% sodium amalgam is added as reducing agent to produce $Na[TcO_4]$. Carbon monoxide at 70 atm at room temperature is introduced and the vessel is heated to 120 °C for 72 h. A 70% yield of $Tc_2(CO)_{10}$ was found. This procedure can be performed in standard readily accessible pressure equipment and is considerably less dangerous than the earlier reported work. In addition, the CO pressure can be provided directly by a tank of carbon monoxide. Another method published in 1991 involves also the conversion to sodium pertechnetate and then the transformation to $Tc_2(CO)_{10}$ by reaction with CO at 100 atm at 230 °C for 12 h in methanol. Four gram quantities have been prepared by this route.[11]

$$NH_4[TcO_4] \xrightarrow{N_2H_4} TcO_2 \xrightarrow{H_2O_2/NaOH} Na[TcO_4] \xrightarrow{CO} Tc_2(CO)_{10} \tag{2}$$

The decacarbonyl is moderately stable in air. It does not require special handling in glove boxes or Schlenk-tube apparatus. It must always be respected for its chemical toxicity, slight volatility, and mild radioactivity. The compound contains a metal–metal bond but no bridging carbonyl groups. The geometry around each Tc atom is octahedral with a Tc–Tc single bond distance is 3.036(6) Å. The four equatorial carbonyls on each metal atom are staggered relative to one another and are slightly bent back from the apical carbonyl. It has the approximately D_{4d} symmetry (Figure 1). The greater π-acceptor character of the axial CO ligands is shown by the shorter Tc–C distances (by 0.10 Å) than those of the equatorial ligands. The IR spectrum has been studied and the axial and equatorial CO stretching force constants have been evaluated

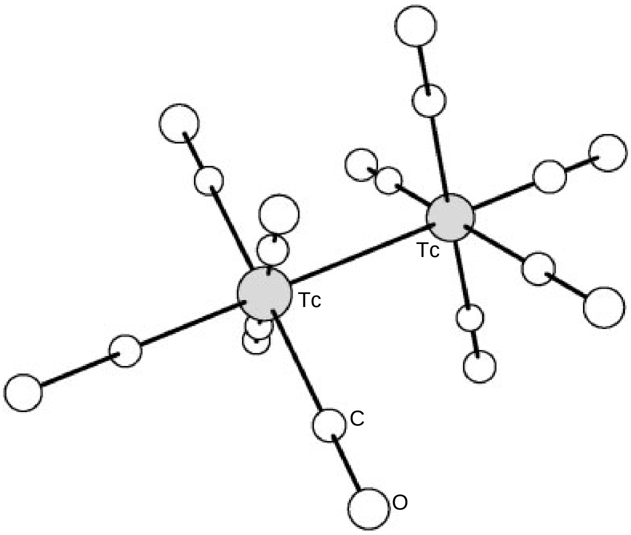

Figure 1 Structure of $Tc_2(CO)_{10}$. (Reproduced by permission of Springer-Verlag.[15])

at 16.316 and 16.642 mdyn Å^{-1} respectively, indicating a stronger equatorial CO bonds and therefore weaker Tc–C equatorial bonds. The ^{99}Tc NMR spectrum of $Tc_2(CO)_{10}$ have shown a single signal at −2777 ppm from $[TcO_4]^-$.

The mixed metal decacarbonyl complexes that have Mn–Tc and Tc–Re metal combinations have been prepared and the compounds have similar structures.

The most extensive substitution into $Tc_2(CO)_{10}$ has been with PF_3, and as many as 24 species have been clearly identified by gas chromatography/mass spectroscopy. Most of the $Tc_2(PF_3)_x(CO)_{10-x}$ species have had only tentative structural assignments.[16]

5 MIXED-LIGAND CARBONYL COMPOUNDS

There are numerous mixed-ligands Tc complexes where CO is present. A crystallographic structure data search of published structures containing the Tc–CO moiety produced 54 different mixed-ligands structures. These cannot be summarized here owing to the great variety of compounds. Only a few among the most simple molecules will be mentioned.

There are several examples of metal carbonyls containing a $Tc(CO)_5$ fragment.[15] The carbonyl halides $Tc(CO)_5X$ (X = Cl, Br, and I) may be prepared by the reaction of the halogen with $Tc_2(CO)_{10}$. The reaction with chlorine or bromine occurs readily at room temperature but the reaction with iodine is very slow. The IR spectra of these compounds have shown three ν(C–O) bands expected for C_{4v} symmetry, between 2153 and 1991 cm^{-1}. Several other technetium carbonyl halide species have been identified by mass spectroscopy (*see Mass Spectrometry*), which has been a primary tool in this gas phase chemistry.[17]

The structures of the halo-carbonyl compounds are usually oligomers. The dimers $\{Tc(CO)_4X\}_2$ where X = Cl, Br or I are formed from the reaction of the halogen with $Tc_2(CO)_{10}$ and the IR spectrum of the dimer has shown the absence of bridging CO vibrations and is consistent with a halo-bridged structure. The structure has been confirmed by crystallographic studies for the bromo compound and the iodo analogue $Tc(CO)_4(\mu\text{-}I)_2Tc(CO)_4$. The same authors have also published the structure of a tetramer $\{Tc(CO)_4Br\}_4$ consisting of a cube with four μ_3-Br bridges. An ionic dimer with three chloro bridges was reported for $NBu_4[Tc(CO)_3(\mu\text{-}Cl)_3Tc(CO)_3]$. A tetramer of formula $\{Tc(CO)_3\}_4(\mu\text{-}Cl)_4$ with a cubane-type structure was also reported. The same cubane structure was observed for the hydroxo analogue. When the halo ligand is replaced by hydride, a trimeric cluster with metal–metal bonds and hydrido bridges of formula $\{Tc(CO)_4\}_3(\mu\text{-}H)_3$ was characterized. Several other dimeric and polymeric complexes are also known.[18]

Several Tc compounds containing carbonyl, halo, and other ligands have been reported. Octahedral complexes of the type *trans*-$Tc(CO)_3Cl(PPh_3)_2$ and *trans*-$Tc(CO)Cl_3(PPh_3)_2$ are known. It is not possible to coordinate more than two PPh_3 ligands to Tc because of steric hindrance. Furthermore, they will always be located in trans position to each other. For less bulky phosphines, it is possible to bind three phosphines as in $Tc(CO)Cl_3(PPhMe_2)_3$ which is a seven-coordinate compound. Phosphite ligands are much less bulky and for example, the octahedral structure of *cis*-$Tc(CO)_2(PPh(OEt)_2)_4$ was reported.

Complexes of the type $Tc(CO)_4L$ have been prepared where L represents a series of anionic β-diketonate ligands (*see Diketones*). Several monomeric compounds can be prepared from dimers such as $[Tc(CO)_5(MeCN)]PF_6$, prepared from the reaction of $Tc_2(CO)_{10}$ with $NOPF_6$ and acetonitrile. The acetonitrile ligand is a good leaving group for the preparation of a variety of other mixed-ligand complexes that are cationic and water soluble. The compound $Na[Tc_3(CO)_9(OMe)_4]$ mentioned in the starting materials section has a cubane-type structure and it is a convenient precursor to carbonyl complexes in the $TcL(CO)_3$ family.

The reactions of the organometallic compound $[Tc(CO)_3X_3]^{2-}$ with three macrocyclic (*see Macrocycle*) thioethers were studied. A monomer $[Tc(CO)_3S_3]^+$ with a S_3 macrocyclic ring and dimers $[(CO)_3Tc(\mu\text{-}S_6)Tc(CO)_3]^{2+}$ with S_6 rings were characterized by X-ray diffraction methods. In the latters, the S_6 macrocyclic thioether forms a bridge between the two Tc atoms.[5] A series of dithiocarbamate and related complexes has been synthesized. These compounds include $Tc(CO)_4(S_2NEt_2)$, $Tc(CO)_2(PPh_3)_2(S_2NEt_2)$, $Tc(CO)_2(PPh_3)_2(S_2OEt)$ and $Tc(CO)_2(PPh_3)_2(S_2P(PMe)_2)$ and they have been characterized by IR and ^{1}H and ^{99}Tc NMR spectroscopies.

Tc in a low oxidation state can sometimes bind to very unusual ligands. Two examples of more complicated compounds are given below. These have been studied by crystallographic methods and have very interesting structures. The first one is a dimeric compound with a N_2 bridge. It can be formulated as $L(CO)_2Tc(\mu\text{-}N{\equiv}N)Tc(CO)_2L$ where L has the formula $BN_6C_{15}H_{22}$ and is a N∩N∩N tridentate ligand. The second compound is an ionic carborane (*see Carborane*) compound $NEt_4[Tc(CO)_3(\eta^5\text{-}2,3\text{-}C_2B_9H_{11})]$ which was prepared from $[Tc(CO)_3Br_3]^{2-}$. The crystal structure of the compound is shown in Figure 2. Bifunctional carboranes have been used successfully as carriers of a variety of different metal radionuclides.

In the ion $[Tc(CO)_3(H_2O)_3]^+$, which has already been mentioned in the section on starting materials, the metal center is in the low oxidation state +1 (diamagnetic, d^6 configuration) and is quite inert to reduction or oxidation. The structure is octahedral and the aqua molecules should be replaced easily in solution by more strongly binding ligands. The development of a kit to prepare this compound should be extremely useful for the labeling of biomolecules. The use of sodium or potassium boranocarbonate $Na_2/K_2[H_3BCO_2]$ was a major breakthrough permitting broader application of organometallic Tc precursors to nuclear medicine. The reagent serves as a solid source of CO and reduces concomitantly Tc(VII) to Tc(I).

$$NH_4[TcO_4] \xrightarrow[H_2O]{Na_2/K_2\,[H_3BCO_2]} [Tc(CO)_3(H_2O)_3]^+ \qquad (3)$$

The aqua complex can be easily prepared in 20 minutes at a temperature not higher than 100 °C. Subsequent substitution of the labile aqua ligands by a bifunctional group attached to a biomolecule enables the introduction of Tc–carbonyl complexes in life science in general and in nuclear medicine in particular. The molecule is remarkably stable in solution for long periods of time, a reflection of its low-spin d^6 electronic configuration. Although the compound is unreactive towards aliphatic amines and thioethers, it does react with the softer nitrogen atom of aromatic amines such as imidazole. As an example for the potential of the compound as an efficient label for derivatived biomolecules, Alberto *et al.* studied its reaction with the multifunctional ligand picolinamine-*N*,*N*-diacetic acid (PADA), which can be considered as a good model, since it provides three coordinating sites and one group for the covalent attachment to a biomolecule.[20]

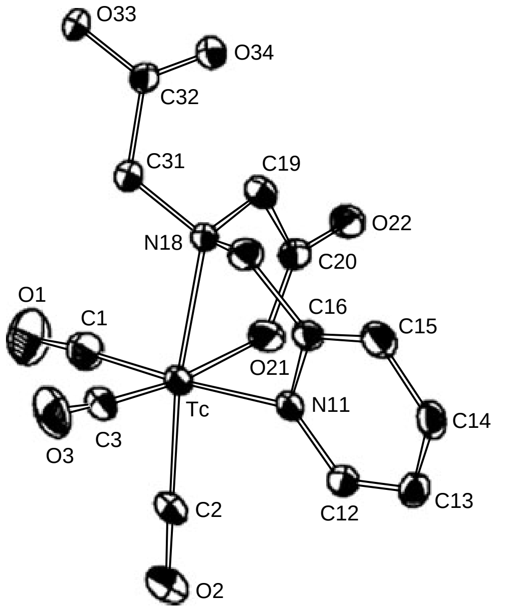

Figure 3 Structure of the compound $Tc(CO)_3(PADA)$. (Reprinted with permission from Ref. 20. © 1998 American Chemical Society)

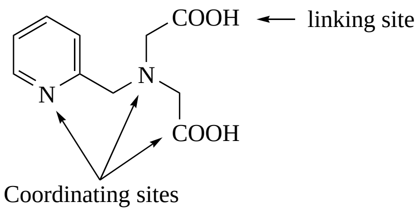
$$[^{99m}TcO_4]^- \longrightarrow [Tc(CO)_3(H_2O)_3]^+ \xrightarrow{PADA} Tc(CO)_3(PADA) \qquad (4)$$

PADA :



The structure of the neutral complex $Tc(CO)_3(PADA)$ was determined and a drawing of the molecule is shown in Figure 3.

Although Tc(I) is a soft metal and amino and carboxylato ligands are rather expected to form stable compounds with harder metal centers, $Tc(CO)_3(PADA)$ exhibits quite high

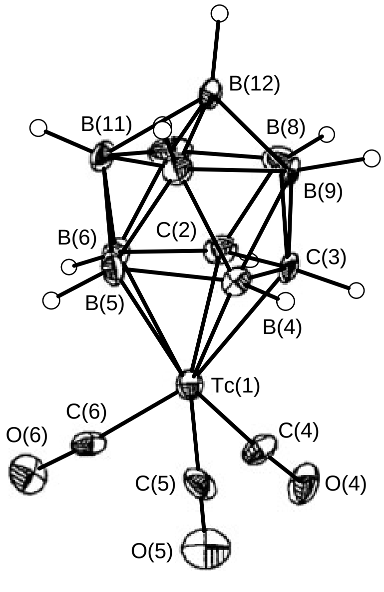


Figure 2 Structure of the anion $[Tc(CO)_3(\eta^5\text{-}2,3\text{-}C_2B_9H_{11})]^-$. (Reprinted with permission from Ref. 19. © 2002 American Chemical Society)

stability. The second carboxylic group on the PADA ligand is accessible for covalent bonding to a biomolecule.

6 CYCLOPENTADIENYL COMPLEXES

Cyclopentadienyl (Cp) complexes (*see Cyclopentadienyl*) are known for almost all the metals of the periodic chart, including technetium. The compounds with transition metals usually possess covalent π Cp–M bonding. The nature of the metal–Cp bond is multiple. The σ-bond is formed from the overlap of an empty d orbital of Tc with one of the filled π bonding molecular orbital on Cp with good symmetry. Back-donation is usually also present from the filled d orbitals of Tc to one of the empty π molecular orbitals on Cp. These molecules are usually called sandwich compounds (*see Sandwich Compound*), when there are two Cp ligands bonded to the metal, or half-sandwich complexes (*see Half-sandwich Complexes*) when only one Cp ligand is present.

The earliest work with cyclopentadienyl was reported independently by Kaesz[6] and by Fischer.[7] They carried out reactions using $TcCl_4$ and sodium cyclopentadienyl in the presence of BH_4^- as a reducing agent. The species $Tc(Cp)_2H$ and $[Tc(Cp)_2H_2]^+$ have been prepared. These compounds are believed to have bent metallocene (*see Bent Metallocenes*) structures. The reaction of $TcCl_4$ and potassium cyclopentadienyl in THF gives the diamagnetic air-stable $Tc(Cp)_2Cl$, whose structure is shown in Figure 4.

Further reaction of the latter compound with KCp yields the red diamagnetic $Tc(\eta^5\text{-}Cp)_2(\eta^1\text{-}Cp)$, where one Cp ring is σ-bonded to Tc (Figure 5). Mass spectral evidence has been reported for a $Tc(Cp)_4$ compound, but it has not been characterized.

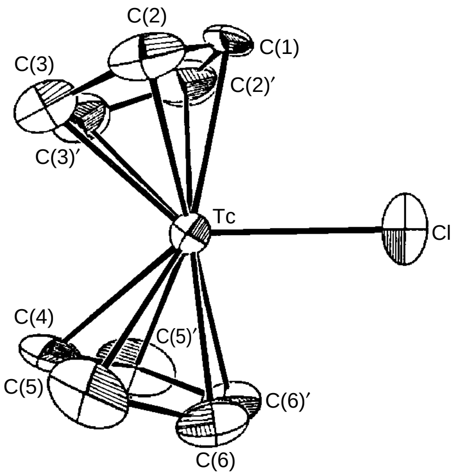

Figure 4 Structure of $Tc(Cp)_2Cl$. (Reprinted from Ref. 21. © 1990 Elsevier)

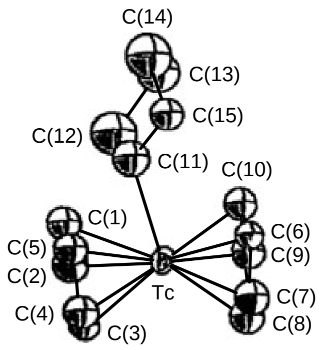

Figure 5 Structure of $Tc(\eta^5\text{-}Cp)_2(\eta^1\text{-}Cp)$. (Reprinted from Ref. 22. © 1991 Elsevier)

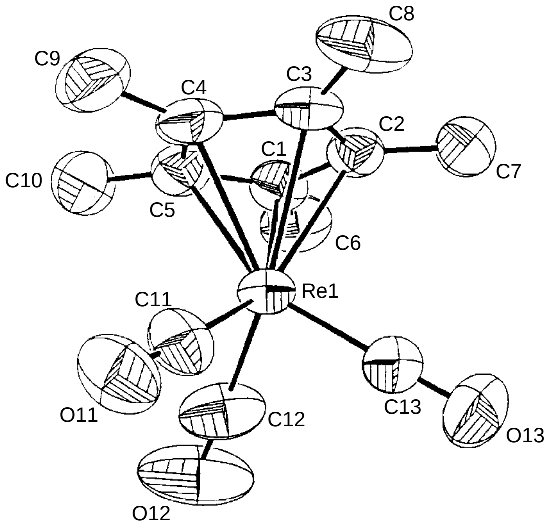

Figure 6 Structure of $Tc(CO)_3(\eta^5\text{-}Cp^*)$. (Reprinted from Ref. 23. © 1991 Elsevier)

The compound $Tc(\eta^5\text{-}C_5H_5)(CO)_3$ was prepared by the reaction of $Tc(CO)_5X$ with NaCp. Complexes with a number of cyclopentadienyl derivatives (Cp′) have been studied especially by the group of Ziegler. The crystal structures of several $Tc(CO)_3(Cp')$ compounds where $Cp' = C_5Me_5$ (Cp*), C_5Me_4Et, indenyl, and $Cp\text{–}COCH_2Ph$ were reported. All these compounds have the piano stool structure (*see Piano Stool Structure*) as shown in Figure 6.

Irradiation of $Tc(CO)_3(Cp^*)$ by a low pressure mercury lamp in dry cyclohexane in the absence of air produces two carbonyl-bridged dimers, $(Cp^*)Tc(\mu\text{-}CO)_3Tc(Cp^*)$ which was characterized by crystallography and $(Cp^*)(CO)_2Tc(\mu\text{-}CO)Tc(Cp^*)(CO)_2$ whose structure was suggested by spectroscopic comparison with the structurally characterized Re analogue. These two compounds can be separated by column chromatography. The IR spectrum of the former compound showed only one carbonyl stretching at $1785\,cm^{-1}$ and its structure is shown in Figure 7.

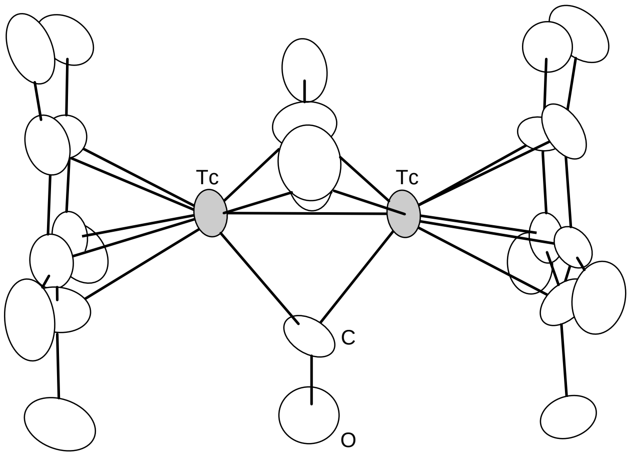

Figure 7 Structure of (Cp*)Tc(μ-CO)$_3$Tc(Cp*). (Reprinted from Ref. 24. © 1991 Elsevier)

The short Tc–Tc bond length 2.413(3) Å corresponds to a bond order of three. In the second molecule, a single Tc–Tc bond order has been proposed to satisfy the 18-electron rule (Cp is a 6 electron donor). The latter compound has shown several ν(C–O) bands between 1738 and 2012 cm^{-1}.

The oxidation of Re^{I}(CO)$_3$(Cp*) by H_2O_2 produces the trioxo compound Re^{VII}O$_3$(Cp*), but with Tc^{I}(CO)$_3$(Cp*), the product was reported as having a polymeric structure {Tc(μ-O)$_3$Tc(Cp*)}$_n$, with parallel Cp* planes and a very short Tc–Tc bond, 1.867(4) Å. But the crystal-structure determination has been questioned and it has been suggested that the product was in fact Tc^{VII}O$_3$(Cp*), which is probably more reasonable.

Attempts were made to use cyclopentadienyl technetium tricarbonyl derivatives for labeling estrogen receptor binding ligands as well as proteins and peptides.[25]

7 ISONITRILE COMPLEXES

A very important major class of organometallic compounds that will be discussed here are those containing isonitrile (or isocyanide) ligands (*see* ***Cyanide Complexes of the Transition Metals***). Isonitriles are bonded to the metal through the carbon atom, allowing them to be classified as organometallic compounds. They are electronically similar to carbon monoxide as a ligand. The isonitrile molecule donates σ electron density to the metal and has empty π-antibonding orbitals to accept back-donating electrons from the metal. These ligands will bind to soft metals like Tc in a low oxidation state.

Davison and coworkers[26] have extensively studied technetium compounds that have potential application in nuclear medicine. In this process, significant advances in the isonitrile chemistry of technetium have been achieved. The type of complex of greatest current interest has the basic formula [Tc(CNR)$_6$]$^+$. Monopositive cations of Tc in a low oxidation state are strongly absorbed by the myocardiac muscle, and technetium-99m complexes can therefore be used for diagnostic purposes in nuclear medicine. Group 1 cations have been known for a long time to accumulate in normal heart tissue. Later thallium(I) was thought to function as a K$^+$ analogue and ^{201}Tl has been used for many years as a heart agent in nuclear medicine. Later, it was suggested that +1 charged Tc complexes could mimic the Tl$^+$ compounds in a more effective way, since ^{201}Tl is a poor radionuclide relative to ^{99m}Tc. Studies on the changes in the R group on the isonitrile compound [Tc(CNR)$_6$]$^+$ have shown considerable property variations in the complexes and suggested the possibility to tailor a compound to meet specific needs. Extensive medical tests have been performed with these compounds. Several patents have been issued for the use of these complexes as imaging agents.

The most important compound is *cardiolite* which is a charged +1 cationic complex containing six isonitrile ligands, [Tc(CNCH$_2$C(CH$_3$)$_2$OCH$_3$)$_6$]$^+$ and has been used for myocardial perfusion imaging for several years now. More recently, it has been approved for breast cancer imaging. The synthesis of this complex is accomplished by the reaction of pertechnetate ion with an excess of the isonitrile ligand in the presence of a reducing agent $Na_2S_2O_4$. The complex is octahedral and is stable under aqueous aerobic conditions in the pH range of 5−7. A kit for the ^{99m}Tc preparation of the compound is commercially available for routine use in hospitals. *Cardiolite* is the first example of an organometallic complex routinely used in nuclear medicine.

Related Tc(I) octahedral complexes have been prepared containing mixed ligands. These include a few +1 ionic isonitrile-phosphine compounds such as [Tc(PPhMe$_2$)(CN*t*Bu)$_5$]$^+$ and *trans*-[Tc(PPhMe$_2$)$_2$(CN*t*Bu)$_4$]$^+$ which were prepared from Tc(PPhMe$_2$)$_{2or3}$Cl$^{10}_{4or3}$ and *trans*-[Tc(dppe)$_2$(CNR)$_2$]$^+$ synthesized from Tc(N$_2$)H(dppe)$_2$. These complexes were studied by crystallography. Other complexes of this type include [Tc(CO)$_3$(CN*t*Bu)$_3$]$^+$ and [Tc(bpy)(CN*t*Bu)$_4$]$^+$. In these structures, the segment Tc–C≡N–C is linear and the C≡N bonds are ~1.16 Å.

A few neutral mixed-ligands compounds were also reported. These are *cis* and *trans*-Tc(CO)$_3$Cl(CN*t*Bu)$_2$ and Tc(NO)Br$_2$(CN*t*Bu)$_3$. Two five-coordinate Tc(III) compounds Tc(*CNiPr*)(L) where L is a tetradentate ligand containing some P and S atoms have been studied. More recently, three five-coordinate neutral compounds with the formula Tc(S$_3$NC$_6$H$_{12}$)(CNR) where R=cyclohexyl, benzyl or CH$_2$COOEt were also reported.

8 CYANIDE COMPOUNDS

Technetium cyanide chemistry is more limited. A few Tc cyanide complexes (*see Cyanides*; ***Cyanide Complexes***

of the Transition Metals) are known, especially in the oxidations states of I, III, and V. The reduction of $[TcO_4]^-$ with KCN produces the Tc(I) compound $K_5[Tc(CN)_6]$, which is probably isostructural with the Mn and Re analogues. The cyanide ligand is a relatively strong π-acceptor. The only Tc(III) cyano compound is the seven-coordinate $K_4[Tc(CN)_7]\cdot 2H_2O$ which was prepared from the reaction of $(NH_4)_2Tc^{IV}I_6$ with KCN. IR and Raman spectroscopy suggest a pentagonal bipyramidal structure with C_{5h} symmetry. In aqueous solution, it decomposes in air to form the greenish Tc(V) compound $[TcO(CN)_5]^{2-}$. The IR spectrum of the latter compound seems to indicate C_{4v} symmetry. The lilac compound *trans*-$[TcO(OMe)(CN)_4]^{2-}$ was isolated from the reaction of $NBu_4[TcOCl_4]$ with CN^- in methanol. The compound NMe_4*trans*-$[TcO(H_2O)(CN)_4]\cdot 2H_2O$ was also isolated and its reaction with the thiocyanate ion produced *trans*-$[Tc^VO(NCS)(CN)_4]^{2-}$ which was studied by crystallographic methods. The thiocyanate ligand is coordinated through the N atom and the Tc=O bond is short (1.612(8) Å). Another interesting Tc(V) compound which was determined by X-ray diffraction methods is $(AsPh_4)_2$*trans*-$[TcN(H_2O)(CN)_4].5H_2O$. Tc-nitrido complexes have some importance in the radiopharmaceutical field.

9 ARENE COMPLEXES

No Tc-arene complexes (*see Arene Complexes*) seem to have been characterized by X-ray diffraction methods, but a few compounds have been reported. The reagent mentioned earlier, $Na[Tc_3(CO)_9(OMe)_4]$, can yield not only the decacarbonyl but also the $(C_5Me_5)Tc(CO)_3$ complex, as well as an arene complex, $[(C_6H_6)Tc(CO)_3]Cl$.

E. O. Fischer was the first to prepare arene complexes of technetium.[27] Arene ligands in these compound are typically six-electron donors. The nature of the Tc-arene bond is probably very similar to the one of the Tc–Cp bond. The $[Tc(arene)_2]^+$ complexes (arene = benzene or hexamethylbenzene) are prepared by the reaction of $TcCl_4$ with the appropriate arene in the presence of $AlCl_3$/Al. In a typical reaction, $TcCl_4$, $AlCl_3$, and aluminum were heated with benzene in a sealed tube to 135 °C for two days. The product is precipitated as a salt using the hexafluorophosphate ion. A variety of other 18-electron compounds can be prepared from this material, particularly through chemical reduction.

Recently, interest in the arene complexes has increased owing to their potential use as ^{99m}Tc imaging agents. Monopositive complexes are of particular interest because they may be suitable for myocardial uptake, and thus for use in heart imaging. Since one must use aqueous $[TcO_4]^-$ ion obtained from the ^{99}Mo generator as the source of ^{99m}Tc, the synthetic chemistry must be rather different from that used by Fischer. Among other things, anhydrous $AlCl_3$ would not be compatible with aqueous solutions. In addition, for such compounds to be of general use in nuclear medicine, it would be highly desirable to develop simplified synthetic procedures. An alternate preparation is cleverly initiated using ultrasound. Both ^{99}Tc and ^{99m}Tc complexes can be prepared and the identity of the two materials is verified by HPLC techniques. A series of arene complexes has been prepared, primarily containing various alkyl-substituted arenes, such as toluene or xylene.

10 MISCELLANEOUS ORGANOMETALLIC COMPOUNDS

Ziegler and coworkers[28] have synthesized a butadiene complex of technetium by the photolysis of $Tc_2(CO)_{10}$ in the presence of butadiene at −20 °C in pentane. The product $\{Tc(CO)_4\}_2(\mu\text{-}\eta^4\text{-}C_4H_6)$ has a butadiene ligand bridging two technetium atoms. A few crystal structures of dimers with metal−metal bonds and containing phenylimido ligands were characterized with the ligand − CH_3 and a similar monomer $Tc(phenylimido)_3(CH_3)$ was reported. An interesting thiocarbonyl compound *trans*-$Tc(CS)(dppe)_2Cl$ was recently characterized by crystallography. In 1994, two unusual organometallic compounds of formula *trans*-$Tc(dppe)_2Cl(C{=}CH\text{–}Ph)$ and *trans*-$[Tc(dppe)_2Cl(C\text{–}CH_2-t\text{Bu})]^+$ were reported.

1 INTRODUCTION

Tellurium was discovered in 1782 by Franz Josef Müller von Reichenstein from Transylvanian gold ore known as aurum album. Initially he believed he had isolated antimony but realized shortly that it was a previously unknown element. Since Müller von Reichenstein published his findings in an obscure journal,[1] the work was forgotten until 1798 when Martin Heinrich Klaproth, a German chemist, confirmed the discovery of the new metal and gave it the name tellurium, which derives from Latin tellus = Earth.[2]

The abundance of tellurium in earth's crust is ca. 0.01 ppm. Tellurium is found free in nature and over 100 tellurium-containing minerals are known (for some examples, see Table 1), but because of their low abundance, it is economically not viable to recover the element from its mineral ores. Since, like selenides, tellurides generally occur together with the sulfide ores, the element is commercially obtained from the anode sludge produced during the refining of copper from $CuSeF_2$.

The estimation of the world production of tellurium is difficult, since the two major producers do not publish production figures. The worldwide consumption in 2002 is estimated as 220 tonnes. It has slightly reduced over the recent years. Metallurgical uses dominate tellurium demand. In 2002, about 60% of tellurium was used as an alloying element to improve the properties of copper, iron, lead, and steel. Other uses include catalysts and chemicals (25%), photoreceptors and thermoelectric devices (8%), and miscellaneous minor uses (7%).[3]

Inorganic compounds of tellurium are considered moderately toxic and should be handled with care. The ingestion of even trace amounts of inorganic tellurium compounds results in the development of 'tellurium breath', caused by the garlic-like odor of dimethyltelluride, which is formed in vivo by slow biochemical methylation. The fatal doses of Na_2TeO_3 are estimated to be 2.25–2.50 mg Te kg^{-1}, and that of $Na_2Te_2O_4$ to be 20.0–30.0 mg Te kg^{-1}. The LD_{50} for tellurium aerosols is of the order of 10 mg m^{-3}. Tellurium is not considered to have carsinogenic, teratogenic, or mutagenic effects in humans.

2 ELEMENTAL TELLURIUM AND RELATED MIXED CHALCOGEN SYSTEMS

2.1 General

Crystalline tellurium is silvery-white and shows a metallic lustre when pure. It is rather brittle and is easily pulverized into dark grey powder. The Pauling electronegativity of tellurium is 2.1 and its absolute electronegativity is 5.49 eV. Some other useful physical properties are listed in Table 2.

Tellurium is a p-type semiconductor. The element shows anisotropy in electrical conductivity that is essentially independent of temperature in the range 78–200 K. It has been reported that single crystals grown in vapor show more strongly metallic conductivity parallel to the Te_n chains. The conductivity of tellurium is much less affected by illumination than that of selenium.

There are eight naturally occurring isotopes of tellurium (see Table 3). Of those, ^{123}Te and ^{125}Te have nuclear spin of 1/2 and are convenient nuclei for NMR spectroscopy. ^{125}Te is also a suitable isotope for Mössbauer spectroscopy.

2.2 Allotropy of Tellurium

Hexagonal tellurium is the thermodynamically stable allotrope of the element. It is isostructural with hexagonal α-selenium[4] and is composed of a network of helical chains (see Figure 1). The Te–Te bond length is 2.831 Å and the closest interchain distance is 3.494 Å.[5] It can be seen from Figure 1 that the interchain contacts expand the coordination around each tellurium atom into a polyhedron. This kind of secondary bonding interactions has originally been proposed by Allcock[6] and discussed on several occasions in connection of a wide variety of tellurium compound (for some examples, see Ref. 7 and references therein). It is interesting to note that the corresponding interchain distances in hexagonal α-selenium are 3.463 Å[4] indicating that the secondary bonding interactions in selenium are weaker than in tellurium (the van der Waals' radii of selenium and tellurium are 1.80 and 2.20 Å, respectively).

The *TP* phase diagram of tellurium is complex[8] and indicates the presence of several high-pressure modifications. Five distinct phases have been isolated and structurally

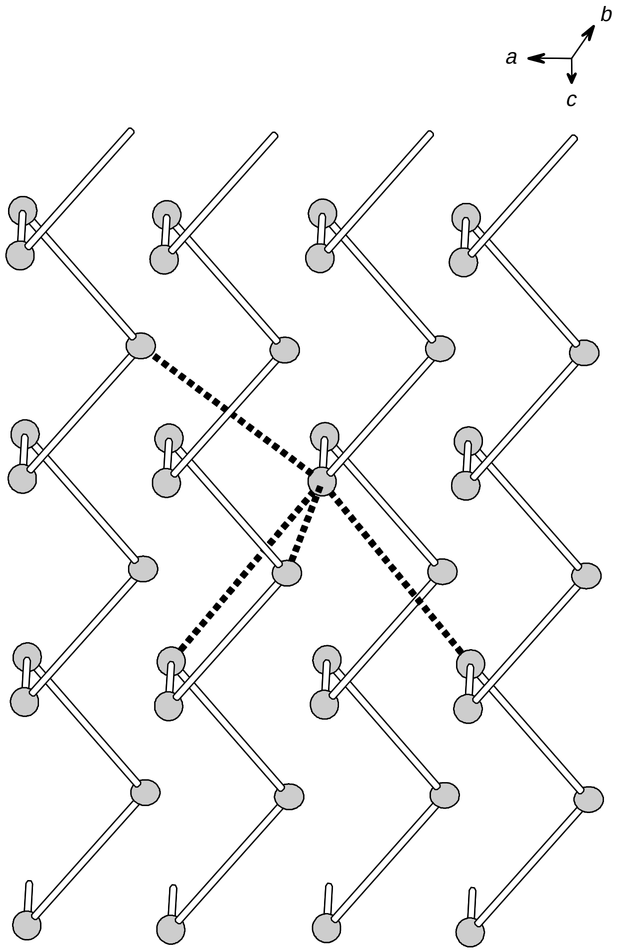

Figure 1 The crystal structure of hexagonal α-tellurium[5]

characterized.[9–13] The crystal structures are shown in Figure 2. It can be seen that as the pressure increases, the packing becomes more efficient and approaches the bcc structure. There is also a wide variety of studies concerning the superconductivity of high-pressure forms of tellurium.[14] The transition temperature seems to increase as a function of pressure and is in the range of 2.5–4.3 K up to 150 kbar and is ca. 6.5 K in the range 150–180 K.

Table 3 Naturally occurring isotopes of tellurium

Isotope	Atomic mass	Natural abundance	Half-life (y)	Nuclear spin	Nuclear magnetic moment	Receptivity in NMR ($^{13}C = 1$)	Magnetogyric ratio ($rad\,T^{-1}s^{-1}$)

Whereas sulfur and selenium exhibit a wide variety of cyclic molecular forms, the evidence of the existence of homocyclic tellurium rings is much hazier.[15] The existence of the Te_8 ring molecule in zeolites has been suggested on the basis of conductivity measurements and Raman spectroscopy.[16,17] The reaction of $[Ti(C_5H_5)_2(\mu\text{-}Te_2)_2Ti(C_5H_5)_2]$ and Te_2Cl_2 could also be expected to afford Te_8. Indeed, a single resonance at 869 ppm is observed in the ^{125}Te NMR spectrum of the reaction mixture.[18] This resonance is in the region that could be expected for Te_8 (c.f. 611.5 ppm for Se_8.[19]). The most direct evidence for the formation of the Te_8 ring comes from reaction of Cs_2CO_3 and As_2Te_3 in MeOH at 195 °C under an argon atmosphere.[20] The product has the composition Cs_3Te_{22} and contains crown-shaped puckered Te_8 rings between the $[Te_4Te_{4/2}]_{2\infty}{}^{3-}$ layer anions (see Figure 3). The Te–Te distances in the ring are 2.787–2.818 Å, the bond angles 99.32–101.12°, and the torsional angles 106.53–106.95°. Cs_4Te_{28} also contains a Te_8 ring in a related layered two-dimensional polytelluride lattice (see Figure 3).[21]

2.3 Tellurium-containing Chalcogen Chains and Rings

Tellurium is chemically similar to selenium and sulfur and though its allotropy is simpler than that of selenium and sulfur, it can form a number of acyclic and cyclic heteronuclear mixed chalcogen species. In the liquid state, tellurium and selenium can form miscible mixtures. The research activity has been boosted by the observation that mixed selenium–tellurium system shows enhanced conducting and photoconducting properties compared to those of selenium.[22] The indexing of X-ray powder diagrams in terms of a hexagonal unit cell indicates an almost linear variation in the lattice constants as a function of the elemental composition.[23] These results can be interpreted by the statistical distribution of tellurium and selenium atoms in the helical chain that is shown in Figure 1.

The formation of eight-membered tellurium sulfide rings in the molten mixtures has been deduced by mass spectrometry,[24] Mössbauer spectrometry,[25] and ^{125}Te NMR spectrometry.[26] The crystal structure of the phase prepared from H_2S and $TeCl_4$ was found to be disordered and was deduced to contain a mixture of the eight-membered crown-shaped ring molecules S_8, TeS_7, and Te_2S_6.[27] A similar eight-membered ring is also found in TeS_7X_2 (X = Cl, Br) with the two halogen atoms bound to tellurium.[28] Nagata *et al.*[29,30] have reported the structures of seven- and eight-membered selenium-rich selenium telluride heterocycles that have conformations similar to the analogous sulfur, selenium, and selenium sulfide ring molecules.[15]

Eight-membered $Te_nSe_mS_{8-(n+m)}$ rings have been detected in the ternary molten mixture containing 1.5 mol-% of both tellurium and selenium and 97 mol-% of sulfur.[31] The ^{125}Te NMR spectrum has been recorded at 145 °C for the melt containing selenium enriched in the ^{77}Se isotope and tellurium enriched in the ^{125}Te isotope (in both cases the enrichment is 92%) and is shown in Figure 4.

Tellurium-containing chalcogen rings are also formed by following the preparative routes known for other chalcogen rings (see Ref. 15 and references therein). The most important processes have been summarized below.

$$\left\{\begin{matrix} [Ti(MeC_5H_4)_2(\mu\text{-}Te_2)_2(Ti(MeC_5H_4)_2] \\ (\boldsymbol{A}) \\ [Ti(MeC_5H_4)_2(\mu\text{-}Te_xS_{2-x})_2Ti(MeC_5H_4)_2] \\ (\boldsymbol{B}) \\ [Ti(MeC_5H_4)_2(\mu\text{-}Te_xSe_{2-x})_2Ti(MeC_5H_4)_2] \\ (\boldsymbol{C}) \end{matrix}\right\} + \left\{\begin{matrix} 2S_2Cl_2 \\ 2S_2Cl_2/Se_2Cl_2 \end{matrix}\right\}$$

$$\longrightarrow \left\{\begin{matrix} Te_xS_{8-x} \\ Te_xSe_yS_{8-(x+y)} \end{matrix}\right\} + 2[Ti(MeC_5H_4)_2Cl_2]$$

$$\underset{(\boldsymbol{D})}{(Me_3Si)_2Te} + ClSeS_5SeCl \longrightarrow 1,2,8\text{-}TeSe_2S_5 + 2Me_3SiCl$$

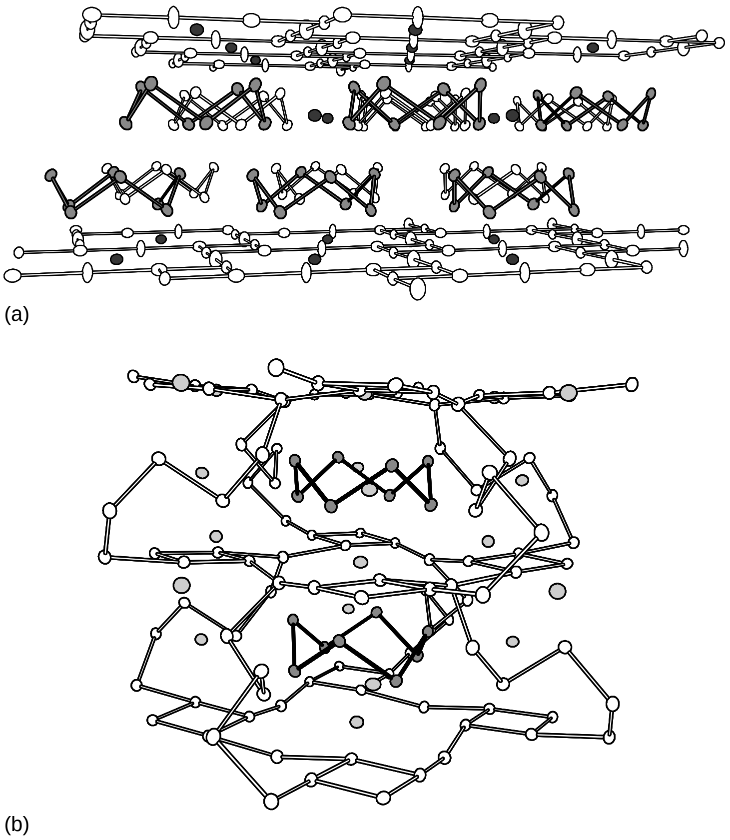

Figure 3 The Te_8 ring molecule in (a) Cs_3Te_{22} lattice[20] and (b) Cs_4Te_{28}[21]

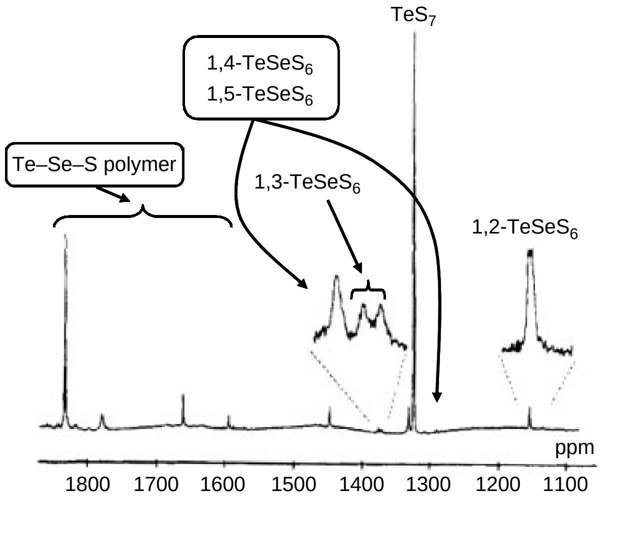

Figure 4 ^{125}Te NMR spectrum of the ternary sulfur–selenium–tellurium melt containing 1.5 mol% of both ^{77}Se-enriched selenium and ^{125}Te-enriched tellurium (enrichment 92%). The spectral assignments and the identification of the molecular species were made on the basis of combined information from the natural abundance and from the ^{77}Se- and ^{125}Te-enriched samples taking the known trends in the ^{77}Se and ^{125}Te chemical shifts into account. Figure 5 The relative stabilites of the isomers of $TeSe_2S_5$ calculated at MP2/3-21G*//HF/3-21G* level of theory. (Ref. 31. Reproduced by permission of Taylor & Francis (www.tandf.co.uk/journals))

An ab initio MO study of eight-membered sulfur-rich tellurium selenium sulfide rings has shown that the most stable species contain Se–Te bonds.[31] This is exemplified by

the relative stabilities of the different isomers of $TeSe_2S_6$ that are shown in Figure 5. 1,2,8-$TeSe_2S_6$ is the most stable of the isomers. The formation of this species was observed in the reaction of $(Me_3Si)_2Te$ with $ClSeS_5SeCl$.[31]

3 TELLURIUM-CONTAINING IONS

3.1 General

Telluride anions have been known for a hundred years. Presently about 200 binary tellurides have been synthesized and there are ca. 50 species that have been structurally characterized. Their synthetic and structural chemistry as well as their ligand properties and applications have recently been reviewed several times.[32–39]

The propensity of tellurium to form intermolecular interactions distinguishes its chemical properties from those of sulfur and selenium for which such secondary bonding is virtually nonexistent (see Ref. 38 and references therein). By contrast to polysulfides and polyselenides, polytelluride anions can exhibit charges that deviate from −2.

The usual preparation of the materials involves direct high-temperature combination of the elements, solution reactions involving elemental tellurium and alkali metal carbonates, solventothermal reactions between the elements, or oxidation-reduction reactions with Lewis acids.[38] These methods have mostly been applied to alkali metal or alkaline earth metal tellurides that can then serve as precursors to other telluride species. The presence of a large organic cation or the encapsulating agent such as the crown ether complex of an alkali metal leads to the stabilisation of otherwise unstable polytellurides. Polytellurides have also been obtained as by-products in the electrochemical reduction processes involving tellurium and an organic cation.

Recently, low-temperature routes have been sought for by decomposition of organometallic complexes with tellurium-containing ligands. The optoelectronic devices normally require the material to be used as thin films. They are fabricated with special methods, such as molecular beam epitaxy, metal-organic chemical vapour deposition, or atomic layer deposition.

3.2 Monotellurides

Binary tellurides are generally solid crystalline substances at room temperature. The most common structural classes have been presented in Table 4. The telluride bulk materials are commonly prepared by the direct reaction between the elements. In recent years, low-temperature routes from transition metal complexes with tellurium-containing ligands are being sought for.

Most tellurides are semiconductors and find applications in the fabrication of electronic devises. Some tellurides, for example, HgTe, Ag_2Te, GeTe, and SnTe, are virtually metallic conductors.

Table 4 Structural classification of metal tellurides

Structure type	Example
Face center cubic lattice	
NaCl	CaTe, SrTe, BaTe, $Sc_{0.666}Te_{0.999}$, YTe, LuTe
Zinc blende	BeTe, ZnTe, CdTe, HgTe
Pyrite	$MgTe_2$, $MnTe_2$, $RuTe_2$, $OsTe_2$
Antifluorite	Li_2Te, Na_2Te, K_2Te, Rb_2Te
Hexagonal close packed lattice	
Wurzite	MgTe, ZnTe
CdI_2	$TiTe_2$, $PdTe_2$, $PtTe_2$, $CoTe_2$, $NiTe_2$, $IrTe_2$
NiS	MnTe, CrTe, PdTe, PtTe, CoTe, NiTe, IrTe

The chalcogenides of Be, Zn, Cd, and Hg are often referred to as II-VI semiconductors. They all have a zinc blende-type structure. The band gap decreases with increasing size of the metal from 3.0 eV in beryllium to 0.02 eV in mercury. The II-VI semiconductors find applications in solar cells, IR detectors, and optical communication devices.

One of the most important semiconductors in optoelectronic devices is cadmium mercury telluride (CMT), $Cd_xHg_{1-x}Te$ ($x = 0-1$). Its band gap can be tuned to any part of the spectral range 0.8–30 µm. Generally, the thermal imagining application requires the band gap to be tuned to the IR transmission windows of the atmosphere (3–5, $x = 0.3$ and 8–14 µm, $x = 0.2$).

3.3 Polytellurides

The homopolyatomic anions of tellurium exhibit a wide structural diversity. Simple polytelluride chains Te_x^{2-} ($x = 2-5$) have been isolated either as alkali metal salts or as salts containing crown ether or cryptate complexes of alkali metals or alkaline earth metals. Large organic cations like Et_4N^+, Ph_4P^+, and $[Ph_3PNPPh_3]^+$ have also been used for their stabilisation. Typical examples of the molecular structures are shown in Figure 6. While Li_2Te_6[40] and Na_2Te_6[41] have

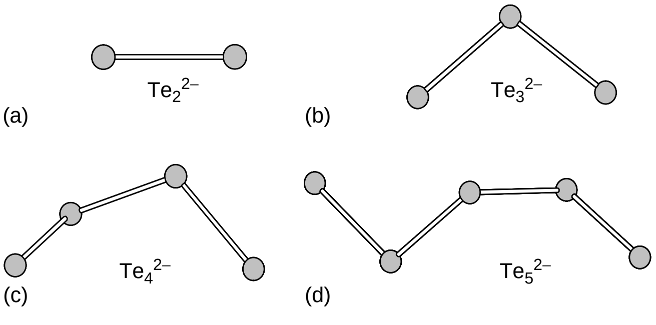

Figure 6 Polytelluride chains Te_x^{2-} ($x = 2-5$)[38]

been reported, they do not contain a discrete Te_6^{2-} ions. The structures rather consist of infinite helical $(Te_6^{2-})_n$ chains.

The Te–Te bond lengths in Te_2^{2-} anions have been tabulated by Smith and Ibers[38] and span a range 2.70(1)−2.86(1) Å. Tritelluride is a bent anion with the Te–Te distances and angles ranging 2.69−2.80 Å and 100−113°, respectively. The bond lengths and angles depend on the interionic interactions.[38] The terminal bond lengths in Te_4^{2-} and Te_5^{2-} chains vary more significantly [2.682(3)−2.964(3) Å and 2.704(1)−2.871(5) Å for Te_4^{2-} and Te_5^{2-}, respectively] than the internal bond lengths [2.686(1)−2.804(4) Å and 2.681(6)−2.793(6) Å for Te_4^{2-} and Te_5^{2-}, respectively]. The effects of the interionic interactions are more marked for Te_4^{2-} and Te_5^{2-} than for Te_2^{2-} and Te_3^{2-}.

The simple stoichiometry of the salts often obscures the complexity found in many polytellurides, the structures of which find few analogs in lighter chalcogen congeners sulfur and selenium. Spirocyclic Te_7^{2-}[42] and Te_8^{2-}[43] both show a square-planar tellurium atom (see Figure 7(a) and (b)). A similar motif is found in Rb_2Te_5 that exhibits a continuous

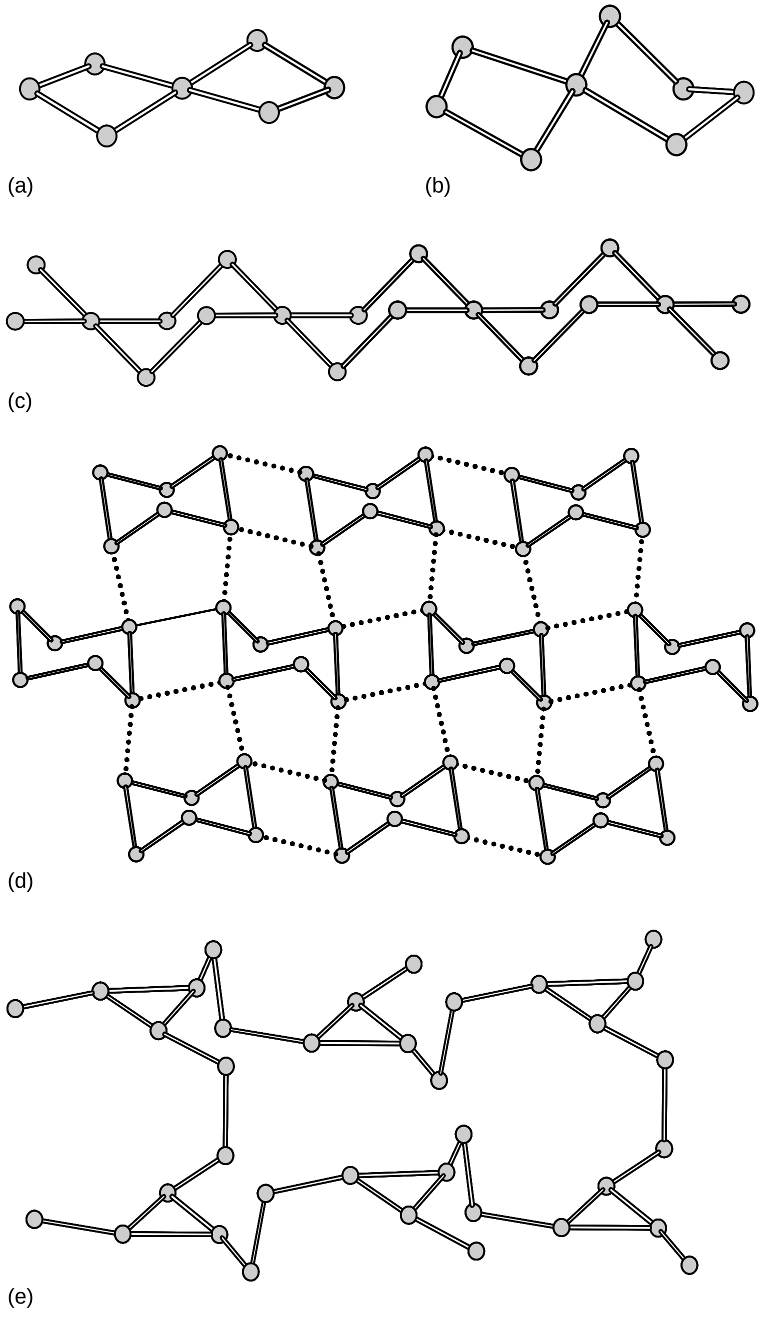

Figure 7 Cyclic and extended polytelluride networks. (a) Te_7^{2-},[42] (b) Te_8^{2-},[43] (c) $(Te_5)_n^{2-}$,[44] (d) $(Te_6)_n^{-}$,[45] (e) $(Te_6)_n^{3-}$[46]

spirocyclic chain $(Te_5)_n^{2-}$.[44] This anion can also be thought as square-planar $TeTe_4$ units stacked together (see Figure 7(c)). Particularly interesting structures of Cs_3Te_{22}[20] and Cs_4Te_{28}[21] have been discussed above and have been shown in Figure 3.

Unlike sulfur and selenium, the charge of the polytellurides can vary from −2. This is exemplified by $RbTe_6$,[45] which is shown in Figure 7(d). It consists of Te_6 rings that show bond lengths of 2.777(3)−3.195(3) Å. They are linked together into a two-dimensional network by two pairs of Te···Te contacts of 3.214(3) and 3.449(3) Å. Another example is $[Cr(en)_3]Te_6$ containing a polymeric Te_6^{3-} anion (see Figure 7(e)).[46]

Tellurium forms a wide variety of tellurometallates that have recently attracted extensive attention.[47–50] They show a rich structural flexibility as exemplified in Figure 8. While no single general method can be assigned for the syntheses of $[M_xY_y]^{n-}$ species, the most important routes involve the reaction of metal fragments with elemental tellurium, hydrogen telluride, polyatomic tellurium cations, and species, like $Te(SiR_3)_2$ or $TePR_3$.[47] Tellurometallates have also been prepared by the extraction of Zintl-anions.[51,52] and by reaction of metal salts with polytellurides in nonaqueous solvents.[53,54]

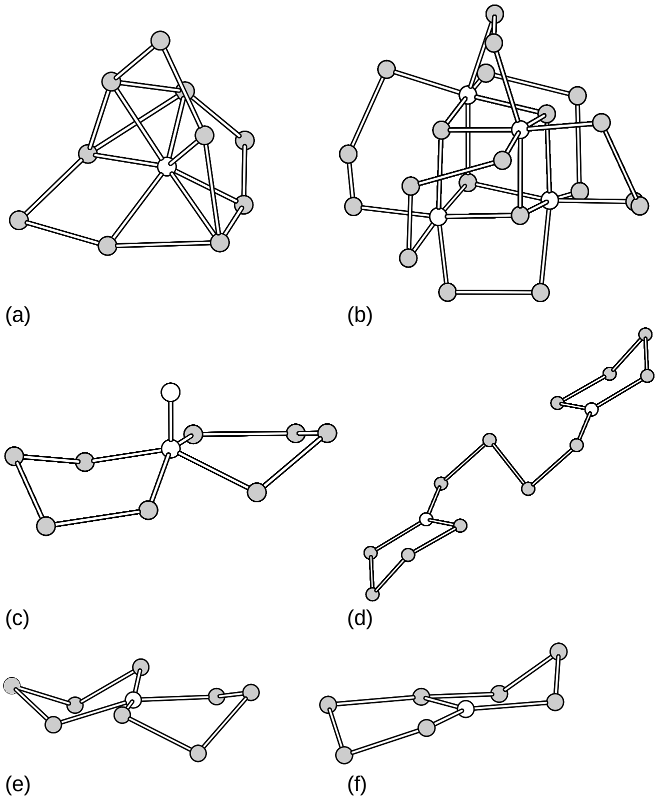

Figure 8 Illustrative examples of tellurometallates: (a) $[NbTe_{10}]^{3-}$,[53] (b) $[Ni_4Te_{20}]^{4-}$,[54] (c) $[MTe_8O]^-$ (M = Pd, Pt),[55] (d) $[M_2Te_{12}]^{3-}$ (M = Cu, Ag),[56] (e) $[MTe_8]^{2-}$ (M = Pd, Pt),[57] (f) $[MTe_7]^{2-}$ (M = Hg, Ag).[58] Tellurium atoms have been indicated in grey, transition metals and oxygen atoms are indicated in white

3.4 Polyatomic Tellurium-containing Cations

Like sulfur and selenium, tellurium forms homopolyatomic cations with weakly coordinating anions in strongly oxidizing media.[59–61] The synthetic routes involve super acids, acidic melts, or SO_2 and related aprotic solvents. Suitable oxidizing agents comprise strong main group Lewis acids, like $AlCl_3$, AsF_5, $SbCl_5$, and $BiCl_5$ and transition metal halides such as MF_6 (M = W, Re, Os, Ir, Pt), MCl_6 (M = V, W, Zr, Hf, Nb, Ta, Re), $VOCl_3$, $NbOCl_3$, and $WOCl_4$. Typical examples involving traditional oxidizing agents are the preparation of Te_4^{2+} from elemental tellurium in the melt containing tellurium tetrachloride and aluminium chloride, or the synthesis of Te_6^{4+} from elemental tellurium and arsenic pentafluoride in sulfur dioxide solution.

$$7Te + TeCl_4 + 4AlCl_3 \longrightarrow 2(Te_4)[AlCl_4]_2$$

$$6Te + 6AsF_5 \xrightarrow{SO_2(l)} (Te_6)[AsF_6]_4 + 2AsF_3 \qquad (1)$$

In recent years, several novel cationic species have been prepared by utilizing chemical vapour transport. These cations exhibit unprecedented structural features that find no analogs in the lighter congeners.[59–61]

The Te_4^{2+} is a 6π electron square-planar dication. Numerous structures containing different counterions have been determined by X-ray crystallography.[60,61] The formal bond order is 1.25, but it has been noted that the bond length depends on the nature of the counterions spanning a range of 2.660−2.695 Å (see Figure 9).[60] In each salt there are close contacts between the cations and anions, in which the halogen

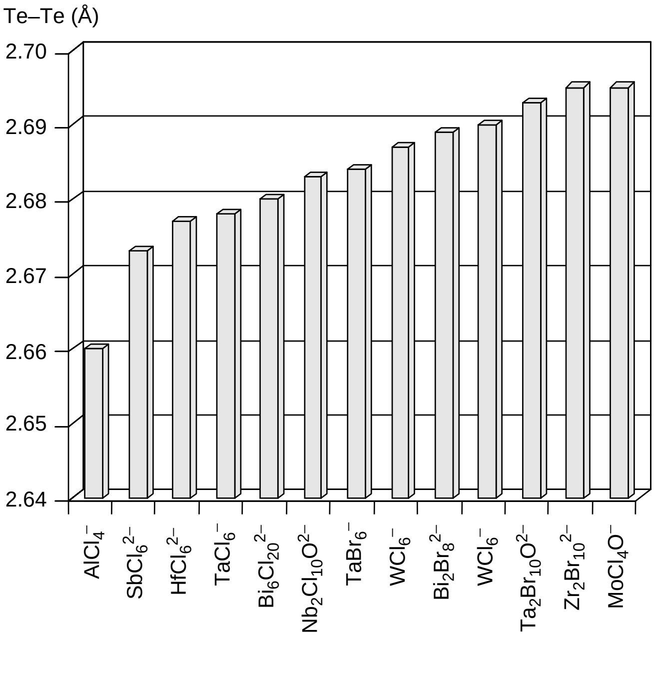

Figure 9 The dependence of the Te–Te bond length in Te_4^{2+} on the counterion[60]

atom bridges the Te–Te edges of the square-planar cation, as exemplified in Figure 10(a) by $(Te_4)[WCl_6]_2$.[62] It has been explained that the bond lengthening is caused by the transfer of electron density from the halogen into the σ* orbital of the cation.[60] Therefore, the more basic anions give rise to longer bonds.[60]

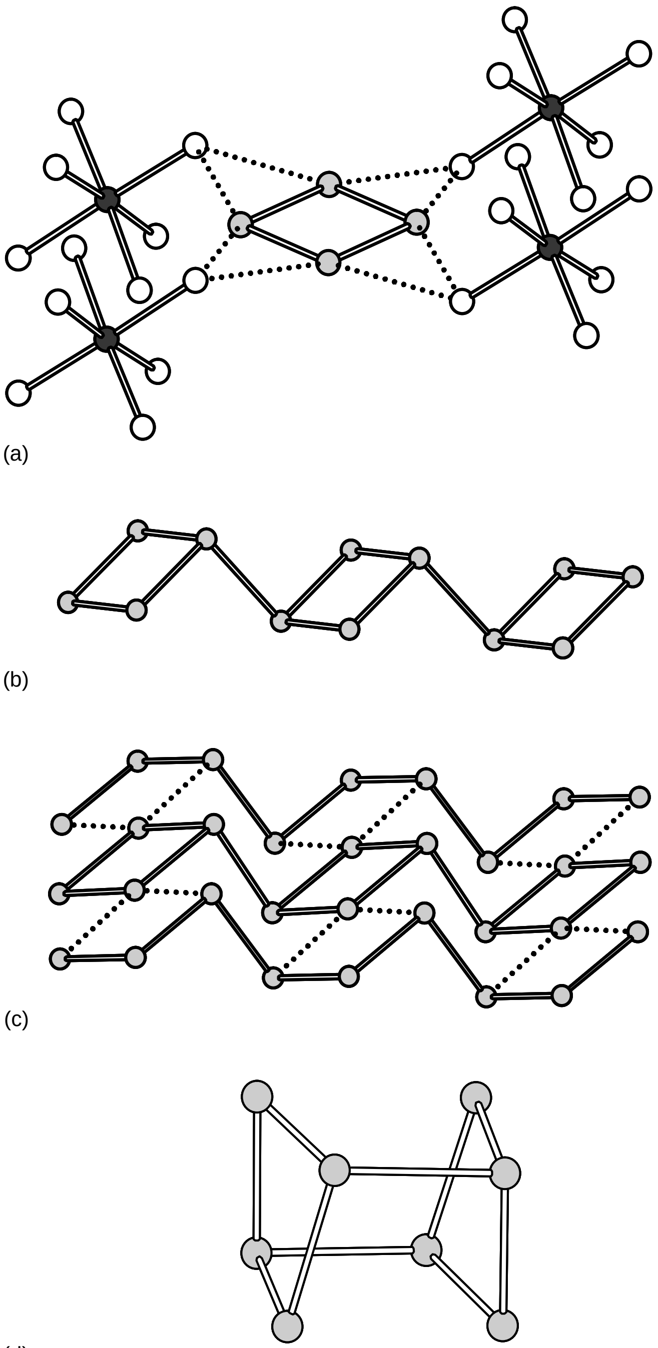

Figure 10 (a) The cation-anion interactions in $(Te_4)[WCl_6]_2$.[62] Tellurium atoms are indicated in grey, chlorine in white, and tungsten in dark grey. (b) The polymeric cation in $(Te_4)(Te_{10})[Bi_2Cl_8]_2$.[63] (c) The Te_8^{4+} cation in $(Te_8)[VOCl_4]_2$[64]

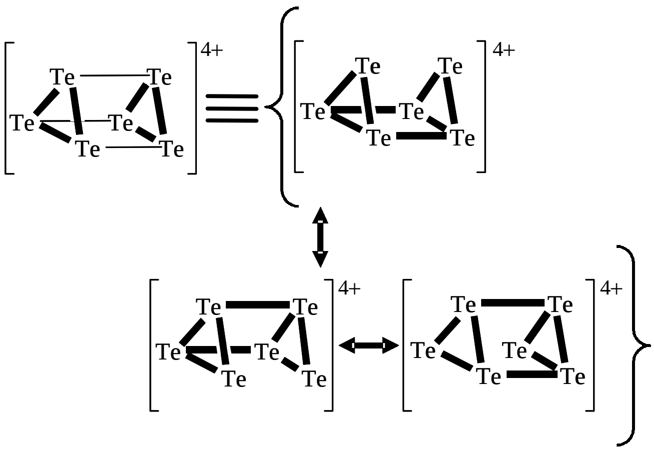
The Te_4^{2+} cation is a 22-electron species like S_4^{2+} and Se_4^{2+}. They should show a butterfly-shaped arachno-structure. The planar structure discussed above is explained by π-stabilisation. The classical bonding arrangement is observed in $(Te_4)(Te_{10})[Bi_2Cl_8]_2$,[63] which shows a polymeric arrangement of four-membered rings that are linked together in 1,3-positions (see Figure 10(b)). The Te_{10}^{2+} cation in the structure can be conceived to be formed of another stack of polymeric four-membered rings surrounded by two polymeric tellurium helical chains. The Te_4^{2+} cations have also been observed to dimerize into a Te_8^{4+} cation (Figure 10(c)).[64]

Te_6^{4+} is a trigonal prismatic cation (see Figure 11(a)) that has been known for a long time.[65,66] The bonds at the triangular face show approximately single bond lengths (2.662–2.702 Å) It is a 32 electron species, the structure of which can be rationalized according to the following resonance:



DFT calculations with local density approximation has indicated that the elongated D_{3h} structure is the ground state of the cation with the extra electron pair causing the simultaneous elongation of the three bonds parallel to the C_3 axis.[70] Recently, also Te_6^{2+} has been prepared and structurally characterized.[67,71] Compared to the classic Te_6^{6+} cage, two bonds should be broken because of two extra electron pairs.[72] However, one bond is delocalized between two positions in the triangular face (the Te–Te distance is 3.209–3,382 Å,[67,71] see Figure 11(b)) and only one bond is completely missing. It is only in the case of hybrid $Te_3S_3^{2+}$ [68] and $Te_2Se_4^{2+}$ [69] cations that the expected more open structure is seen, as shown in Figure 11(c) and 11(d).

Te_8^{2+} has several isomeric forms. The cation commonly shows the same structure as S_8^{2+} and Se_8^{2+} (see Figure 12(a)), but the transannular interaction seems to be stronger in tellurium than in sulfur or selenium.[60,61] An even more pronounced bicyclic nature is found in the Te_8^{2+} cation in $Te_8[WCl_6]$[73] (see Figure 12(b)). The transannular bond is only 2.993 Å. In addition, Te_8^{2+} has other isomers. It has been found to show a bicyclo[2,2,2]octane structure[60]

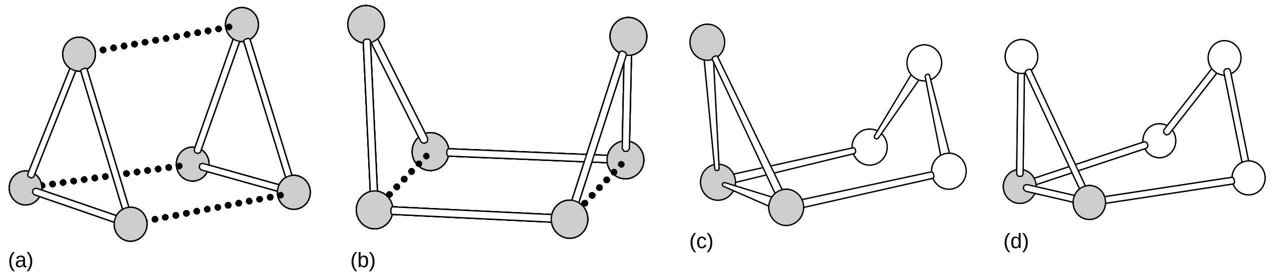


Figure 11 (a) The structure of the Te_6^{4+} cation.[65] (b) The structure of Te_6^{2+}.[67] (c) The structure of $Te_3S_3^{2+}$ cation.[68] Tellurium atoms are indicated in grey and sulfur atoms in white. (d) The structure of $Te_2Se_4^{2+}$ cation.[69] Tellurium atoms are indicated in grey and selenium in white

similar to that observed in $Te_2S_6^{2+}$[74] (see Figure 12(c)). Two polymeric forms of $(Te_8)_n^{2+}$ both contain six-membered rings in boat conformation that are linked together by Te_2 fragments in 1,4-positions.[75,76] The main difference between the two isomers is the relative orientations of adjacent ring fragments

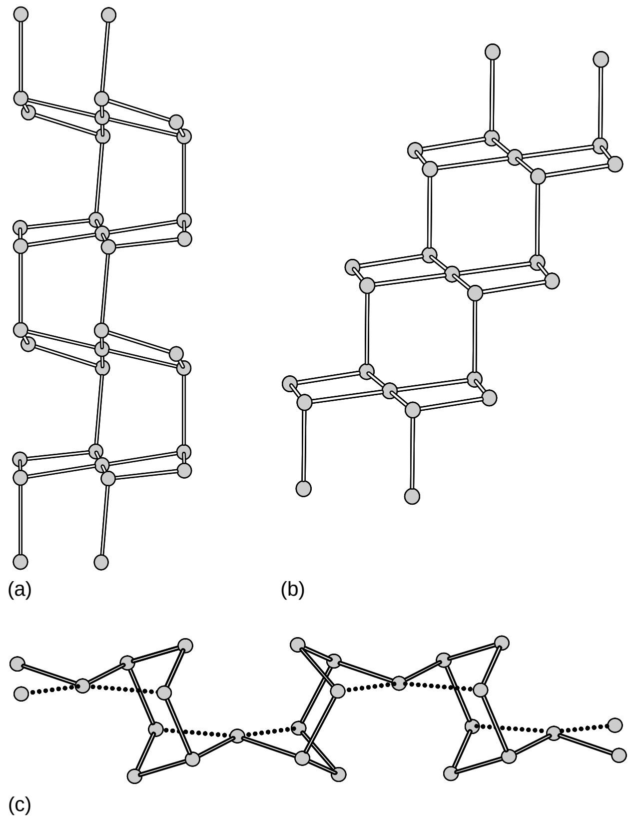

Figure 13 Examples of extended tellurium cations based on the Te_7 unit. (a) $(Te_7)[NbCl_4O]Cl$.[78] (b) $(Te_7)[Be_2Cl_6]$.[79] (c) $(Te_7)[AsF_6]_2$[80]

(see Figures 12(d–e)). More extensive homonuclear tellurium cations have also been recently prepared, as shown in Figure 13. They are all based on repeating $(Te_7)_n^{2+}$ units.

4 TELLURIUM–HALOGEN COMPOUNDS

4.1 General

Like lighter chalcogens, tellurium readily forms a number of compounds with halogen elements. Tellurium tetrahalides

are the most stable species, but other binary compounds are also known, some of which do not find analogs with lighter chalcogen congeners. The bonding in these compounds eludes simple description and concepts, like hypervalence, multi-center bonding, charge-transfer interactions, and secondary bonding, have been evoked in the understanding of their structural and chemical properties (for a recent review of chalcogen halides, see Ref. 81).

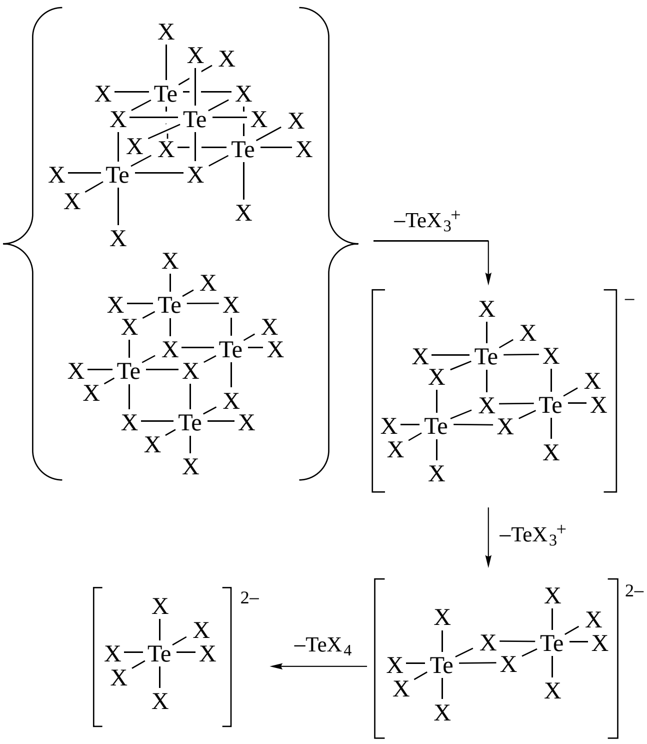
4.2 Tellurium(IV) Halides

Tellurium tetrafluoride can be obtained by the reaction of SeF_4 with TeO_2 at 80 °C.[82] While it is considered to be monomeric in the gas phase, the low-temperature X-ray structure is a polymeric chain of *cis*-linked square-pyramidal TeF_5 groups (see Figure 14(a)).[82] Tellurium tetrafluoride is reactive giving mixtures of tellurides and fluorides with many metals such as copper and nickel. It also fluorinates silicon dioxide above the room temperature. Tellurium tetrafluoride decomposes at 190 °C to give octahedral TeF_6(g), the structure of which has been determined by electron diffraction.[83] The low-temperature crystal structure of the solid TeF_6 has also been recently determined.[84] In the solid state, the Te–F bonds span a range of 1.750–1.803 Å and the bond angles are 89.61–90.61°.

Gaseous $TeCl_4$ is also monomeric displaying a Ψ-tbp structure with a point group C_{2v}.[87] In the solid state, $TeCl_4$[85,88] and $TeBr_4$[89] have a tetrameric cubane-like structure (see Figure 14(b)). The terminal Te–X bonds are shorter than those involving the triply bridging halogen atoms and the structure can be rationalized either as covalently bound (Te_4X_{16}) molecules or as ionic $[(TeX_3{}^+X^-)_4]$.[85,90,91] The stereochemical activity of the tellurium lone-pairs are directed towards the center of the cubane cage.

TeI_4 has five different polymorphs (α-ε) that crystallize simultaneously from the methanol solution of TeI_4 containing HI.[90,91] The orthorhombic δ-TeI_4 is the thermodynamically stable polymorph at normal conditions.[81,92] It shows another tetrameric structure (Figure 14(c)) that can be formulated as $[(TeI_3{}^+ I^-)_2(TeI_4)_2]$. The TeX_6-octahedra in TeI_4 are less distorted than those in $TeCl_4$ and $TeBr_4$. The different structure of TeI_4 is a consequence of a smaller electronegativity difference between tellurium and iodine compared to that between tellurium and chlorine or tellurium and bromine. The cubane structure is expected to favor larger charge separation and more polar bonds.[81] Orthorhombic β-TeI_4 and monoclinic γ-TeI_4 also exhibit the structure shown in Figure 14(c).[90,91] Trigonal α-TeI_4 shows a continuous 2H-CdI_2 structure that can also be understood in terms of a related repeating structural unit. Interestingly, only the thermodynamically least-stable tetragonal ε-TeI_4 shows the cubane structure.[90,91]

The tetrameric tellurium tetrachlorides, -bromides, and -iodides undergo a systematic stepwise degradation in the presence of stoichiometric amounts of halides in nonpolar solvents and form oligonuclear halogenotellurates(IV). There are numerous examples of the formation and equilibria between the different anions (for a detailed discussion, see Ref. 81).



It is interesting to note that the coordination environment in the halidotellurate anions is an almost regular octahedron in apparent violation of the VSEPR rules for a 14 electron AX_6E system. It has been suggested that the lone electron pair of tellurium resides in the stereochemically inactive 6s orbital and the six Te–X bonds form three pairs of 3c–4e bonds involving the three 6p orbitals (for a more detailed discussion, see Ref. 81).

4.3 Tellurium(II) Halides

The existence of tellurium dichloride and dibromide has been shown in gaseous state[81] and their structures have been determined by electron diffraction.[92,93] Both molecules are expectedly bent with C_{2v} symmetry. The Te–Cl and Te–Br bonds are 2.329(3) Å and 2.51(2) Å, respectively, and the respective bond angles are 97.0(6) and 98(3)°.

The preparation of liquid or solid $TeCl_2$ or $TeBr_2$, on the other hand, is still controversial. It has been reported that the Te–TeX_4 (X = Cl, Br) phase diagrams give no evidence for the formation of TeX_2.[94] However, Paul *et al.*[95] have reported the preparation of $TeCl_2$ from $Me_3SiSiMe_3$ and $TeCl_4$. When the reaction was carried out in CS_2, polymeric $(MeTeCl_3)_n$ was obtained instead of $TeCl_2$.[96] It has also been reported

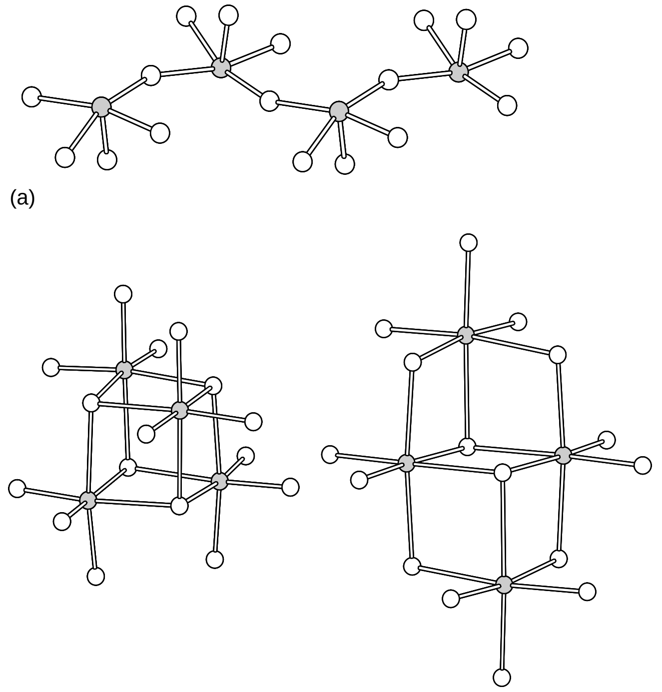


Figure 14 (a) The structure of TeF_4.[82] (b) The structure of $TeCl_4$.[85] $TeBr_4$ is isostructural with $TeCl_4$. (c) The structure of TeI_4.[86] Tellurium atoms are indicated in grey and halogens in white

Figure 15 The EI mass spectrum of Te_2Cl_2[18]

that the reaction of liquid tellurium with CF_2Cl_2 affords black $TeCl_2$, which rapidly disproportionates to tellurium and $TeCl_4$.[97]

It was recently found that selenium dichloride can conveniently be prepared by the reaction of elemental selenium and SO_2Cl_2.[98] It is relatively stable in coordinating solvents and can be used as a reagent for synthetic applications. The attempt to prepare $TeCl_2$ in the analogous manner from elemental tellurium and SO_2Cl_2 resulted in the formation of various chloridotellurate anions with different counterions.[99] The solvent and the possible presence of a small amount of residual moisture probably determine the identity of the main product in each individual case.

The existence of TeI_2 is even more uncertain than that of $TeCl_2$ and $TeBr_2$.

Ditellurium dichloride and dibromide can be prepared in moderate yields by reducing elemental tellurium with $LiBHEt_3$ in thf followed by the treatment with TeX_4 (X = Cl, Br).[18] Both Te_2Cl_2 and Te_2Br_2 are dark brown liquids that decompose rapidly. In CS_2 solution, they turned out to be rather stable. The molecular species were identified by EI mass spectroscopy, as exemplified for Te_2Cl_2 in Figure 15. Furthermore, the reaction of Te_2Cl_2 and $[Ti(C_5H_5)_2S_5]$ or $[Ti(C_5H_5)_2Se_5]$ expectedly afforded 1,2-Te_2S_5 and 1,2-Te_2Se_5, respectively, that were identified by ^{77}Se and ^{125}Te NMR spectroscopy.

4.4 Tellurium Subhalides

Tellurium subhalides form an interesting class of solid phases.[81,100] The main characterized species comprise Te_3Cl_2, Te_2X (X = Cl, Br, I), and two polymorphs of TeI. They can be prepared by heating the elements at 200–300 °C followed by homogenization, annealing, quenching, and extraction to remove excess tellurium tetrahalide.[94,101–103] Single crystals of Te_2I, and α- and β-TeI have been grown by hydrothermal methods in concentrated aqueous hydroiodic acid.[102–104] Crystals of thermodynamically stable Te_3Cl_2, Te_2Br, and α-TeI can also be grown from the melt.[100] Tellurium subbromides and iodides have also been prepared by reducing tellurium tetrahalides with corresponding tin dihalides.[105,106]

Because of high tellurium content, the crystal structures of all subhalides show cumulated Te–Te bonds and bear a structural relationship with hexagonal tellurium. Te_3Cl_2 contains a continuous twisted tellurium chain with every third tellurium atom bonded to two chlorine atoms in axial positions of the trigonal bipyramidal coordination environment (see Figure 16(a)). The Te–Te bonds within the chain span a range of 2.670–2.861 Å. The axial Te–Cl bond lengths are 2.501 and 2.536 Å. The chains are connected by secondary Te···Cl contacts of 3.363 and 3.400 Å.[103,104] Te_2Cl, Te_2Br, and Te_2I show mutually similar structures (see Figure 16(b)) containing fused Te_6 rings in boat conformation. The ring fragments are also connected together by two halogen bridges in 1- and 4-positions.[103,104] The Te–Te bonds within the cyclic arrangement range 2.808–2.919 Å and 2.861–2.917 Å for Te_2Br and Te_2I, respectively. The respective Te–X bond lengths are 2.904–3.017 Å and 3.084–3.179 Å. The polymeric units are linked together by very weak Te···Br and Te···I secondary contacts.

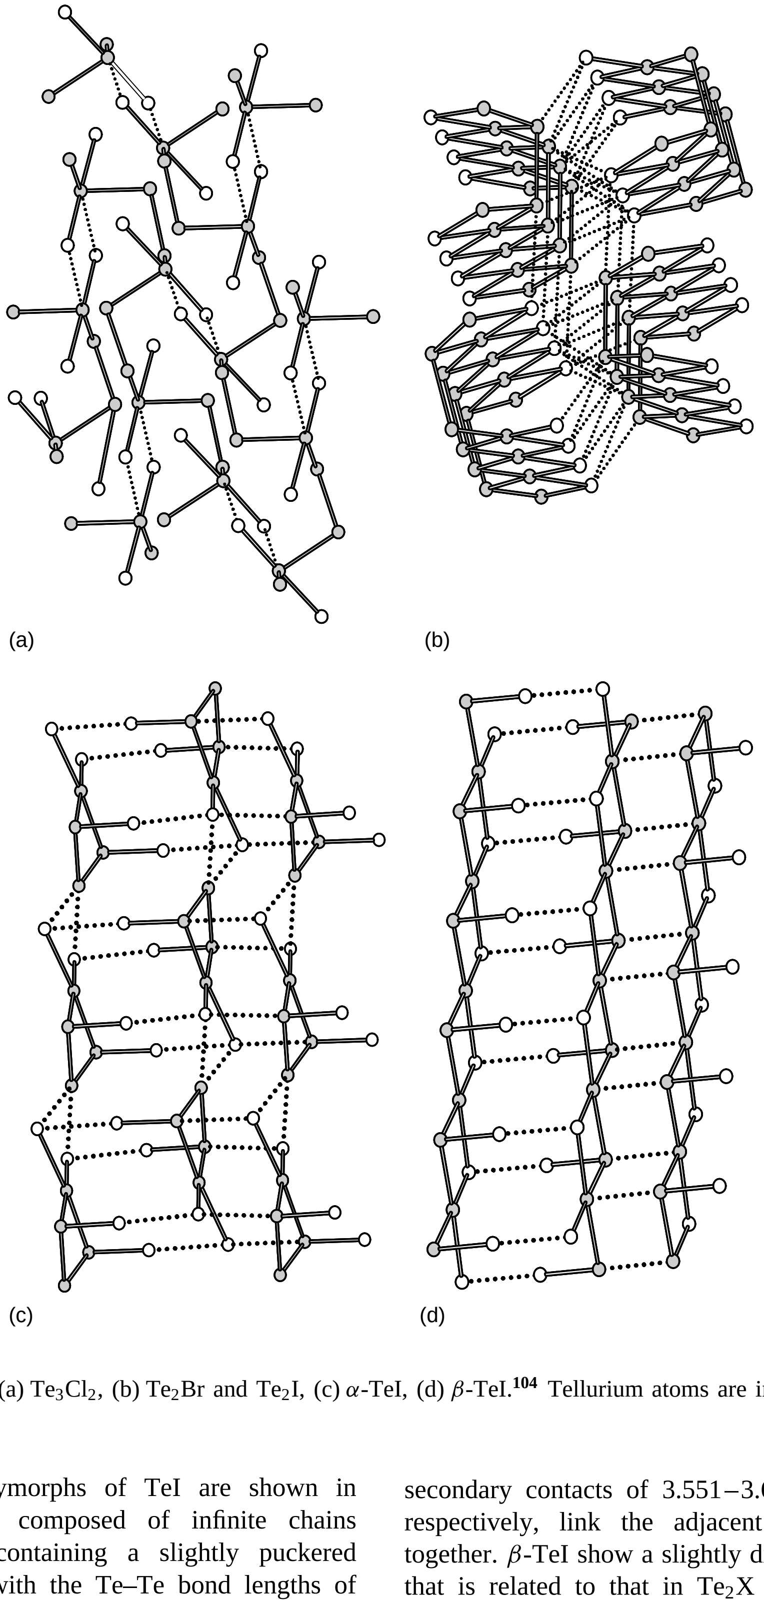

Figure 16 The structures of (a) Te_3Cl_2, (b) Te_2Br and Te_2I, (c) α-TeI, (d) β-TeI.[104] Tellurium atoms are indicated in grey and halogens in white

The two different polymorphs of TeI are shown in Figure 16(c–d). α-TeI is composed of infinite chains of $Te(TeI)_2(TeI_2)$ units containing a slightly puckered four-membered Te_4 ring with the Te–Te bond lengths of 2.786–2.928 Å.[104] There are two exocyclic Te–I bonds of 2.740 and 2.742 Å. One tellurium atom is bound to two iodine atoms (bond lengths of 3.042 and 3.110 Å) that also exhibit the Te···I close contacts of 3.349 and 3.404 Å to the adjacent unit (see Figure 16(c)). The Te···I and I···I secondary contacts of 3.551–3.601 Å and 3.627–3.690 Å, respectively, link the adjacent $[Te(TeI)_2(TeI_2)]_n$ chains together. β-TeI show a slightly different polymeric structure that is related to that in Te_2X (see Figure 16(d)).[104] The structure is composed of four-membered spirocyclic $(Te_3I_2)_n$ fragments with one exocyclic and one endocyclic iodine atoms. The Te–Te bond length is 2.909 Å. The exocyclic Te–I bonds are shorter (2.742 Å) than the endocyclic Te–I bonds (3.127 Å). The polymeric units are linked together by

Te···Te and I···I secondary contacts of 2.492 and 2.598 Å, respectively.

The optical, electrical, and thermodynamic properties of tellurium subhalides have attracted considerable research interest.[100] For instance, α-TeI has been suggested to find applications as solid electrolytes in galvanic cells.

4.5 Tellurium Oxohalides

One of the oldest tellurium oxofluorides is $(F_5Te)_2O$, which was originally thought to be Te_2F_{10}. It was prepared by fluorinating TeO_2 with a stream of N_2/F_2. Its structure was determined in the gas phase by electron diffraction[107,108] and was shown to contain two linked F_5Te fragments with an oxygen bridge resulting in the octahedral coordination environment around both tellurium atoms. The Te–O–Te bond angle of 145.5° and the two Te–O bonds of 1.83 Å have been rationalized in terms of pπ-dπ bonds.

The heating of equimolar amounts of TeO_2 and TeF_4 in a sealed platinum tube for 24 h at 250 °C or 140 °C affords $Te_2O_3F_2$[109] and $TeOF_2$,[110] respectively. The crystal structure of $Te_2O_3F_2$ is shown in Figure 17(a) and that of $TeOF_2$ in Figure 17(b). Both compounds show a continuous chain structure that bear similarities to α-TeO_2.

The teflate ion, $(OTeF_5)^-$, plays an important role in synthetic main group chemistry. Its effective electronegativity is similar to that of fluoride. A group of anions with a general formula of $[M(OTeF_5H)_6]^-$ (M = As, Sb, Bi, Ti, etc.) have recently been prepared.[111,112] They are only weakly coordinating and serve to stabilize otherwise unstable cations.

$Te(OTeF_5)_6$[113] can be prepared from tellurium tetrafluoride and $B(OTeF_5)_3$[114] upon treatment with $Xe(OTeF_5)_2$.[115]

$$TeF_4 + B(OTeF_5)_3 \longrightarrow Te(OTeF_5)_4 \xrightarrow{Xe(OTeF_5)_2} Te(OTeF_5)_6 \qquad (2)$$

When $Te(OTeF_5)_4$ is fluorinated with XeF_2, *cis*- and *trans*-$TeF_2(OTe_5)_4$ are obtained.[114] $Te(OTeF_5)_6$ crystallizes as two different polymorphs.[113] The molecule is an almost spherical molecule (see Figure 18(a)) with the central and outer Te–O distances of 1.903 Å and 1.893 Å, respectively. The structure of *trans*-$TeF_2(OTeF_5)_4$ (Figure 18(b)) is also based on octahedral Te(IV) with the bond lengths very near to the corresponding bonds in $Te(OTeF_5)_6$.[114]

The teflate anion has also been utilized in the preparation of a variety of species containing transition metals, as exemplified by $[Fe(OTeF_5)_3]$,[116] $[Nb(OTeF_5)_6]^-$,[117] and $[[\{(\eta^2\text{-tol})Ag\}_2(\mu\text{-}OTeF_5)_2]$.[118]

Though the structures of a tellurium oxochloride[119–121] and oxobromide[122] have also been reported, their chemistry is not as well-established as that of oxyfluorides. In addition, some organic species, like $(n\text{-}Pr_4N)[TeCl_4(OH)]$,[123] are known.

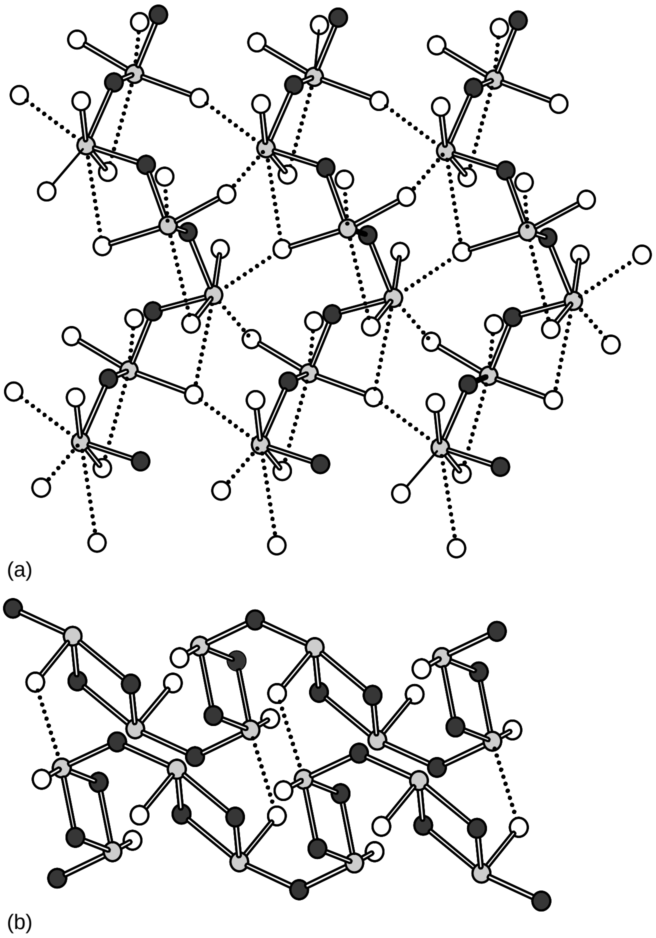

Figure 17 (a) The structure of $Te_2O_3F_2$.[100] (b) $TeOF_2$.[101] Tellurium atoms are indicated in grey, oxygen in white, and fluorine in dark grey

5 TELLURIUM–OXYGEN COMPOUNDS

5.1 Tellurium Oxides

Tellurium–oxygen system comprises a wide number of phases. Tellurium monoxide TeO probably exists only in the gas phase. No evidence of its existence in the solid state has been obtained. The He(I) photoelectron spectrum of the molecular beam that has been formed by heating TeO_2 in vacuo indicates that TeO is the dominant species in the vapor phase.[124] Studies of the absorption and emission spectra of TeO(g) have yielded the bond dissosiation energy of 263.2 kJ mol^{-1}.[125] The Te=O bond length of 1.828 Å.[126] is estimated from the rotational fine structure of the electronic absorption spectrum.

Tellurium dioxide exists as three crystallographic forms, the structures of which have been determined several times. Tetragonal, colorless α-TeO_2 is formed when elemental

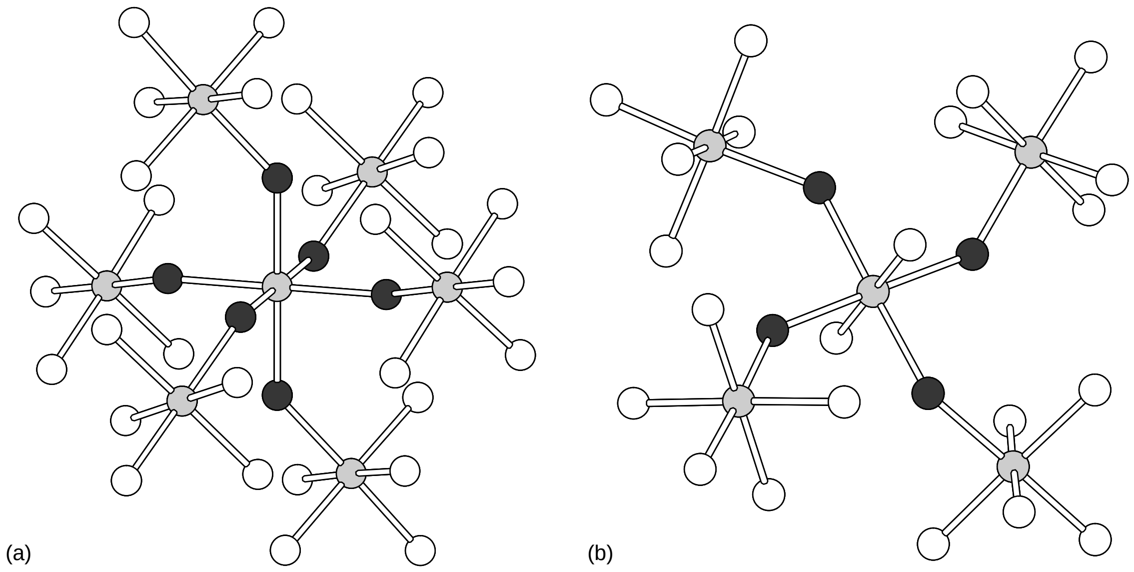

Figure 18 The structure of (a) $Te(OTeF_5)_6$[113] and (b) *trans*-$TeF_2(OTeF_5)_4$.[114] Tellurium atoms are indicated in grey, oxygen in dark grey, and fluorine in white

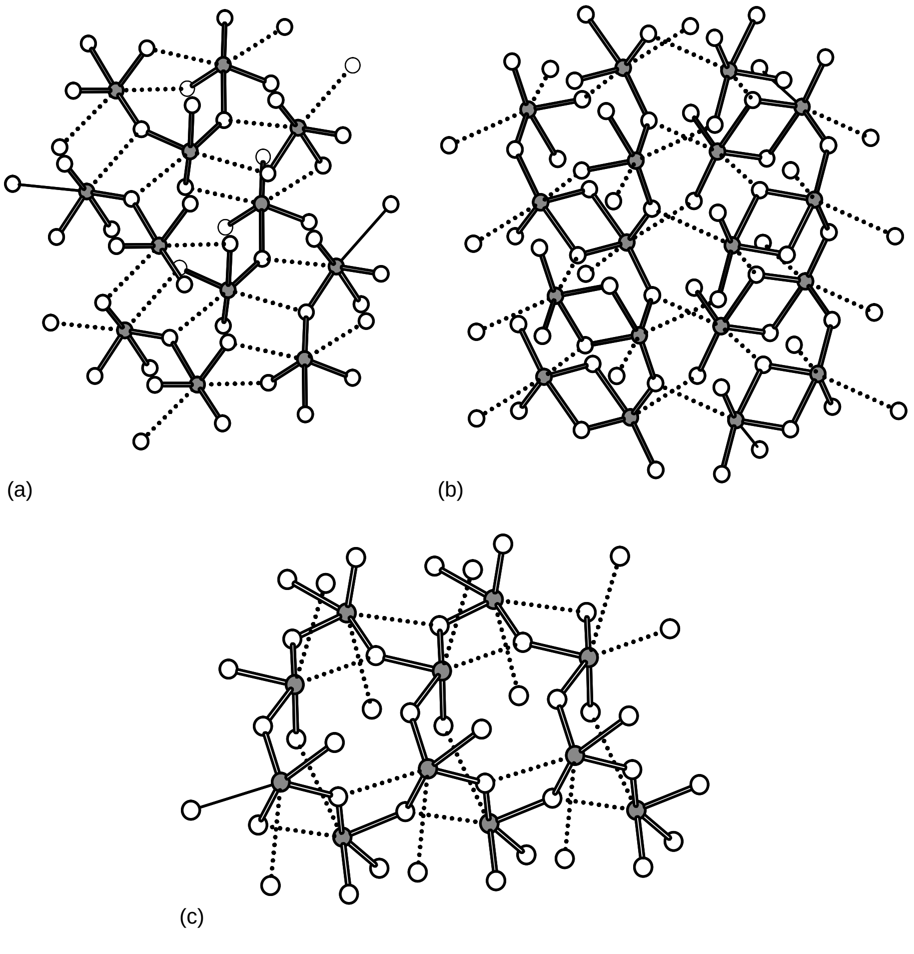

Figure 19 The crystal structures of (a) α-TeO_2,[127] (b)β-TeO_2,[128] and (c) γ-TeO_2.[129] Tellurium atoms are indicated in grey and oxygen in white

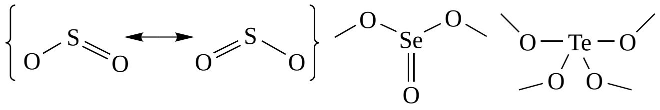
tellurium reacts with O_2,[127] yellow orthorhombic β-TeO_2 occurs naturally as the mineral tellurite,[128] and γ-TeO_2 has recently been isolated.[129] The coordination geometry around tellurium in all three oxides is a Ψ -trigonal bipyramid with the tellurium lone pair of electrons occupying one of the equatorial positions. The secondary bonding interactions, however, expand the coordination environments into distorted octahedra (see Figure 19). It is worth noting that there is a clear trend in the structures of sulfur dioxide, selenium dioxide, and tellurium dioxide: Sulfur dioxide is monomeric, solid selenium dioxide forms one-dimensional polymeric chains, and each crystallographic modification of tellurium dioxide is composed of a continuous three-dimensional network. At the same time, the bond order of the chalcogen-oxygen bond becomes smaller.



Tellurium dioxide is sparingly soluble in water but is a strong oxidizing agent for a number of elements. In hot alkaline solutions TeO_2 forms tellurates. With selenium halides it is readily halogenated:

$$TeO_2 + 4Se_2Cl_2 \longrightarrow TeCl_4 + 2SeOCl_2 + 6Se$$
$$TeO_2 + SeF_4 \longrightarrow TeF_4 + SeO_2 \qquad (3)$$

Two crystallographic modifications have been reported for tellurium trioxide.[130] A definite structure determination has been carried out only for the more stable grey β-TeO_3 that is made by heating $Te(OH)_6$ in a sealed tube at 320 °C for 12 to 15 h in the presence of traces of H_2SO_4 and O_2.[131,132] α-TeO_3 is yellow. It is also made by dehydrating $Te(OH)_6$ at 300 °C. Further heating transforms it to β-TeO_3. Prolonged heating at 405 °C affords Te_2O_5, which is considered an intermediate product in the transformation of α-TeO_3 to TeO_2.[133] Its structure is based on a network in which $Te^{VI}O_6$ octahedra

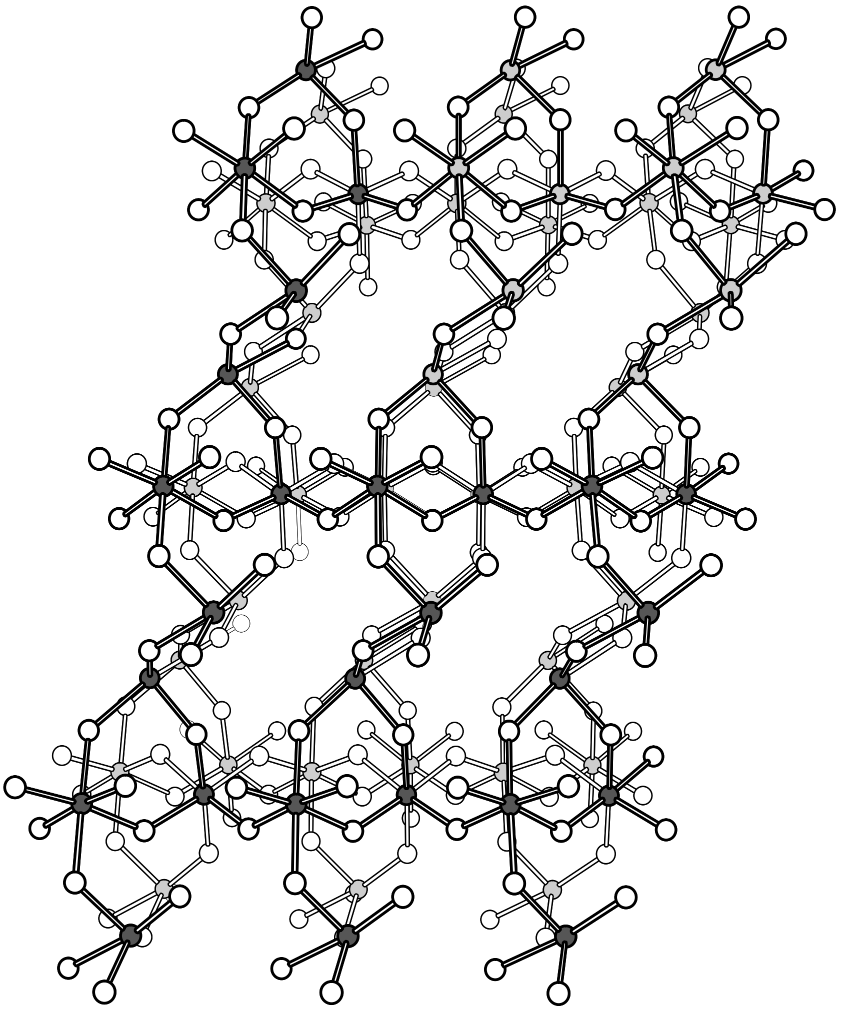


Figure 20 The crystal structure of Te_2O_5.[133] Tellurium is indicated in grey and oxygen in white

share oxygen vertices to form infinite sheets that are linked by four-coordinate Te^{IV} (see Figure 20).

5.2 Oxoacids of Tellurium

Telluric acid is a white solid the crystal structure of which is built up of discrete regular octahedral molecules of $Te(OH)_6$. It can conveniently be obtained by oxidizing TeO_2 in aqueous solution by, for example, $KMnO_4$. Anhydrous telluric acid can be crystallized in cubic, tetragonal, and monoclinic modifications. Structural data exist for the cubic and monoclinic forms. They both consist of discrete $Te(OH)_6$ molecules that are linked together by hydrogen bonds.[134–136]

In contrast to H_2SO_4 and H_2SeO_4, $Te(OH)_6$ is a weak three-basic acid. The acid constants are estimated to be $K_1 = 2 \times 10^{-8}$, $K_2 = 10^{-11}$, and $K_3 = 3 \times 10^{-15}$. It is a relatively strong oxidizing agent and is reduced to the element by SO_2 and to H_2TeO_3 by HCl:

$$\begin{aligned} Te(OH)_6 + 3SO_2 &\longrightarrow Te + 3H_2SO_4 \\ Te(OH)_6 + 2HCl &\longrightarrow H_2TeO_3 + Cl_2 + 3H_2O \end{aligned} \quad (4)$$

The crystal structure of H_2TeO_4 has also been determined. It has a slightly puckered planar structure in which the octahedral TeO_6 units share equatorial oxygen atoms (see Figure 21). Hydrogen atoms are bound to two exoplanar oxygen atoms that lie in trans- positions.[137] Another interesting oxoacid of tellurium is $H_2Te_2O_6$. It contains a network of alternating $Te^{VI}O_6$ and $Te^{IV}O_4$ fragments that share oxygen atoms (see Figure 22).

Tellurates are generally formed by solid-state reactions rather than by neutralization of aqueous $Te(OH)_6$ solutions. A typical example is the heating of the acid in the presence of copper carbonate:

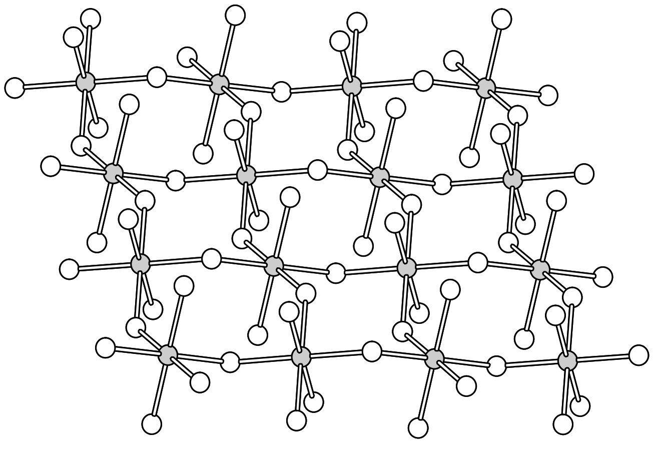

Figure 21 The crystal structure of H_2TeO_4.[137] Tellurium atoms are indicated in grey and oxygen in white

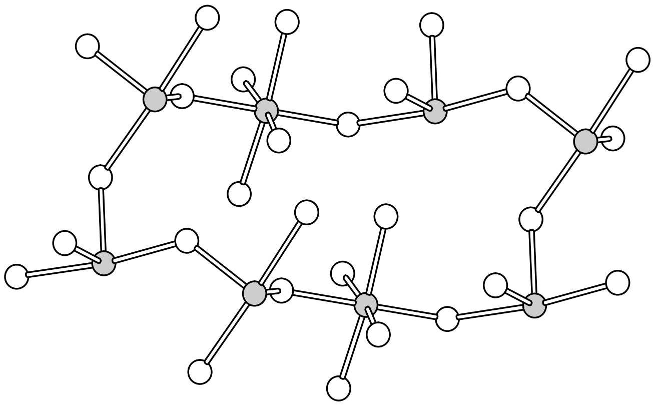

Figure 22 The crystal structure of $H_2Te_2O_6$.[138] Tellurium atoms are indicated in grey and oxygen in white

$$3CuCO_3(s) + Te(OH)_6(s) \xrightarrow{heat} Cu_3TeO_6(s) + 3CO_2(g) + 3H_2O(g) \quad (5)$$

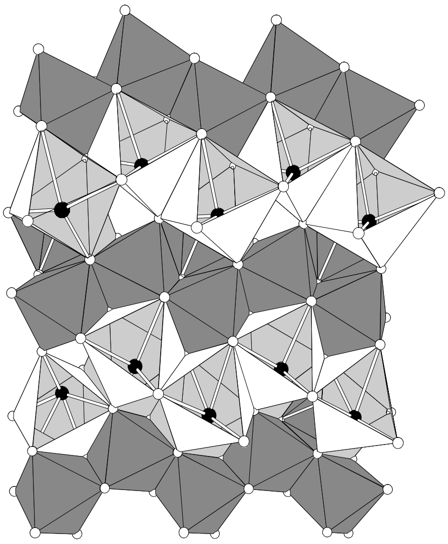
Tellurium(VI) salts exhibit a large range of stoichiometries. Typical examples are Li_6TeO_6,[139] Na_2TeO_4,[140] Be_4TeO_7,[141] and Mg_3TeO_6.[142] As shown in Figure 23, all structures are based on TeO_6 octahedra and are generally more complex than what could be expected from the deceptively simple stoichiometry of the species. For example, the formula Na_2TeO_4 implies the presence of a TeO_4^{2-} ion that could be analogous to SO_4^{2-} and SeO_4^{2-}, but the structure is composed of chains of edge-shared TeO_6 octahedra (see Figure 23(a)) that are linked by NaO_6 polyhedra.

Tellurous acid H_2TeO_3 is also a weak acid with the acid dissociation constants of $K_1 = 2.7 \times 10^{-3}$ and $K_2 = 1.8 \times 10^{-8}$. By contrast to tellurates(VI), the tellurates(IV) can exist in solid state as discrete TeO_3^{2-} anions as in $NaKTeO_3 \cdot H_2O$[143] and $K_2TeO_3 \cdot 3H_2O$.[144] The anion in $K_2Te_2O_5 \cdot 3H_2O$ consists of Te_2O_5 units that are linked into infinite chains by sharing a terminal oxygen.[145] Tellurium shows a distorted trigonal bipyramidal coordination environment.

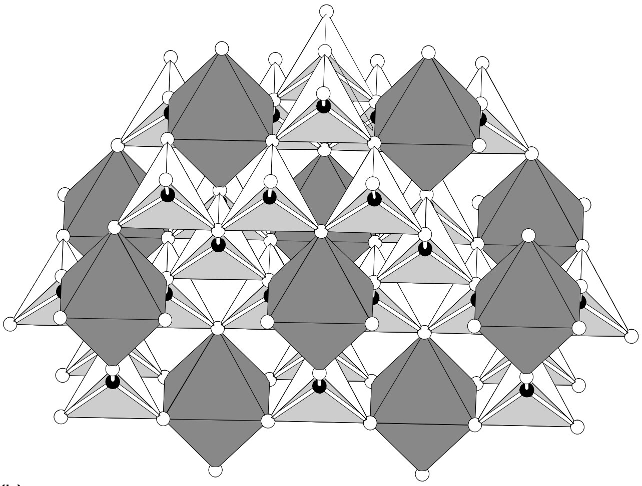
6 TELLURIUM–NITROGEN COMPOUNDS

While sulfur–nitrogen chemistry has a long and extensive history, selenium–nitrogen and tellurium–nitrogen chemistry has seen more extensive progress only during the recent decade.[59,146,147] One reason for the recent progress is the availability of versatile reagents, like $Te\{N(SiMe_3)_2\}_2$[148] and $\{Te(N^tBu)_2\}_2$.[149]

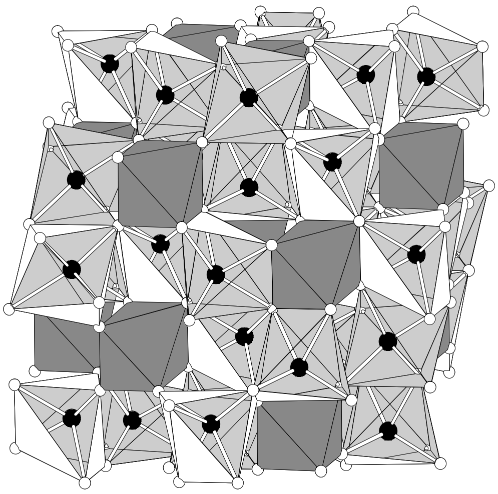
The existence of the tellurium analogue of S_4N_4 is unclear. It has long been known that explosive lemon-yellow nitride with the composition Te_3N_4 (**1**) can be prepared.[150–152] While the molecular structure is not known, it is conceivable that it has a tricyclic structure:[59]



(a)

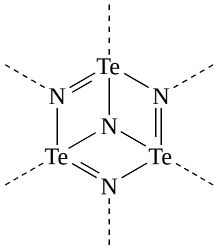


(b)



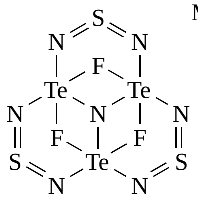
(c)

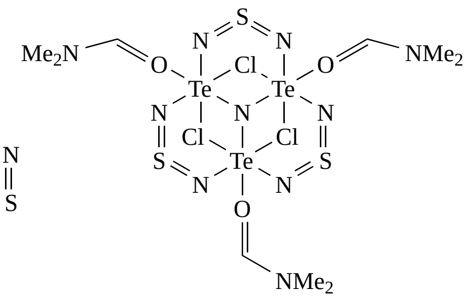
Figure 23 The crystal structures of (a) Na_2TeO_4,[140] (b) Be_4TeO_7,[141] and (c) Mg_3TeO_6[142]



(**1**)

This is in contrast to the cage-like structures of S_4N_4 and Se_4N_4, which show weak transannular chalcogen–chalcogen interactions.[153–156] The very slight solubility of Te_3N_4 indicates that the molecules are strongly associated in the solid state as a result of intermolecular Te···N interactions. Support for the Te_3N_4 structure comes from $N(XTeNSN)_3$ (X = F (**2**), Cl (**3**)),[157,158] which also show a central nitrogen atom coordinated to three tellurium atoms.





(**2**) (**3**)

A core with similar features is also found in $[Te_6N_8(TeCl_4)_4\cdot(thf)_4]$ (see Figure 24).[159]

Tellurium imides comprise another class of tellurium–nitrogen compounds of recent interest.[59,147] Diorganotellurium imides RR′TeNR″ can formally be considered to contain a Te=N double bond, but the Te–N distance generally falls between the single and double bond lengths.[160,161] While the existence of monomeric tellurium diimides $(RN)_2Te$ have been suggested,[162] the recent structural characterization $RNTe(\mu\text{-}N^tBu)_2TeNR$ (R = ^{t}Bu[149] or PPh_2NSiMe_3[163]) shows them to be dimeric. Indeed, DFT calculations at different levels of theory[164,165] have shown that while the dimerization of $(MeN)_2S$ is clearly endothermic and that of $(MeN)_2Se$ is slightly endothermic, the dimerization of $(MeN)_2Te$ is clearly exothermic (see Figure 25). The exocyclic Te–N bonds show approximate double bond lengths[149,163] but the endocyclic bonds are longer exhibiting distance expected for a Te–N single bonds.[166] It has been deduced by ^1H, ^{31}P, and ^{125}Te NMR studies that both $RNTe(\mu\text{-}N^tBu)_2TeNR$ (R = ^{t}Bu[149] or PPh_2NSiMe_3[163]) species may exhibit isomerism in solution.[167] The main isomers have their exocyclic RNTe groups either in cis (**4**) or trans (**5**) positions with respect to the four-atomic Te_2N_2 ring:

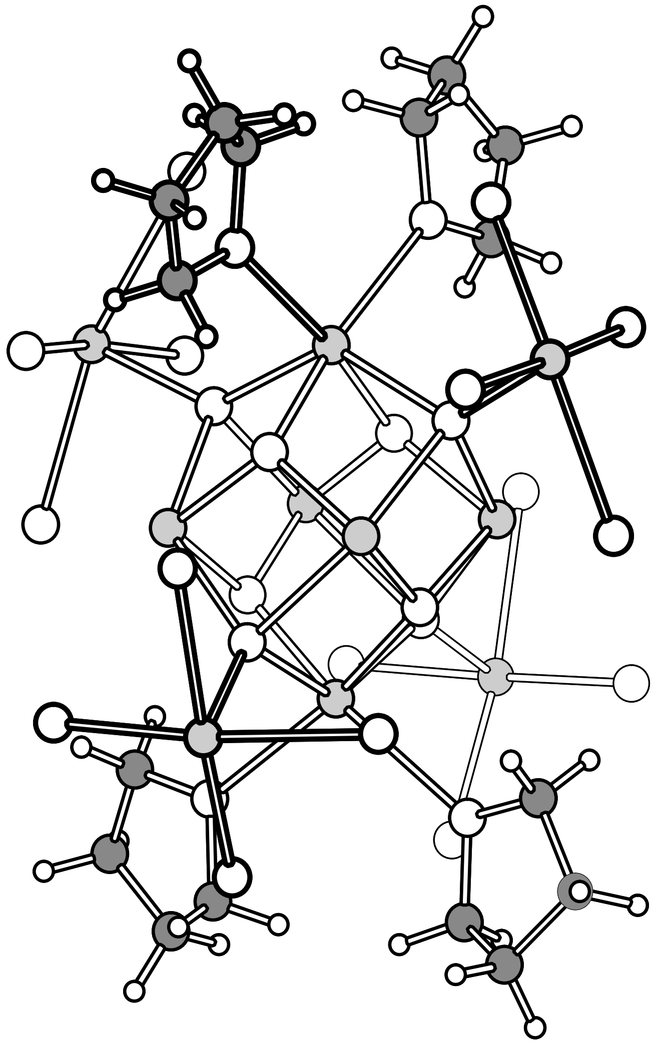


Figure 24 The structure of $[Te_6N_8(TeCl_4)_4{\cdot}(thf)_4]$.[159] Tellurium atoms are indicated in grey, nitrogen, oxygen, and chlorine in white, and carbon atoms from the tetrahydrofuran rings in dark grey

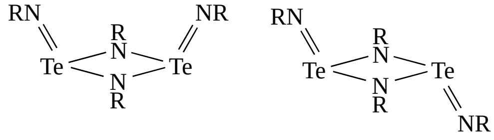

cis

(**4**)

trans

(**5**)

It is interesting to note that the solid-state conformation of ${}^tBuNTe(\mu\text{-}N^tBu)_2TeN^tBu$ is cis,[149] whereas that of $Me_3SiN(Ph)_2PNTe(\mu\text{-}N^tBu)_2TeNP(Ph)_2NSiMe_3$ is trans.[163]

Tellurium diimide dimers are thermally stable. For instance, ${}^tBuNTe(\mu\text{-}N^tBu)_2TeN^tBu$ sublimes at 85 °C, 10^{-3} Torr and melts at 100–102 °C without decomposition.[149] This is a marked contrast to selenium diimides. $(RN)_2Se$ (R = ${}^tBu$[167,168] or adamantyl[169,170]) are monomeric species that are thermally unstable and decompose spontaneously in solution to a variety of selenium–nitrogen species.

The dimeric structure of tellurium diimides is retained upon complexation. The coordination with coinage metals leads to dinuclear complexes in which tellurium diimide can act either as a chelating or bridging ligand, as exemplified by $[Ag_2\{{}^tBuNTe(\mu\text{-}N^tBu)_2TeN^tBu\}_2(CF_3SO_3)_2]$ and $[Cu_2\{{}^tBuNTe(\mu\text{-}N^tBu)_2TeN^tBu\}_3](CF_3SO_3)_2{\cdot}2CH_2Cl_2$ (see Figure 26).[171] The two ligands in the silver complex retain the cis-conformation of the free ligand, but the exocyclic ${}^tBu$ groups are both in exo positions to accommodate the coordination with Ag^+ ion. There is a Ag···Ag close contact of 2.888(2) Å in the structure that provides a contribution to controversy of the existence of metal–metal bonding in the d^{10}-d^{10} systems.[172–175] In the dinuclear copper complex cation, the two Cu^+ centers are coordinated to the exocyclic nitrogen atoms of two chelating and one bridging *tert*-butyl tellurium diimide dimer ligands. The chelating ligands show the exocyclic RN groups in cis positions while those of the bridging didentate ligand display them in trans positions.

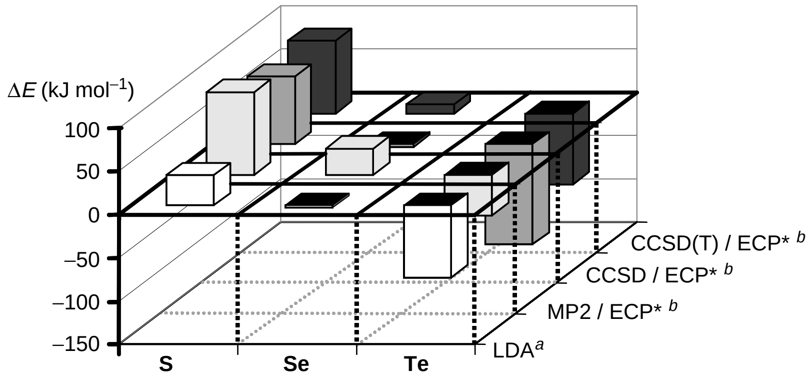

Figure 25 The calculated energy change in the [2 + 2] cyclodimerization of chalcogen diimides $E(NMe)_2$ (E = S, Se, Te). The calculations have been performed at [a]LDA[164] as well as at [b]MP2/ECP, CCSD/ECP, and CCSD(T)/ECP[165] levels of theory (© 2005 from Ref. 165 Reproduced by permission of Taylor & Francis, Inc. http://www.taylorandfrancis.com)

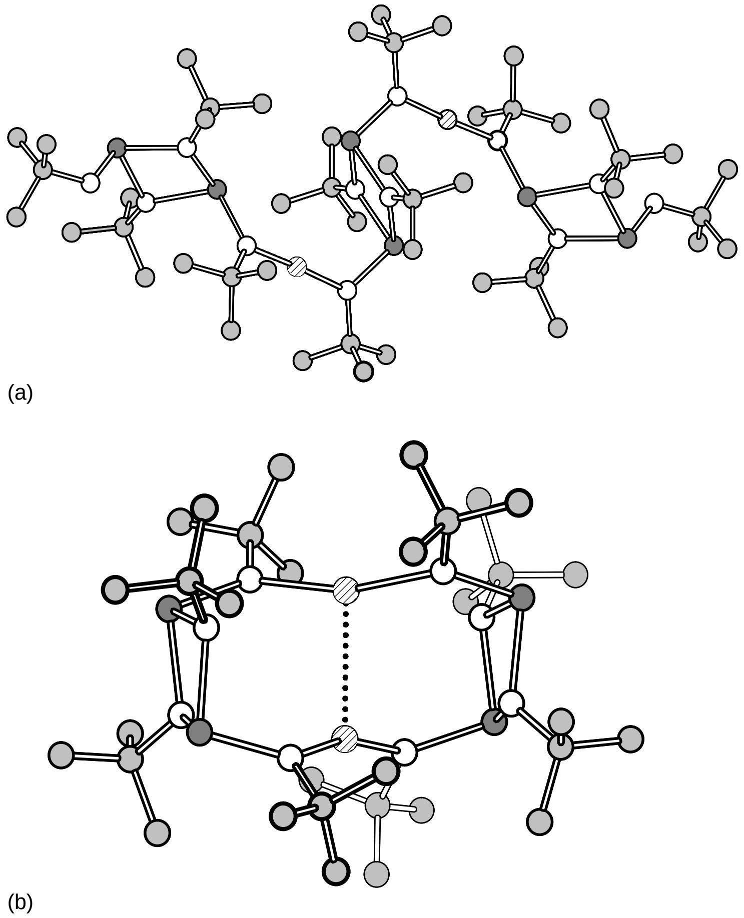

Figure 26 The structures of the complexes of $\{Te(N^tBu)_2\}_2$ with coinage metals: (a) $[Cu_2\{^tBuNTe(\mu\text{-}N^tBu)_2TeN^tBu\}_3](CF_3SO_3)_2\cdot 2CH_2Cl_2$, (b) $[Ag_2\{^tBuNTe(\mu\text{-}N^tBu)_2TeN^tBu\}_2(CF_3SO_3)_2]$.[171] Tellurium is indicated in dark grey, carbon in lighter grey, nitrogen in white, and transition metals as striped spheres

The tellurium diimide dimer readily reacts with nucleophiles. The treatment with potassium *tert*-butoxide generates the pyramidal *tert*-butoxybis(*tert*-butylimido)tellurite anion $[Te(N\text{-}^tBu)_2(O^tBu)]^-$.[176] In the solid state, the anion as its potassium salt adopts a dimeric arm-chair structure (see Figure 27(a)) The similar reaction with lithium *tert*-butylamide affords a centrosymmetric structure consisting of a distorted hexagonal prism involving two pyramidal tris(*tert*-butylimido)tellurite dianions linked by four lithium cations (see Figure 27(b)).[177,178]

7 OUTLOOK

While the chemistry of tellurium compounds is still in its infancy, the rapid recent progress has shown that tellurium has many unique properties compared to other chalcogen elements. The advent and development of modern instrumental structural methods of analysis have had a strong influence in the development of tellurium chemistry. Tellurium has two NMR-active $I = 1/2$ nucleii of which ^{125}Te (natural abundance 7.1%) is particularly useful for monitoring chemical reactions and identifying new species. X-ray crystallography has shown that the structural features of tellurium compounds often differ from those of sulfur and selenium.

Binary tellurides are convenient materials in many electronic devices. Active research interest is currently being directed into synthesis and characterization of novel nonmetallic tellurium compounds and transition metal compounds with tellurium-containing ligands, as well as into organic and organometallic tellurium chemistry. The goal is to use these compounds as single-source precursors for the generation of thin films for electronic applications. Many inorganic tellurium compounds also find utility in organic synthetic chemistry (*see* ***Tellurium: Organotellurium Chemistry***). Tellurium research is a prime example of the advances achieved by combining forces of fundamental and applied research.

1 INTRODUCTION

The preparation of diethyl telluride in 1840 by F. Wöhler[1] marks the beginning of organic chemistry of tellurium. After the pioneering period during which several new organotellurium compounds were synthesized, the organic chemistry of tellurium saw only slow development for almost a century. However, during the recent decades the progress has been rapid and tellurium reagents have opened new vistas for the design of synthetic methodologies in organic chemistry. The utility of inorganic tellurium and organic tellurium reagents in synthetic chemistry are exemplified by the reduction of different functional groups and the reductive cleavage of carbon-heteroatom bonds. Tellurium reagents can be employed in mild conditions. The yields are generally high, the selectivity is good, and many reagents can be generated in situ leading to 'one-pot' syntheses. Organotellurium ligands have attracted interest in coordination chemistry with the goal of designing suitable precursors for chemical vapour deposition processes in order to fabricate thin-films that can be utilized in electronic materials such as II–VI semiconductors.

While organic tellurium derivatives are often thought to be malodorous, this reputation is deserved only by the light alkyl derivatives. With the exception of diphenyl telluride, the aromatic derivatives are solids at room temperature.

The research volume in organic and organometallic tellurium chemistry has grown very rapidly in recent years, as seen in Figure 1. A comprehensive review of the whole field is therefore beyond the scope of this article. The emphasis is on the preparation and structural characterization of some main classes of organic tellurium compounds and their organometallic complexes that are deemed of interest for inorganic chemists. Several books and monographs,[1–13] as well as review articles,[14–35] are available for more complete coverage of this vast subject.

2 DIORGANYL TELLURIDES

2.1 Preparation

Diorganyl mono- and ditellurides are the best-known classes of organic tellurium compounds comprising symmetric and unsymmetric alkyl, aryl, and alkyl–aryl tellurides. In addition to acyclic tellurides, heterocyclic aliphatic telluroethers as well as aromatic tellurophene-derivatives are known (for a review, see Ref. 36).

The original synthesis of diethyl telluride by Wöhler[1] was carried out by treating potassium telluride with ethyl sulfate. The preparation of potassium telluride was rather inconvenient and involved the reduction of elemental tellurium by heating the element at red heat with potassium–hydrogen *D*-tartrate.[37] An early report of Natta[38] demonstrated that the treatment of aluminium telluride by alcohols or ethers at 250–300 °C is also a promising route to diorganyl tellurides.

One common present day preparation of dialkyl mono- and ditellurides involves the reaction of alkyl halides with alkali metal tellurides that have been prepared in situ. The reactions are commonly carried out in aqueous or nonaqueous solutions.[39–41] Solutions of sodium in liquid ammonia also provide a useful media for the reduction of tellurium.[42]

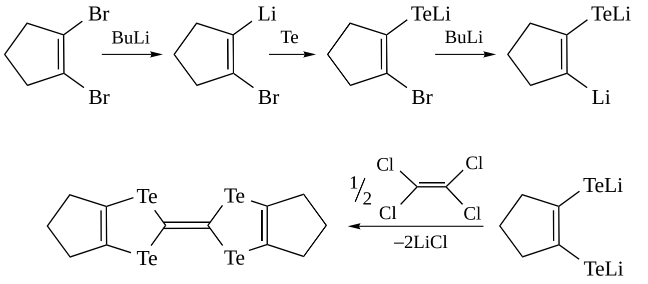
$$M_2Te_n + 2RX \longrightarrow R_2Te_n + 2MX \quad \{M = Na, K; R = alkyl; n = 1, 2\} \qquad (1)$$

The telluride-anions are sufficiently nucleophilic to react also with aryl halides to afford aryl tellurides, but generally the aryl group must be activated either by an additional substituent, or the reaction must be carried out at higher temperatures.[8] For example, *para*-iodobenzene reacts at 110–120 °C with sodium telluride to form polymeric poly-*p*-phenylenetelluride.[43,44]

$$p\text{-}IC_6H_4I + Na_2Te \xrightarrow{DMF} p\text{-}(C_6H_4Te)_n \qquad (2)$$

Aryl tellurides can be prepared by utilization of Grignard or alkyl lithium reagents, since elemental tellurium can conveniently be inserted into Mg–C or Li–C bonds. The one-pot synthesis of tetratellurafulvalene illustrates the use of

organolithium reagents.



(3)

These reactions are commonly utilized in the preparation of ditellurides.[45,46]

$$\mathrm{Ar} + n\text{-}\mathrm{BuLi} \xrightarrow{\mathrm{THF},\ -78\,^{\circ}\mathrm{C}} \mathrm{ArLi} \xrightarrow{\mathrm{Te},\ 25\,^{\circ}\mathrm{C}} \mathrm{ArTeLi} \xrightarrow{\mathrm{K_3[Fe(CN)_6]\ (aq)}} \mathrm{Ar_2Te_2} \quad (4)$$

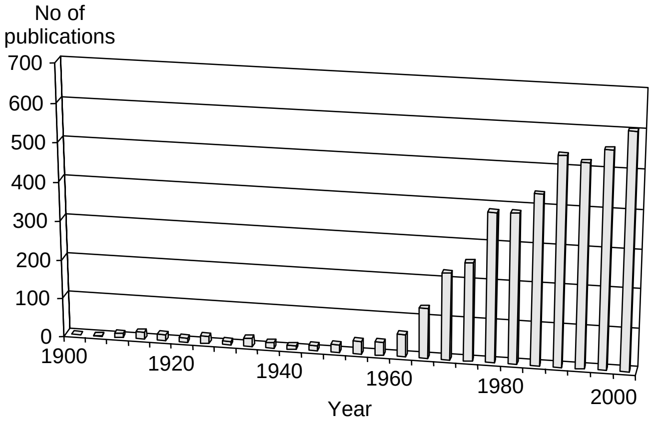


Figure 1 The growth of publication volume of organotellurium compounds

The final step in the reaction involves the oxidation of ArTeLi. Initially it has been carried out by oxygen in air, but it has been reported that $[Fe(CN)_6]^{3-}$ (aq) is a superior choice of the oxidant.[46]

n-Butyllithium does not lithiate pyridine in the 2-position, because of the preferential ring alkylation to proton abstraction. 2-lithiopyridine can, however, be produced by treating 2-bromopyridine with *tert*-butyllithium.[45] Also pyrrole and indole can be regiospecifically lithiated in the 2-position when bearing a suitable nitrogen protecting group.

Treatment of alkali metal alkyl or aryltellurolates (Section 5) with alkyl halides, aryl halides, alkenes, or alkynes have been used to prepare unsymmetrical tellurides, as exemplified by the reaction of sodium phenyl tellurolate or paramethylphenyl tellurolate with PhC≡CHCOPh.[47]

$$\mathrm{RTeNa} + \mathrm{PhC{\equiv}CHCOPh} \xrightarrow{\mathrm{EtOH}} \mathrm{RTeC(Ph)CHOPh} \quad (\mathrm{R} = \mathrm{Ph},\ p\text{-}\mathrm{MeC_6H_4}) \quad (5)$$

One convenient method for the preparation of organyl tellurolates is the treatment of diorganyl ditellurides with $NaBH_4$.

Diaryltellurium trichlorides and dichlorides (Section 3.2) can be converted to diorganyltellurides and ditellurides upon treating with reducing agents such as sodium sulfide,[48,49] potassium hydrogensulfite,[50] hydrazine,[51] or thiourea *S,S*-dioxide.[52] A typical example is shown in Eg. (6).[51]

$$2(4\text{-}\mathrm{CH_3OC_6H_4})_2\mathrm{TeCl_2} + \mathrm{N_2H_4} \longrightarrow 2(\mathrm{CH_3OC_6H_4})_2\mathrm{Te} + \mathrm{N_2} + 4\mathrm{HCl} \quad (6)$$

Tellurium tetrachloride and Grignard reagents can also be used for the preparation of activated diaryl tellurides.

2.2 Molecular Structures

Various diaryl tellurides have been structurally characterized by single-crystal X-ray diffraction. Some illustrative

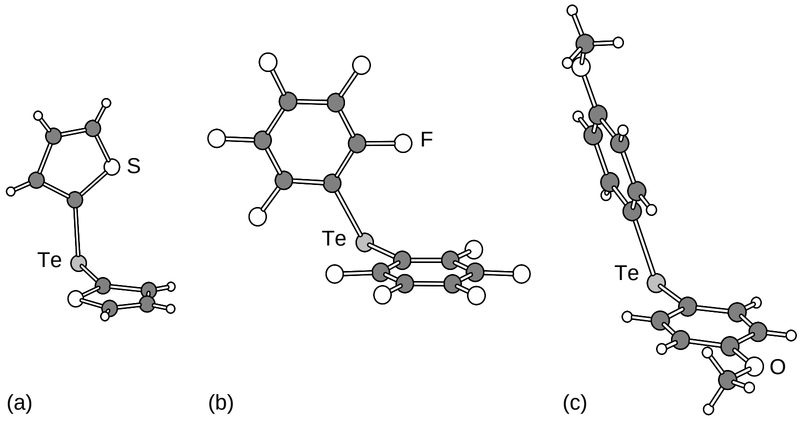

Figure 2 The crystal structures of (a) Th_2Te (Th = 2-thienyl, C_4H_3S),[54] (b) $(F_5C_5)_2Te$,[55] (c) $(MeOC_6H_4)_2Te$[56]

structures are shown in Figure 2. The Te–C bond lengths are close to the single bond length of 2.10 Å (the sum of the covalent radii of carbon and tellurium is 2.14 Å[53]). The C–Te–C bond angle is close to 100°.

The Te–Te bond lengths in various diorganyl ditellurides are close to 2.70 Å defining an approximate single bond. The C–Te–Te bond angles span a range of 95–105°. In absence of steric effects, the C–Te–Te–C dihedral angles (τ) in ditellurides are close to 90° because of the minimized p lone-pair repulsion between the adjacent chalcogen atoms (see Figure 3).[57] For example, the dihedral angle of both $(C_6H_5)_2Te_2$[58] and $(C_8H_5S)_2Te_2$[59] is 88.5°; $(C_4H_3S)_2Te_2$ 86.5°,[57] and $(C_4H_3O)_2Te_2$ 91.6°.[57] It is well-established that the chalcogen–chalcogen bonds are lengthening, as the dihedral angle deviates from 90°. Like in the case of diselenides, bulky organic groups in ditellurides may lead to dihedral angles significantly above 90°, as exemplified by $\{2\text{-}(Re_2N)\text{-}4,6\text{-}(CF_3)_2C_6H_2\}_2Te_2$ ($\tau = 145.1°$)[60] and $(o\text{-}ClC_5H_3N)_2Te_2$ ($\tau = 180°$).[61] It has been suggested[62] that the steric strain is relieved by increasing the dihedral angle rather than by increasing the chalcogen–chalcogen and chalcogen-carbon bond lengths. Interactions between the p lone-pairs of tellurium and the π-electrons of the aromatic rings also explain why the Te–Te bonds are preferentially either perpendicular to the plane of the aromatic rings or lie on the same plane (see Figure 4).

The molecular structures of some diorganyltritellurides have been reported (see Figure 5). $\{(Me_3Si)_3C\}_2Te_3$ contains a bulky $(Me_3Si)_3C$ group.[63] The Te–Te bond shows a length of 2.710(1) Å and the Te–C bond is 2.213(7) Å. $\{2\text{-}(C_5H_4N)C_6H_4\}_2Te_3$[64] is probably stabilized by intramolecular Te···N interactions, as shown in Figure 5(b). The Te–Te bond shows a length of 2.776(1) Å and the Te–C bond shows a length of 2.130(9) Å. The Te–Te–Te bond angles are 103.8 and 100.4° for $\{(Me_3Si)_3C\}_2Te_3$ and $\{2\text{-}(C_5H_4N)C_6H_4\}_2Te_3$, respectively.

Tellurium has two NMR-active nucleii: ^{125}Te and ^{123}Te. Both have a nuclear spin of 1/2 (*see* ***Tellurium: Inorganic Chemistry***). ^{125}Te is more abundant and has a better receptivity than ^{123}Te. It has therefore found more general use in NMR spectroscopic characterization of tellurium-containing compounds. Some examples of the ^{125}Te chemical shifts of diorganyl tellurides and ditellurides are shown in Table 1. The lightest compound, Me_2Te, is the conventional reference for the ^{125}Te chemical shifts.

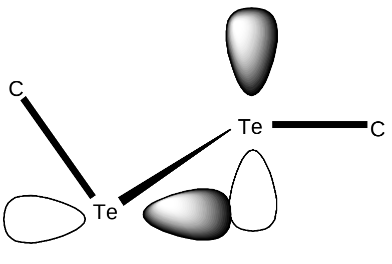

Figure 3 The observed torsional angle of ca. 90° is a consequence of minimized p lone-pair repulsion of adjacent tellurium atoms

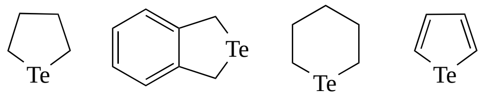
[a]The chemical shifts are reported relative to neat Me_2Te. The NMR spectra have been recorded in $CDCl_3$ unless otherwise indicated. [b]The NMR spectrum has been recorded in CH_2Cl_2.

Several cyclic telluroethers and their derivatives are known, as exemplified by some common examples below (for a more detailed discussion, see Ref. 36):



Tellurophene (C_4H_4Te; liquid; b.p. 151°; m.p. – 36°) was synthesized in 1972, disproving the suspected instability of the compound.[66]

It has been suggested that the ground-state aromaticity of furan and its heavier congeners follows the trend below (see Ref. 36 and references therein): thiophene > selenophene > tellurophene > furan.

Tellurophene reacts with Cl_2 to produce a stable 1,1-dichloro compound.[66] 2-Lithiotellurophene is obtained by α-metalation of the tellurophene. It can be used as starting product for the synthesis of some 2-substitued tellurophenes.

2.3 Uses

Diorganyl tellurides often serve as intermediates in organic reactions. An organic compound is first treated with an appropriate tellurium compound to give a diorganyl telluride. Subsequent reactions cleave at least one of the carbon–tellurium bonds and functionalize the group cleaved from the tellurium atom. This way alkenes can be converted to 4,5-dihydroxyoxazoles, cycloalkenes to acetals, and alkynes can be converted to vinyllithium compounds (see, for instance, Ref. 8).

Diorganyl tellurides are starting materials for the preparation of diorganyltellurium dihalides, pseudohalides, and carboxylates, of telluroxides, and of telluronium salts, and are used as ligands for the synthesis of transition metal complexes.

Diorganyl ditellurides can be used for the preparation of lithium and sodium tellurolates, which are frequently used for the introduction of the organyltelluro group into organic molecules, for the synthesis of organyltellurium chlorides or bromides, of organyltellurium trihalides, of symmetrical and unsymmetrical diorganyl tellurides, of telluroacetals, and of *Te*-organyl tellurocarboxylates (for recent reviews, see, for example, Refs. 5,6,8).

3 ORGANIC TELLURIUM-HALOGEN COMPOUNDS

3.1 Organotellurenyl Halides RTeX

While generally simple RTeX molecules are unstable, they can be stabilized by bulky organic group R or by secondary bonding interactions that were originally suggested by Allcock.[67] A recent example is illustrated in

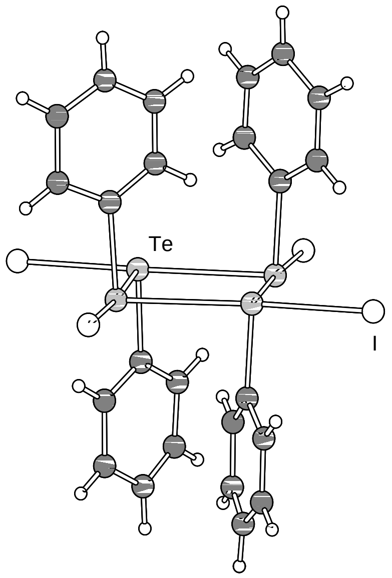


Figure 6 The crystal structure of $(PhTeI)_4$[68]

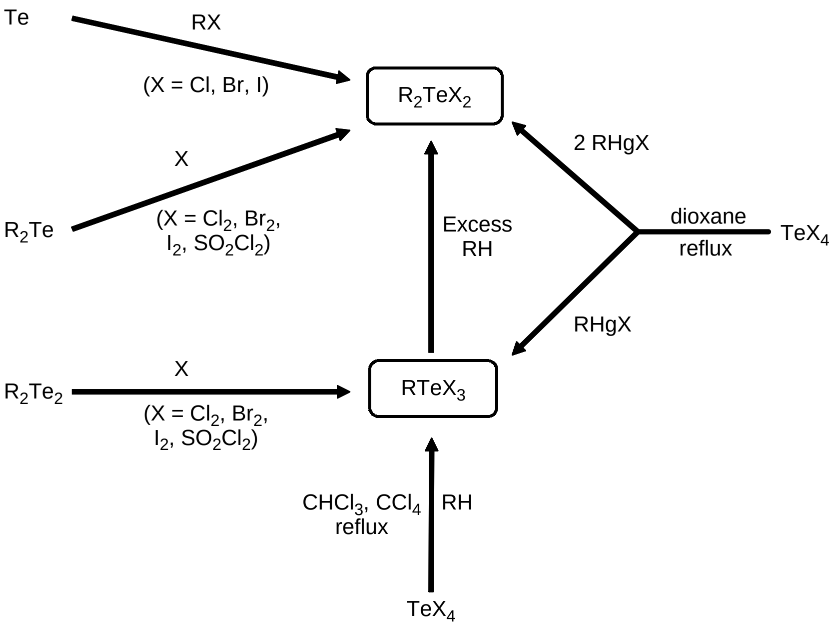

Figure 7 Common synthetic routes to organyltellurium halides

Figure 6 by $(PhTeI)_4$[68,69] that has been prepared by the reaction of Ph_2Te_2 and I_2. The molecules are arranged into tetramers by secondary bonding Te· · ·Te interactions spanning 3.151–3.180 Å.

3.2 Diorganyltellurium Dihalides and Organyltellurium Trihalides

Dialkyl- and diaryltellurium dihalides are crystalline solids that can be easily purified by recrystallization. While a large number of chlorides, bromides, and iodides have been prepared,[4,5] only a few fluorides are known.

There are several convenient synthetic routes to organyltellurium halides. Some of the most common methods are summarized in Figure 7. Diorganyltellurium dihalides can be prepared in good yields from elemental tellurium and alkyl halides, or by halogenation of diorganyl tellurides with elemental halogens, sulfuryl, and thionyl halides. The latter reaction also affords organyltellurium trihalides, when the starting material is a ditelluride.

Tellurium tetrachloride is also a convenient synthon for diorganyltellurium dihalides and organyl trihalides (the most important preparative methods have been summarized by Irgolic;[13] see also Refs. 3, 4 and 8). The condensation reactions with aromatic compounds like alkoxybenzenes, hydroxybenzenes, and (diorganylamino)benzenes yield diaryltellurium dichlorides with the tellurium group in the para-position relative to the ring substituent. The reactions involving unsubstituted aromatic compounds require elevated temperatures and the presence of aluminium trichloride catalyst for the condensation to proceed at a reasonable rate. Tellurium tetrachloride also adds to carbon–carbon double bonds of alkenes and yields bis(2-chloroalkyl)tellurium dichlorides. The reaction with another molecule of the alkene affords 2-chloroalkyltellurium trichloride. Heterocyclic tellurium dichloride derivatives can be obtained, when $TeCl_4$ reacts with 1,5- or 1,6-dienes.

Unsymmetrical diorganyltellurium dihalides are formed upon condensation of aryltellurium trichlorides with activated aromatic compounds and with ketones. The addition of the trichloride across carbon–carbon double bonds in alkenes, as well as the reaction with aryl(trimethyl)silane, hexaphenyldilead, and arylmercury chlorides leads to the transfer of the aryl group to the tellurium atom.

It should also be noted that the chlorine atoms in diorganyltellurium dichlorides can be exchanged by other halogens or anionic groups.

Most diorganyltellurium dihalides are stable in air. This facilitates a convenient method to purify diorganyl tellurides that are liquid at room temperature. The raw product is converted to a dichloride or dibromide by direct chlorination or bromination, and the pure dihalides are easily be reduced back to the original telluride.[48–52]

Three representative diorganyltellurium dihalides are shown in Figure 8. It can be seen that in all cases the tellurium atom possesses the Ψ-trigonal bipyramidal coordination geometry with the halogen atoms occupying the axial positions and the tellurium lone-pair occupying the third equatorial position. The mean Te–Cl distance is 2.515 Å in Me_2TeCl_2,[70] 2.508 Å in $(PhOC_6H_4)_2TeCl_2$,[71] and 2.502 Å in the cyclic $\{(CH_2)_3TeCl_2\}_3$.[72] The mean Cl–Te–Cl bond angles

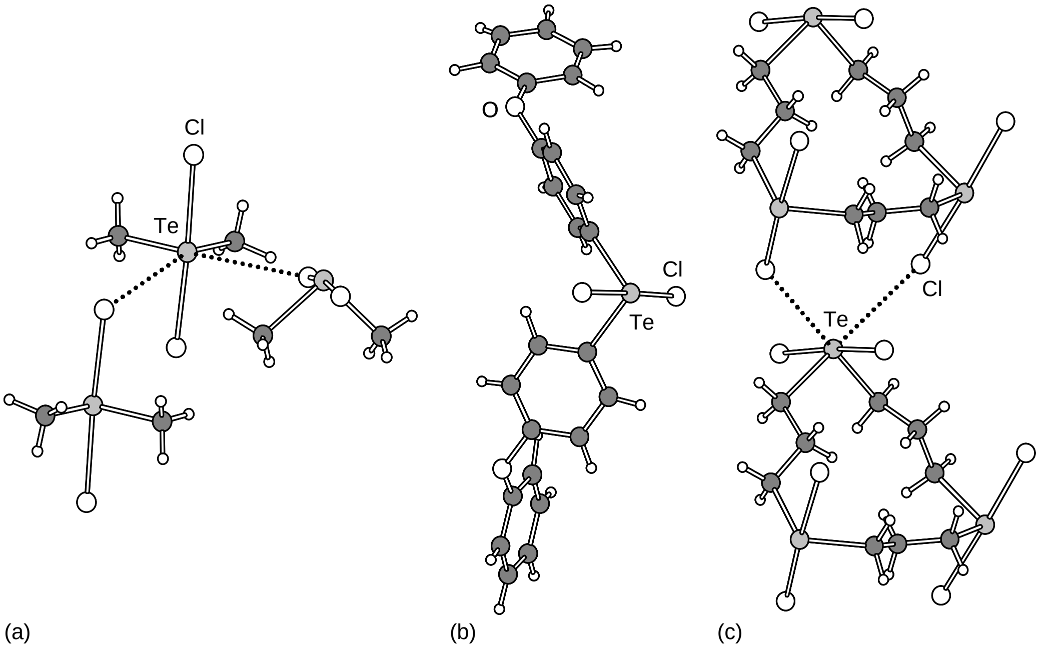

Figure 8 The crystal structures of (a) Me_2TeCl_2,[70] (b) $\{p\text{-}(PhOC_6H_4)_2TeCl_2$,[71] (c) $\{(CH_2)_3TeCl_2\}_3$[72]

are 172.4, 177.2, and 175.8° for the three compounds, respectively, and the respective mean C–Te–C bond angles are 96.6, 98.7, and 102.4°.

However, tellurium commonly shows secondary bonding interactions that expand the coordination environment. It can be seen in Figure 8 that both Me_2TeCl_2 and $\{(CH_2)_3TeCl_2\}_3$ show two close Te···Cl close contacts of 3.412–3.478 Å[70] and 3.359–3.479 Å,[72] respectively. The coordination environment around tellurium can therefore be considered as AX_4Y_2E in which X represents the primary bonding interaction, Y the secondary bonding interaction, and E the tellurium lone-pair.

The secondary bonding interactions are particularly important in diorganyltellurium diiodides, since in addition to Te···I close contacts there can also be I···I close contacts. It has been reported that there is a qualitative correlation between the lengths of the Te–I bonds in R_2TeI_2 and the strength of the secondary bonding interactions,[73] though the bond lengths are naturally also affected by the organic group. McCullough *et al.*[74] have correlated the secondary bonds with the color of the crystalline material. In absence of I···I close contacts, the crystals appear orange. As the I···I interactions become stronger, the color becomes deeper red and tends towards purple and black. This is well illustrated by $(CH_2)_4TeI_2$. It had been reported already in the early 1930s that this compound crystallizes as two different polymorphs: one form is orange–red and the other deep red.[75] The crystal structures of both polymorphs were established recently[73] and show that the I···I contacts in the deeper red polymorphs are shorter than in the orange–red polymorph. The packing of molecules in both polymorphs is shown in Figure 9.

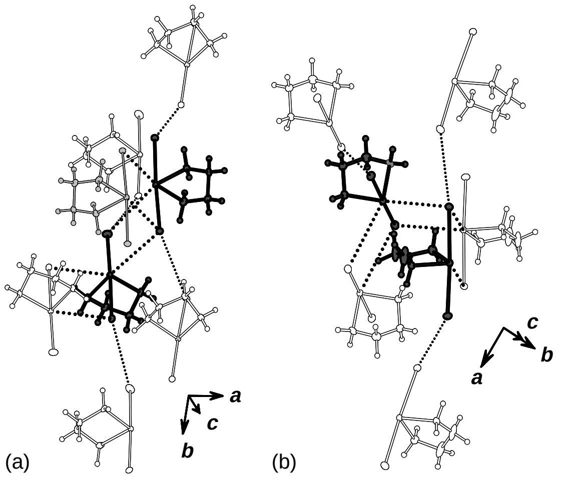

Figure 9 The packing in the two polymorphs of $(CH_2)_4TeI_2$. (Reprinted with permission from Ref. 73. © 2004 American Chemical Society)

Aryltellurium trihalides are generally more stable than alkyltellurium trihalides. They are relatively strong Lewis acids. Their most common coordination number is five based on the approximate square pyramidal coordination environment. As seen by some illustrative examples in Figure 10, these species can consequently exist as polymers (Figure 10(a)) or dimers (Figure 10(b)). In some cases there are also intramolecular interactions of variable strength. For instance, the Te–O distance of 2.441 Å[76] in Figure 10(c) and the Te···N distance of 2.402 Å[77] in Figure 10(d) imply

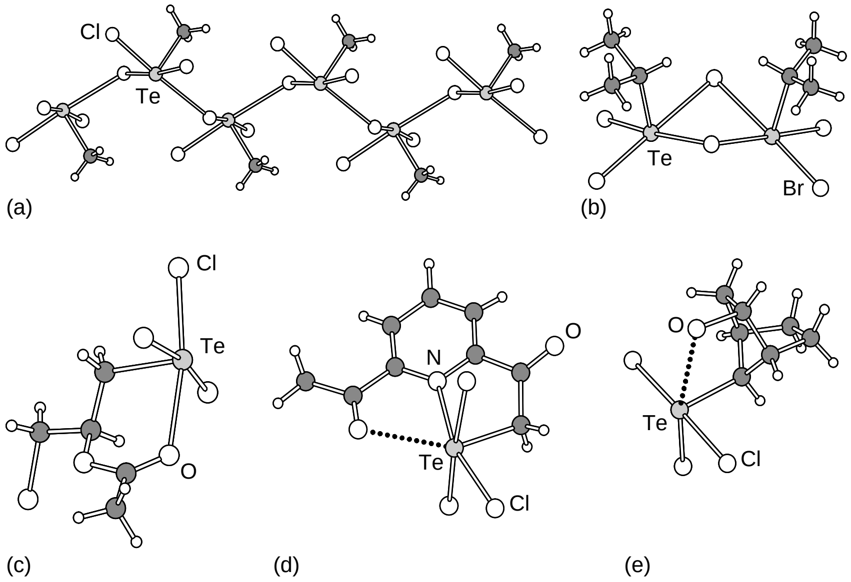

Figure 10 Organyl trihalides exist generally as (a) polymers[79] or (b) dimers.[80] Alternatively they may show intramolecular interactions of variable strength as an almost single Te–O bond in (c)[76] or weak secondary Te···Cl bonds in (d)[77] and (e)[78]

significantly stronger bonds than the clearly secondary Te···Cl interaction of 3.013 Å[78] in Figure 10(e). The trihalide in Figure 10(d) exceptionally shows an additional secondary bonding interaction of 2.878 Å, expanding the coordination sphere of tellurium to six.[77] The Te–Cl bonds cis to the Te–O, Te–N, or Te–Cl interactions span a narrow range of 2.462–2.500 Å, whereas the Te–Cl bond trans to them is strongly affected by the strength of the interaction. In case of strong Te–O and Te–N interactions, the Te–Cl bond is longer (2.354 and 2.438 Å, respectively), whereas the Te–Cl bond trans to the Te···Cl secondary bond is 2.298 Å. For comparison, the lengths of the terminal Te–Cl bonds in $(MeTeCl_3)_n$ are 2.352 and 2.366 Å, while the bridging Te–Cl distances are 2.759 and 2.814 Å.[79] The same trend is observed in the $\{(i\text{-Pr})TeBr_3\}_2$ dimer: the mean length of the terminal Te–Br terminal bonds is 2.545 Å while the bridging Te–Br bonds show the mean length of 2.922.[80]

4 TRIORGANYLTELLURONIUM SALTS

Triorganyltelluronium salts, R_3TeX, have been known for over a century.[81] In recent years, they have attracted considerable interest because of their role in organic synthetic chemistry.[8] For example, it has recently been reported that the telluronium salts are precursors for telluronium ylides that react with the carbonyl compounds, forming a variety of products like oxiranes and secondary alcohols.[82]

The X-ray structure determinations (see Ref. 83, and references therein) of several organotelluronium salts have established that in the solid state the structural features are governed by weak secondary tellurium-anion interactions[67] that expand the AX_3E (X = bonding pair, E = lone pair) trigonal pyramidal geometry around tellurium into a five- or six-coordinate entity. In the absence of these secondary interactions, simple ionic structures are expected.[84] Christian *et al.*[85] and Collins *et al.*[86] have discussed the nature of the secondary bonding and rationalized the structures in terms of the coordination geometry around tellurium. It has also been shown that solid-state ^{125}Te NMR spectroscopy is a sensitive tool to identify covalent secondary bonding interactions between the cations and anions.[40] Some illustrative examples are shown in Figure 11. The mean Te–C bond lengths are 2.131, 2.116, and 2.120 Å for $Ph_3TeCl\cdot 1/2CHCl_3$,[86] $(Ph_3Te)[AuCl_4]$,[83] and $(Ph_3Te)_2[TeCl_6]$,[87] respectively, and are close to single bond lengths. The respective mean C–Te–C bond angles are 94.2, 97.9, and 97.8°.

It can also be seen from Figure 11 that in every case the trigonal pyramidal coordination around tellurium is expanded into an AX_3Y_3E octahedron by Te···Cl secondary contacts of 3.219–3.716 Å. In the case of Ph_3TeCl one of the three secondary contacts is to the center of a phenyl ring of the adjacent Ph_3Te^+ cation.[86]

In addition to the two polymorphs of $(CH_2)TeI_2$ discussed in Section 3.2, the reaction of TeI_4 and PPh_3 in THF affords also $\{(CH_2)_4TeI^+\}_2[Te_2I_{10}{}^{2-}]$ and $\{(CH_2)_4TeI^+\}_2(TeI_3{}^+)_2(I^-)_4$, both of which contain a related telluronium cation (see Figure 12).[73] The bond lengths and angles in the $[Te_2I_{10}]^{2-}$ anion are virtually identical to those found in $\{(C_7H_7)(C_2H_5)_3N^+\}_2[Te_2I_{10}{}^{2-}]$.[88] The Te–I bond in the $\{(CH_2)_4TeI\}^+$ cation is shorter than the axial Te–I bonds in $(CH_2)_4TeI_2$ with the Ψ-trigonal

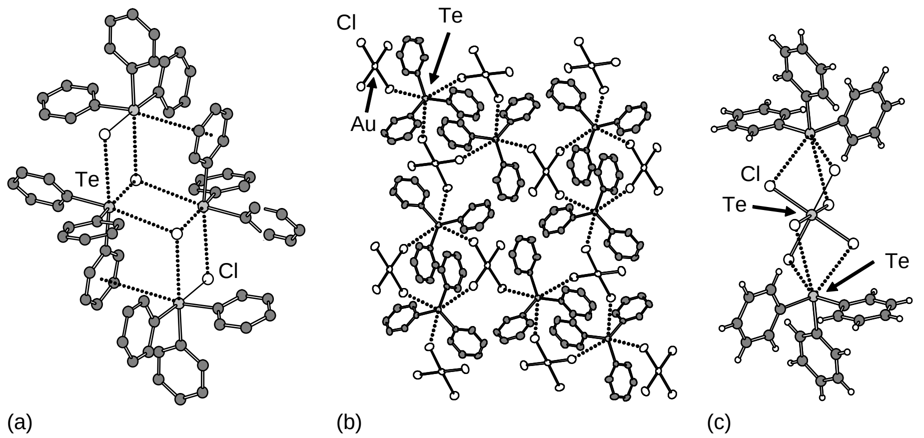

Figure 11 The crystal structures of (a) $(Ph_3Te)Cl$,[86] (b) $(Ph_3Te)_2[AuCl_4]$,[83] and (c) $(Ph_3Te)[TeCl_6]$.[87] Secondary bonds are indicated by dashed lines

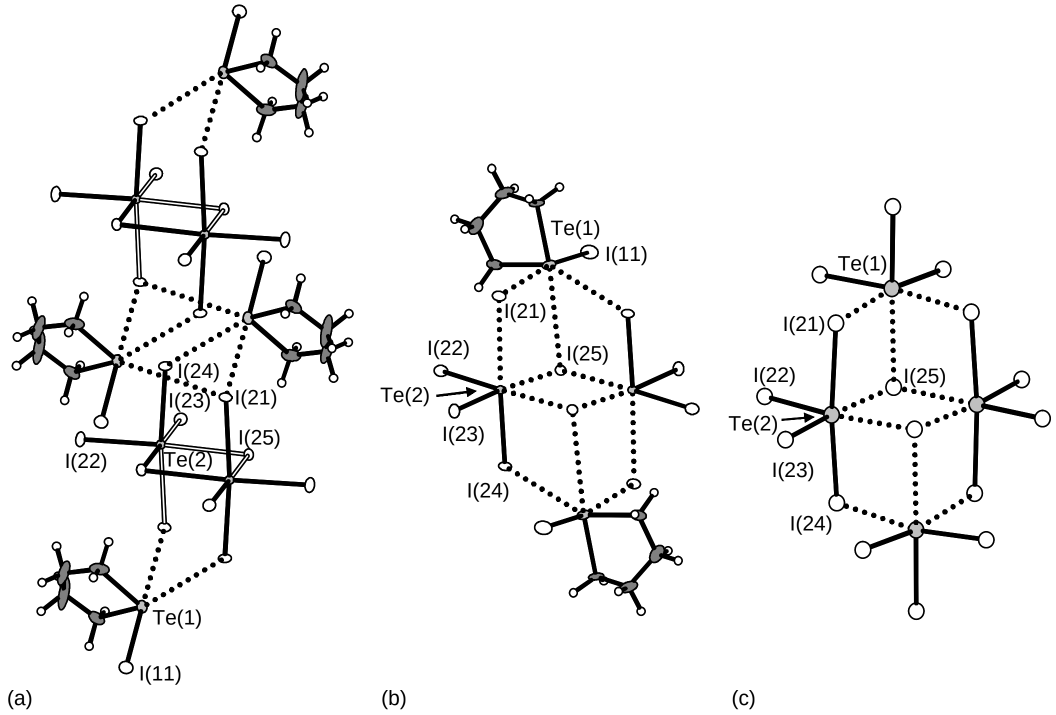

Figure 12 Comparison of the structures of (a) $\{(CH_2)_4Te^+\}_2[Te_2I_{10}{}^{2-}]$ and (b) $\{(CH_2)_4TeI^+\}_2(TeI_3{}^+)_2(I^-)_4$[73] with that of (c) $(TeI_3{}^+)_2(I^-)_2(TeI_4)_2$.[89] (Reprinted with permission from Ref. 73. © 2004 American Chemical Society)

bipyramidal coordination environment of tellurium, and is close to the single bond length, as expected for the eight-electron AX_3E cation. The I–Te–C bond angles of 93.3(2) and 96.8(2)° and the C–Te–C bond angle of 83.7(4)° are also consistent with the three-coordinate telluronium cation.[73]

$\{(CH_2)_4TeI^+\}_2(TeI_3{}^+)_2(I^-)_4$ (see Figure 12(b)) shows a structural framework that is similar to that of the tetramers in γ- and δ-TeI_4[90–93] and that have been formulated as $(TeI_3{}^+)_2(I^-)_2(TeI_4)_2$ based on the interatomic distances (see Figure 12(c)).[89]

5 ORGANYLTELLUROLATES

Organyl tellurolates are unstable, air-sensitive species and are normally used in situ without isolation. Some methods

for their generation are described below. As discussed in Section 2.1, lithium tellurolates can be prepared by insertion of tellurium into the carbon–lithium bond by a direct reaction.

$$RLi + Te \longrightarrow RTeLi \quad (7)$$

The insertion tendency decreases in the order t-BuLi > s-BuLi > n-BuLi > PhLi > MeLi.[94] These insertions can be carried out by using lithium alkanides, alkenides, alkynides, and aromatic or heterocyclic lithium compounds. The lithiation should not be carried out by using alkyl halides, because the lithium tellurolates that are formed in the reaction may react with the alkyl halide reagent to produce organyl alkyl tellurides.[13]

Tellurolates can also be produced by reducing diorganyl ditelluride with sodium or lithium tetrahydridoborate:

$$RTeTeR \xrightarrow{NaBH_4} RTeNa \quad (8)$$

The reaction can be performed in different organic solvents. Currently ethanol seems to be the most common solvent. This method has been employed almost exclusively for the preparation of sodium alkyl-, alkenyl-, aryl-, and heteroaryl tellurolates. Metallic lithium and sodium can also be used for the reduction of diorganyl ditellurides.

Although the organotellurolates are normally used without isolation, some tellurolate salts have been isolated and structurally characterized. The structure of $(Ph_4P)[C_4H_3STe]$[95] (see Figure 13(a)), as well as $(Ph_4P)[5\text{-}CH_3\text{-}C_4H_3STe]$,[96] consists of well-separated organotelluride anions. The tellurolates with bulky aryl groups have also been isolated with alkali metals utilizing crown-ethers, as exemplified in Figure 13(b) by $[K(18\text{-crown-}6)][Te\{2,4,6\text{-}(Me_2CH)_3C_6H_2\}]$.[97] Insertion of elemental Te into the C–Li bond of n-BuLi in the presence of TMEDA gave $[n\text{-BuTeLi}\cdot\text{TMEDA}]_2$, which was characterized in the solid and solution state resulting in the first crystal structure of a lithium alkyltellurolate.[98]

The reductive cleavage of diorganyl ditellurides with sodium borohydride is more complex than anticipated, as suggested by the isolation of a catenated organotelluride anion, $(C_6H_5Te)_3^-$ when molar ratio between diphenyl ditelluride and $NaBH_4$ was 3:2.[99] The tetraphenylphosphonium and tetraphenylarsonium tri(tellurophenolate) salts were isolated and structurally characterized, as shown in (Figure 14).[99] $(C_6H_5Te)_3^-$ has also been isolated as $[Sm\{hydrotris(3,5\text{-}dimethylpyrazolyl)borate\}_2(TeC_6H_5Te)_3]$ salt.[100]

Organyltellurolates are useful synthons in organic chemistry.[9,21,27,101] Tellurolates can be alkylated or arylated to afford diorganyl tellurides and they add to alkenes and alkynes. The latter reaction is both regioselective and trans-stereospecific. They can also be utilized in the generation of tellurium-containing heterocycles.

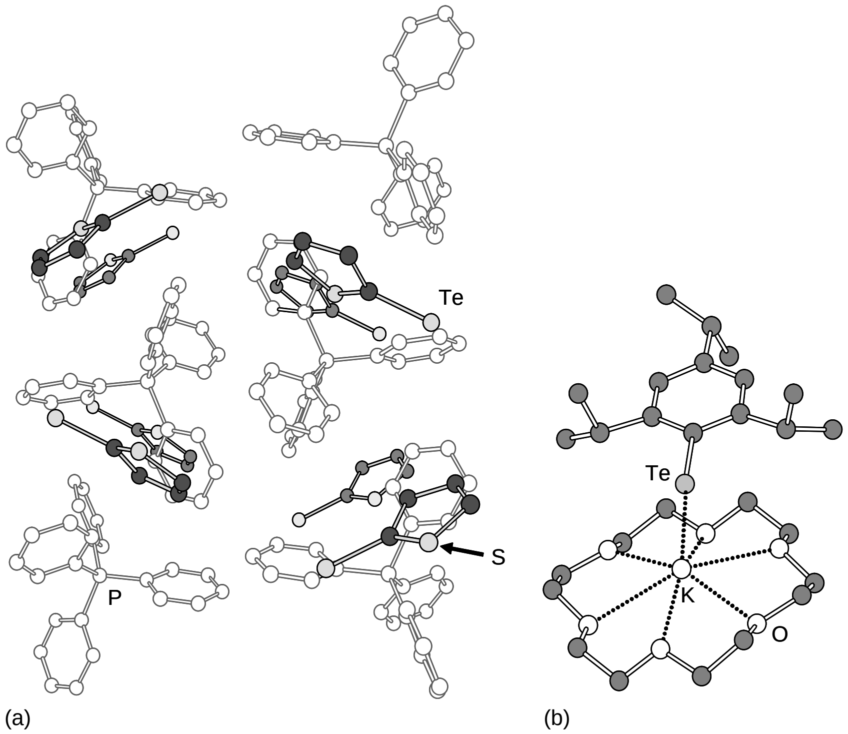

Figure 13 The discrete tellurolate anions in (a) $(Ph_4P)(TeTh)$ (Th = 2-thienyl, C_4H_3S)[95] and (b) $[K(18\text{-crown-}6)][Te\{2,4,6\text{-}(Me_2CH)_3C_6H_2\}]$[97]

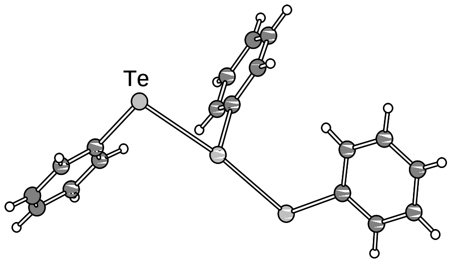

Figure 14 The structure of the $(Ph_3Te_3)^-$ anion[99]

6 METAL COMPLEXES

6.1 Organyltellurolato Complexes

Anionic organotellurolates can act both as terminal and bridging ligands. Their transition metal complexes can conveniently be prepared by the treatment of halogenated metal complexes with RTe^-, or by the oxidative addition of the R_2Te_2 to low-valent transition metal centers. The product distribution depends on the choice of the metal center, organic group, solvent, and the molar ratio of the reagents (for more detailed discussion, see, for instance, Refs. 15 and 27).

The examples of the structures of some typical mononuclear complexes are presented in Figure 15 and those for polynuclear complexes in Figure 16. It is conceivable that the more complicated polynuclear complexes are formed from mono- and dinuclear complexes by successive condensation reactions (see Figure 17).[102] This scheme follows the initial suggestion of Brennan *et al.*[102] They formulated a pathway for the formation on hexanuclear $[Pd_6Te_6(PEt_3)_8]$ with a dinuclear intermediate $[Pd_2Te_4(PEt_3)_4]$.[103,104] Because $[Pd_6Cl_2Te_4(TeR)_2(PPh_3)_6]$ contains the same framework as $[Pd_6Te_6(PEt_3)_8]$, their formation probably goes through similar stages. The suggested formation of $[Pd_2(TeTh)_4(PPh_3)_2]$ from Th_2Te_2 and $[Pd(PPh_3)_4]$ in benzene[105] and the formation of a trinuclear complex $[Pt_3Te_2(Th)(PPh_3)_5]Cl$ from Th_2Te_2 and $[Pt(PPh_3)_4]$[106] lends credibility to the reaction pathway in Figure 17.

Some main group metals also form mononuclear and dinuclear tellurolato complexes.[21,27,29] A few examples are shown in Figure 18.

6.2 Telluroether Complexes

Several types of telluroether (diorganyl telluride) ligands are known. They can be monodentate or polydentate, acyclic, cyclic, and macrocyclic as well as hybrid telluroether ligands containing other donor atoms in addition to tellurium. Complexes with telluroether ligands have seen extensive research activity in recent years (for two most recent reviews, see Refs. 27 and 35).

Though telluroether ligands have been known for almost a hundred years, the advent of their coordination chemistry dates back only to the 1970s. There are several reasons for this lack of interest: Telluroethers were considered weak donors with poor coordinating ability except to soft metals and they were thought to be only little different from the thioether analogs. Their reputation as toxic and malodorous compounds dates back to the original reports by Wöhler,[1] their commercial availability was very

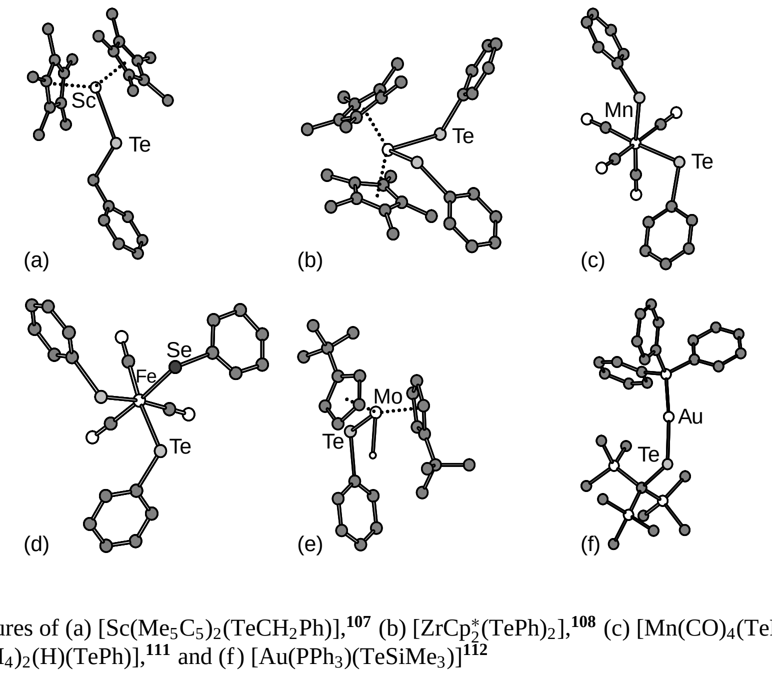

Figure 15 The crystal structures of (a) $[Sc(Me_5C_5)_2(TeCH_2Ph)]$,[107] (b) $[ZrCp^*_2(TePh)_2]$,[108] (c) $[Mn(CO)_4(TePh)_2]^-$,[109] (d) $[Fe(CO)_3(SePh)(TePh)_2]^-$,[110] (e) $[Mo(^tBuC_5H_4)_2(H)(TePh)]$,[111] and (f) $[Au(PPh_3)(TeSiMe_3)]$[112]

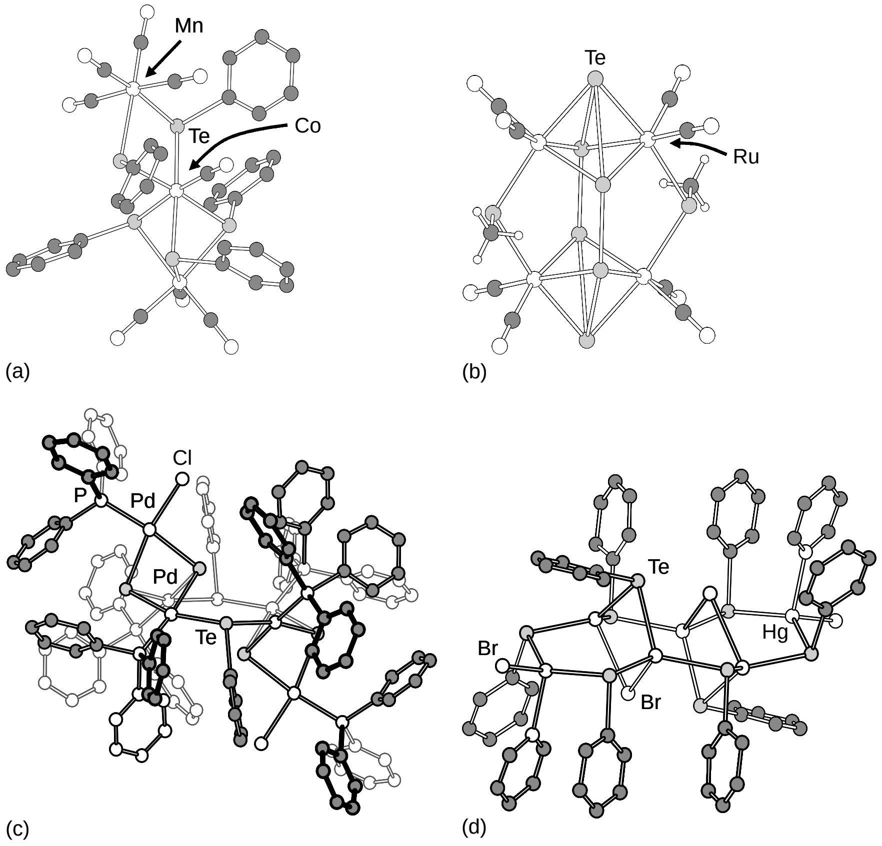

Figure 16 The crystal structures of (a) $[Mn_2Co(CO)_8(TePh)_5]$,[109] (b) $[Ru_4(CO)_8Te_6(TeMe)_2]^{2-}$,[113] (c) $[Pd_6Cl_2(SePh)_2(PPh_3)_6]$,[102] and (d) $[Hg_6Br_4(py)_2(TePh)_8]$[114]

limited, and the complexes were considered to have no applications.

Recent decades, however, have seen rapidly growing interest in this area. New synthetic approaches in the production of novel telluroether ligands have been designed. The advent of modern FT NMR techniques has enabled improved understanding of the tellurium-containing species in solution. The coordination chemistry of telluroether ligands has also proven to be much more varied than what was initially assumed.

Dialkyl as well as diaryl tellurides behave as monodentate ligands. Consistent with their soft character, their best explored group of complexes involves Pd(II) and Pt(II) centers. A variety of techniques have been applied to the characterization of their solid state and solution structures. In such square-planar complexes, $[MX_2(TeR_2)_2]$ (M = Pd, Pt; X = Cl, Br, I), cis – trans isomerization, intramolecular ligand exchange and tellurium inversion processes have all been observed by detailed far-infrared and variable-temperature NMR studies (see Refs. 14,15,17,35 for a more detailed review of the subject).

In the solid state, the characteristic feature in such mononuclear $[MX_2(TeR_2)_2]$ complexes is the formation of Te···X secondary bonding contacts, as shown in Figure 19. They link individual complexes into dimeric units. The Te···Cl distances in these complexes span a range of 3.393–3.523 Å, the Te···Br distances 3.623–3.647 Å, and the Te···I distances 3.679–3.862 Å.[119]

The ^{125}Te NMR chemical shifts of the complexes are found to high frequency of those of the free ligands, and vary with the metal, its oxidation state, the trans ligand, and the other (cis) ligands in the coordination sphere. Solvent effects appear to be considerably smaller for the complexes than for free ligands. Isomerism in solution can readily be detected for the square-planar $[ML_2TeR_2]$ (M = Pd, Pt; X = halide), since the chemical shifts of cis and trans isomers show a small difference of ca. 20 ppm.[17] In the case of NMR inactive metal, the chemical shift alone is an uncertain guide to the identification of the individual isomer. For the platinum complexes, the ^{195}Pt chemical shifts and the coupling constants are much better indicators. The $^1J(^{125}Te\text{-}^{195}Pt)$ coupling constants are larger for the cis-isomers than for the trans isomers and provide a better indicator of the structures when both forms are present in solution (see, for instance, Refs. 27,35 and references therein).

In almost all complexes, R_2Te acts as a terminal ligand. $[PtCl(Th)(TeMeTh)_2]_n$ (Th = 2-thienyl, C_4H_3S) is an exception (see Figure 20).[120] Two bridging ThTeMe ligands

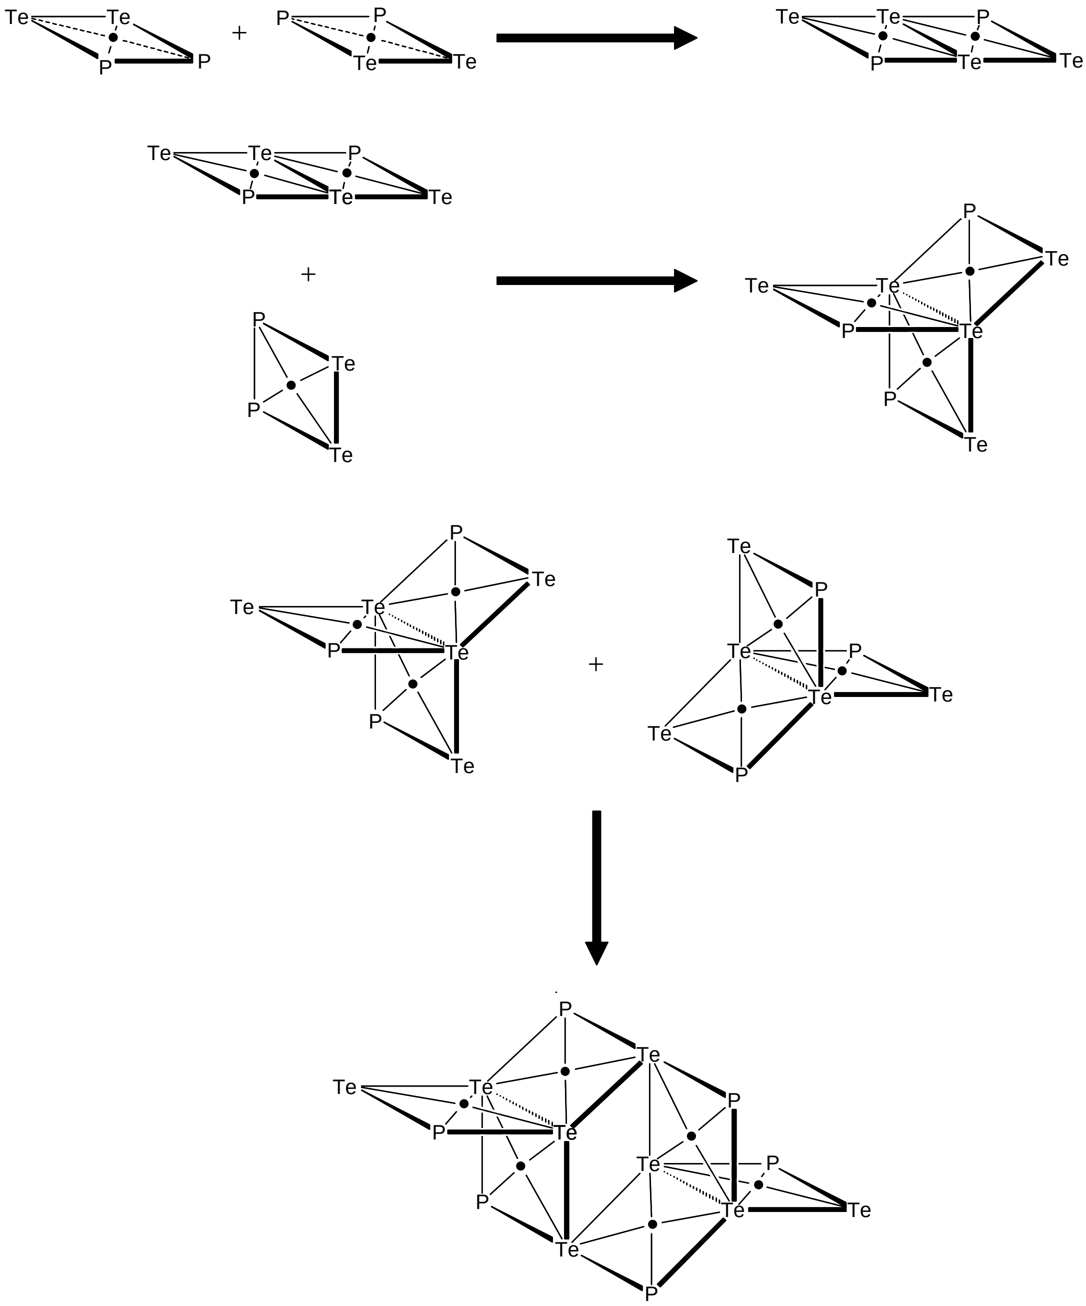

Figure 17 Structural relationships between the mono- and polynuclear frameworks of tellurolatopalladium complexes.[102] (Reprinted from Ref. 105. © 2000, with permission from Elsevier)

link the metal centers into polymeric chains and create a quasi-octahedral coordination environment around Pt(II) with two very long Pt–Te bonds of 2.898(1) and 3.419(1) Å.

$[PdCl_2(TeC_4H_8)_2]$ is an example of a complex with heterocyclic telluroether ligand (Figure 21). The molecules show Te· · ·Cl close contacts of 3.462 and 3.472 Å and consequently form dimeric units.[121] 1,3-dihydrobenzo[*c*]tellurophene (L) also behaves as a simple monodentate Te donor ligand with metals as exemplified by $[Mo(CO)_{6-n}L_n]$ ($n = 1-3$).[122]

The reaction with $Fe_3(CO)_{12}$, however, results in the loss of tellurium and formation of tellurium-free organoiron complexes.[123,124] Similar loss of tellurium has reported on the reaction with tellurophenes and benzotellurophenes.[124]

6.3 Diorganyl Ditellurides Complexes

Although upon complex formation, ditellurides generally undergo cleavage of the Te–Te bond with formation of

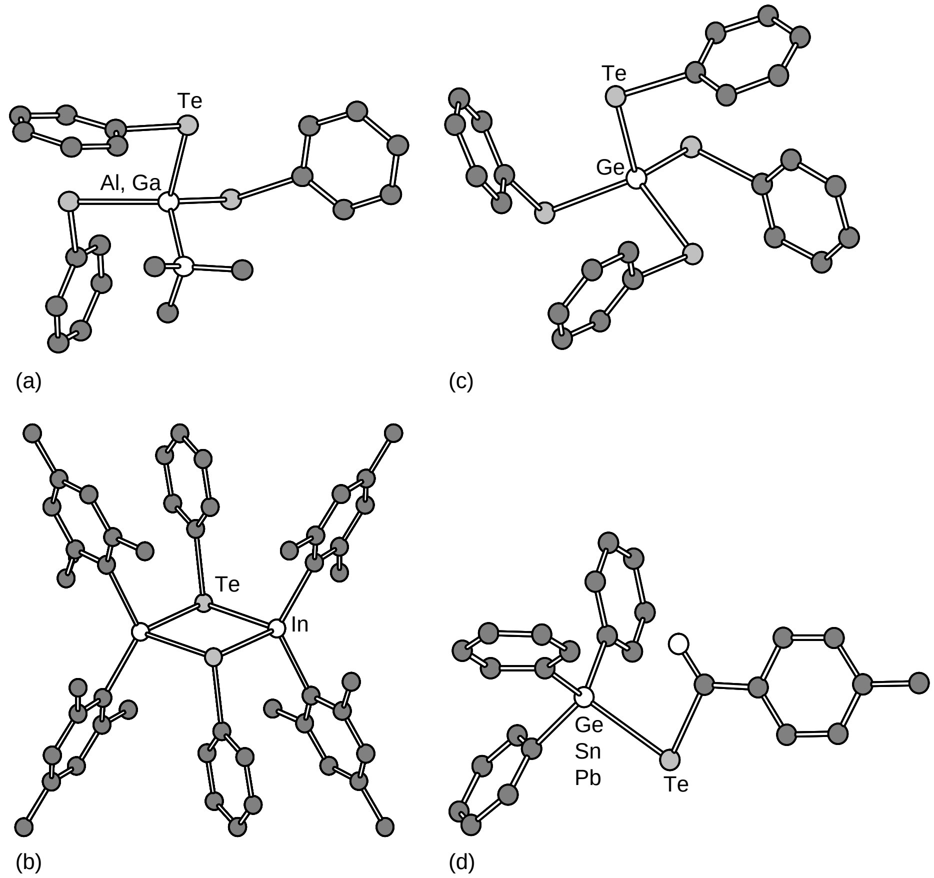

Figure 18 Examples of main group aryltellurolato complexes[115–118]

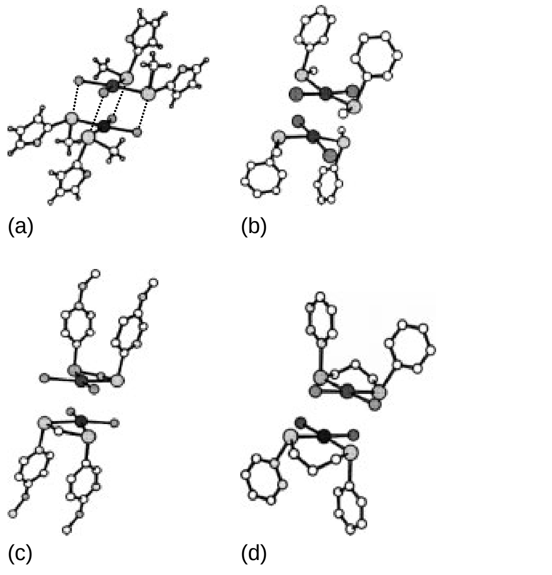

Figure 19 Secondary bonding interactions in (a) *cis*-$[PdCl_2\{(C_4H_3E)TeMe\}_2]$ (E = S, O), (b) *trans*-$[PtI_2(TePhMe)_2]$, (c) *cis*-$[PdCl_2\{$*meso*-$(4\text{-}MeOC_6H_4Te)_2CH_2\}_2]$, and (d) *cis*-$[PdBr_2\{$*meso*-$PhTe(CH_2)_3TePh\}_2]$.[119] (Reprinted from Ref. 119. © 1998, with permission from Elsevier)

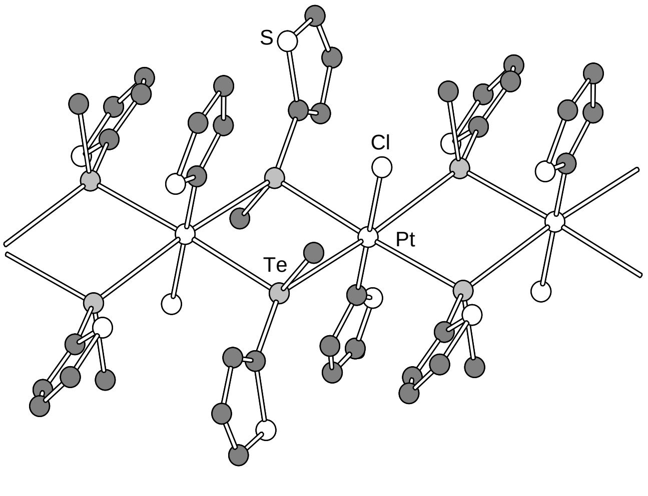

Figure 20 The crystal structure of $[PtCl(Th)(TeMeTh)_2]_n$ (Th = 2-thienyl, C_4H_3S)[120]

terminal or bridging TeR–ligands, in some cases they can also coordinate without Te–Te bond cleavage The ditelluride can act either as a monodentate terminal ligand or as a bridging bidentate ligand (see Figure 22).

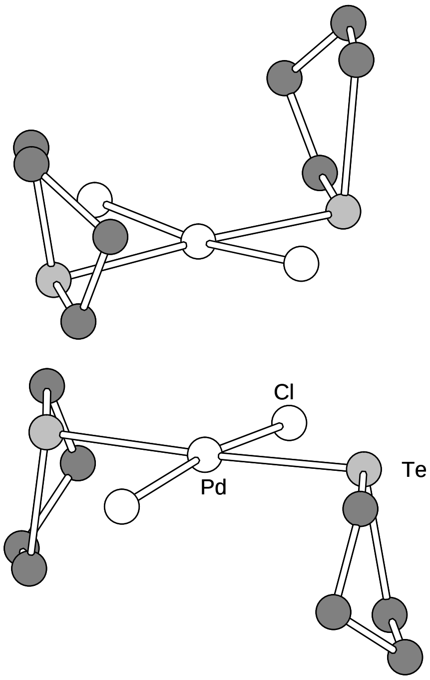

Figure 21 The crystal structure of $[PdCl_2(TeC_4H_8)_2]$[121]

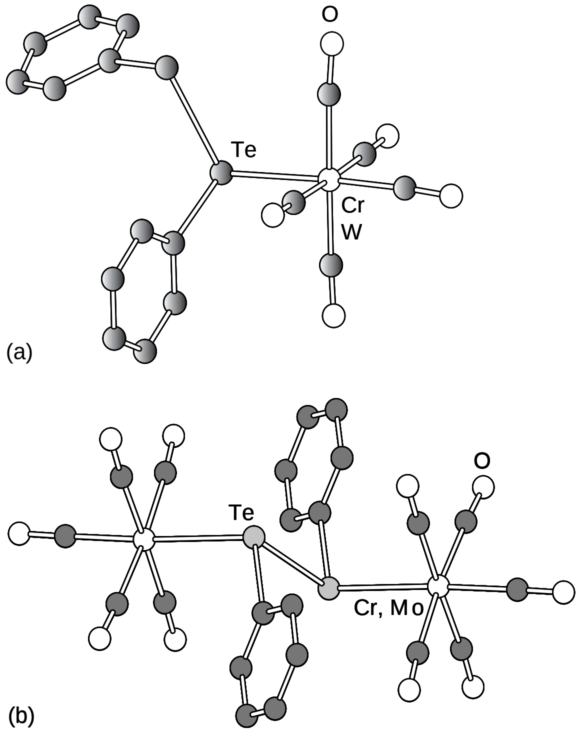

Figure 22 (a) The crystal structures of $[M(CO)_5(Te_2Ph_2)]$ (M = Cr, W) containing a monodentate terminal phenyldi telluride ligand.[127] (b) The crystal structures of $[\{M(CO)_5\}_2(\mu\text{-}Te_2Ph_2)]$ (M = Cr, Mo)[128,129] containing a bridging didentate phenyl ditelluride ligand[128]

The reaction of Me_3SiTeR (R = 4-MeC_6H_4, C_6H_5) with $[(\eta^5\text{-}C_5Me_5)RuCl_2]_2$ generates R_2Te_2 at the metal center resulting in $[Ru(\eta^5\text{-}C_5Me_5)(\mu_2\text{-RTeTeR})(\mu_2\text{-TeR})_2Ru(\eta^5\text{-}C_5Me_5)]$.[125] This metal complex contains both bridging ditelluride and tellurolate ligands (see Figure 23(a)). The Te–Te bond of 2.901 Å is very long. It is due to strong repulsion of the p lone-pairs of adjacent tellurium atoms that is a consequence of a very small torsional angle of 4.7° (for a discussion of the lone-pair interactions in chalcogen–chalcogen bonds, see Ref. 126).

The treatment of $(p\text{-}C_6H_4F)_2Te_2$ with an equimolar amount of $AgBF_4$ in acetonitrile at ambient temperature leads to the formation of a ditelluride bridged $[Ag_2(NCCH_3)_4\{\mu_2\text{-}(p\text{-}C_6H_4F)TeTe(p\text{-}C_6H_4F)\}_2][BF_4]_2$ in 96% isolated yield.[130] The interesting coordination mode can be seen in Figure 23(b). The two silver atoms are bridged by two ditellurides, resulting in a six-membered Ag_2Te_4 ring that adopts a chair configuration. The Te–Te bond of 2.752(1) Å is shorter than the Te–Te bond of 2.794(5) in $[(OC)_3Re(\mu\text{-Br})_2(\mu\text{-}Te_2Ph_2)Re(CO)_3]$,[131] but can be compared to the Te–Te bond of 2.749(2) Å in $[(PtMe_3)_2(\mu\text{-I})_2\{\mu\text{-}Te_2(p\text{-}MeOC_6H_4)\}_2]$.[132]

7 OUTLOOK

While organotellurium compounds have been known for a long time, it is only in recent decades that this area of chemistry has seen rapidly expanding interest. The thrust of research activity is being motivated by increasing number of applications of organic tellurium compounds in organic and inorganic syntheses, and by use of organometallic tellurium-containing complexes for catalytic and electronic applications.

The synthetic applications of organotellurium compounds can be divided into carbon–carbon bond forming reactions and various types of functional group interconversions. The tellurium reagents are primarily used in oxidation and reduction reactions. Indeed, new reactions are constantly being found that are entirely unique for tellurium reagents and cannot be executed by other means. The advantages of tellurium-mediated reduction reactions over conventional reagents include milder reaction conditions, better regioselectivity, in situ preparation of the reducing agent, and the ease of recovery of tellurium. Like selenium compounds, tellurium reagents can be used as mild oxidizing agents.

Other potential applications of novel organotellurium compounds include the conducting materials, nonlinear optical devices, polymer light emitting diodes (LEDs), and other materials for electronic devices. Major areas of current interest in organometallic complexes containing organic tellurium ligands is concerned with the fabrication of binary transition metal telluride thin films by MOCVD techniques.

While organotellurium chemistry has opened new avenues for applications, their structural chemistry is very varied. The

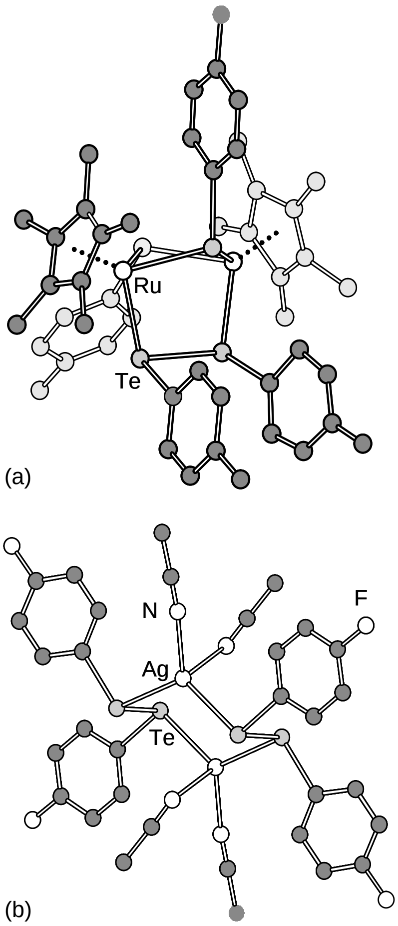

Figure 23 (a) A dinuclear ruthenium complex with a bridging $(CH_3C_6H_4)_2Te_2$ ligand and two bridging $CH_3C_6H_4Te$–ligands,[125] (b) A cyclic Ag complex with two bridging $(FC_6H_4)_2Te_2$ ligands[130]

field is still in its pioneering stage and rapid development both in terms of fundamental information of structures, bonding, and reactions, as well as in new applications can be expected in the coming years.

1 INTRODUCTION

The metallic element thallium, atomic number 81 (relative atomic mass 204.38), is the heaviest member of group 13 of the periodic table. The ground-state electron configuration is $[Xe]4f^{14}5d^{10}6s^26p^1$.

Thallium chemistry was divided into two independent fields nine years after the discovery of the element, with the first preparation of diethylthallium chloride. Organothallium chemistry thus became an independent and fruitful counterpart to the inorganic chemistry of this element (*see* ***Thallium: Organometallic Chemistry***).

The best-known property of this element to the layperson is its toxicity (*see* ***Metal Ion Toxicity***); indeed, the use of thallium as a 'rat poison' was the most important application for decades. Thallium appeared to be merely an exotic *Trace Element*, seeming to merit little attention from the scientific community. As a result, there are only a few books[1–7] specializing in the inorganic chemistry of thallium, and most of the recent papers have been published by a small group of research workers. However, subject areas such as coordination chemistry, redox reactions with inorganic and organic substrates (*see* ***Electron Transfer in Coordination Compounds***), solid structures and *High-Temperature Superconductivity*, metal–metal bonds (*see also* ***Polynuclear Organometallic Cluster Complexes***) should be mentioned as examples where the inorganic chemistry of thallium is ongoing (though, some of these fields are certainly related to the organometallic chemistry of thallium). NMR spectroscopy is the primary physical method used in studies of thallium chemistry. The thallium nuclei ^{205}Tl and ^{203}Tl both have spin $I = \frac{1}{2}$ and are suitable for NMR spectroscopy, the absolute sensitivities with respect to ^1H NMR being 0.13 and 0.055, respectively. Furthermore, the observation of large multibond coupling constants in many thallium compounds allows structural information to be obtained from ^1H or ^{13}C NMR spectra, which may be recorded routinely in most laboratories.

1.1 Discovery and History

The element thallium was discovered relatively recently. In 1861, the British chemist William Crookes attributed a bright green line in the emission spectrum of some residues from a sulfuric acid plant to a new element. However, the Frenchman C. A. Lamy was the first to obtain thallium in any quantity. Crookes named his discovery after the 'Latin *thallus*, a budding twig – a word that is frequently employed to express the beautiful green tint of young vegetation'.[8] However, his original idea that thallium was a member of the sulfur family was short lived, and on the basis of its chemical and physical properties Mendeleev rightly placed it in group 13.

1.2 Occurrence and Distribution[2]

Thallium is a relatively abundant element and is widely distributed in nature. Estimates for the abundance of thallium in the earth's crust range from 0.3 to 3 ppm, though about 1 ppm is the generally accepted value. The wide distribution is due to several factors, the most important being the isomorphous replacement of K^+ in potassium feldspars and micas (silicates) by Tl^+. Additionally, thallium sulfide is found in sphalerite, galena, pyrite, and other sulfide ores. Thallium also behaves as an accessory to manganese in geological processes; for example, manganese oxides and deep-sea manganese nodules may be enriched in thallium to levels of 0.01% and 0.1% respectively. The few existing thallium-based minerals such as lorandit ($TlAsS_2$), crookesite ($(Cu,Tl,Ag)_2Se$), and avicennite (Tl_2O_3) are very rare and have no commercial importance.

In the aquatic environment, thallium is present as Tl^I at a level of about 0.01 ppb in seawater. Tl^I is also strongly adsorbed by soils.

Of the total quantity of thallium mobilized by industry amounting to about 1600 tons in the United States during 1977, 70% was reemitted to the environment either in the form of air pollution (15%) or as solid waste (55%). Coal burning power plants account for the greater part of this air pollution, but the smelting of copper, zinc, and lead may also result in concentrated local emissions. The remaining 30% is incorporated in the final products, though usually at a lower level than in the raw materials.[2]

1.3 Production and Use

Thallium is manufactured commercially as a by-product from the roasting of pyrite ores, from sulfuric acid plants, and from the smelting of lead, zinc, and copper. The global

production is estimated to be in the range of only 13–16 tons per annum during the last two decades.[9–12] Volatile compounds of thallium are gaseous at the temperature of these smelting operations and are collected in the flue dust in the form of oxides or sulfates. In a typical procedure for the recovery of thallium, the flue dust is first boiled in sulfuric acid, after which the dissolved thallium in the filtrate is precipitated by the addition of zinc. Impurities such as zinc, copper, lead, cadmium, and indium may be removed by dissolving the metal in dilute sulfuric acid and precipitating the trace elements with hydrogen sulfide. Thallium is recovered from saturated solutions of Tl_2SO_4 by electrolysis at low current density. The raw product is compressed into blocks and melted at 350–400 °C under a layer of oxalic acid or in a stream of H_2 gas. The metal obtained may be protected with a coating of paraffin or stored under glycerol or petroleum.

The commercial applications of thallium are limited, and at present there are no bulk consumers. Consumption of thallium in the United States has fallen steadily from 1.4 tons in 1987 to 0.3 tons in 1998.[11] Previously, though, over a period from 1920 to 1970, several tons of thallium were used each year in the form of insecticides and rodenticides. However, many countries have terminated its use because of accidental or secondary poisoning of wild animals and birds; even children have been known to be severely poisoned as a result of ingesting thallium-containing bait.

There are several uses of thallium in the optical industry. For example, mixed TlBr–TlI crystals may be used as optical elements for IR applications. Thallium is also added in small amounts to glass to increase the density and refractive index. For example, patents have been filed for thallium-containing glasses for use as sealants or coatings for semiconductor elements.

In the field of electronics, thallium oxysulfide is used in the so-called ‘Thalofide cell’, which has sensitivity for low-intensity, long-wavelength light better than that of the selenium cell, and thus has important military and research applications. Thallium-activated NaI or NaCl crystals are used in the photomultiplier tubes present in some scintillation counters. Future uses of thallium in this field can be expected because of its incorporation in thallium-based high-temperature superconductors.

Some of the alloys of thallium have found applications as a result of their unique properties. For example, the Tl–Hg alloy containing 8.7% thallium forms a eutectic mixture freezing at −59 °C, and has been considered for applications in low-temperature thermometers, switches, closures, and seals. Alloys of thallium are also used in good quality bearings, having a very high resistance to corrosion and low coefficients of friction. Thallium is also used in gold plating applications.

In spite of their known toxicity, compounds of thallium have been used in medicine and as cosmetics. Thallium has been used internally in the treatment of gonorrhea, syphilis, dysentery, and tuberculosis and externally as a depilatory. Serious cases of poisoning were recorded, some of which were even fatal. At present, the only medical application of thallium is its use in the form of intravenous injections of ^{201}Tl (half-life = 12.2 days) for myocardial imaging to diagnose the distribution of regional myocardial perfusion.

Most of the thallium in circulation today is probably present in research laboratories; in 1977 this share was estimated at 50% in the United States.[2] Thallium compounds are mainly used as intermediates or catalysts in organic synthesis and ‘must now be regarded as essential reagents for modern organic synthesis’.[12] Thallium-based superconducting materials are presently being prepared and characterized in material science laboratories.[13] The first large scale commercial application of $Ba_2CaCu_2Tl_2O_8$ thin films for a microwave device has recently been reported.[14] An X-ray laser using energized atoms of thallium has been developed.[15] Thallium has also found some applications in biological research;[16] for example, Tl^+ is able to mimic K^+ in certain biological reactions and can be easily detected using ^{205}Tl NMR or fluorescence methods. Metal activated enzymes such as pyruvate kinase, ATPase, and aldehyde dehydrogenase have been studied in this way. Tl^{III} has also been used as a probe to investigate the iron sites in human transferrin.

2 PROPERTIES OF THE ELEMENT

Thallium is a silver–gray, soft, heavy, and ductile metal having three forms. The normal close-packed hexagonal lattice transforms to a body-centered cubic structure above 230 °C and a face-centered cubic form is stable at high pressures. The triple point is at 110 °C and 30 kbar. Thallium vapor is essentially monatomic, but on heating to 2000 °C, the vapor emits a visible band due to Tl_2. Some properties are listed in Table 1.[9]

There are two stable isotopes of thallium, ^{203}Tl (29.5%) and ^{205}Tl (70.5%), and numerous radioactive isotopes; in the mass range 184–210, there are 41 isotopes including 16 with half-lives longer than 10 minutes.

Thallium has the stable oxidation states I and III; there are also several compounds in which thallium exists with the *Formal Oxidation State* II, though stable compounds of Tl^{II} are not known in aqueous solution. It has been proposed that Tl^{II} is present in reactions with one-electron reactants; half-lives of 0.5 ms have been measured for the Tl^{2+} intermediate by flash photolysis. It has been shown that the electron transfer in most Tl^{I}/Tl^{III} redox systems is a two-electron process[17] (*see* ***Electron Transfer Reactions: Theory***). However, thallium is present as Tl^{II} in the trinuclear $(NBu_4)_2[Tl\{Pt(C_6F_5)_4\}_2]$; an unpaired electron makes the solid compound paramagnetic.[18] Isolable molecular organothallium(II) compounds, $[(Me_3Si)_3Si]_2Tl{-}Tl[Si(SiMe_3)_3]_2$ and $(^tBu_3Si)_2Tl{-}Tl(Si^tBu_3)_2$ have been reported recently; the Tl–Tl contacts (resembling the well known $Hg_2{}^{2+}$) are 2.91 and 2.97 Å, respectively.[19]

Table 1 Some properties of thallium

Atomic number	81
Relative atomic mass	204.3833
Ground-state electron configuration	$[Xe]4f^{14}5d^{10}6s^{2}6p^{1}$
Radii (pm)	
atomic (α form)	170.4
Tl^{I}	149
Tl^{III}	105
covalent	155
Electronegativity (Pauling)	
Tl^{I}	1.62
Tl^{III}	2.04
Tl^{I}/Tl	−0.3363
Standard reduction potentials (V)	
Tl^{III}/Tl	0.72
Tl^{III}/Tl^{I}	1.25
$Tl \rightarrow Tl^{I}$	589.3
Ionization energies ($kJ\,mol^{-1}$)	
$Tl^{I} \rightarrow Tl^{II}$	1971.0
$Tl^{II} \rightarrow Tl^{III}$	2878
$Tl^{III} \rightarrow Tl^{IV}$	(4900)
Density ($g\,cm^{-3}$)	
at 293 K	11.850
liquid at mp	11.290
Melting point (K)	576.7
Boiling point (K)	1730
Electrical resistivity (Ωm) at 273 K	18.0×10^{-8}

The Tl^{I}–Tl^{III} relationship is therefore a dominant feature of thallium chemistry. The standard reduction potentials at 25 °C and unit activity of H^{+} are: $Tl^{I}/Tl = -0.336$ V, $Tl^{III}/Tl = +0.72$ V, and $Tl^{III}/Tl^{I} = +1.25$ V.[9] Estimates have also been made for the couples $Tl^{III}/Tl^{II} = +0.33$ V and $Tl^{II}/Tl^{I} = 2.22$ V. The generally valid limitations concerning the use of standard electrode potentials to predict the redox chemistry of 'real' systems are especially important in the case of thallium: factors such as complex formation in the presence of coordinating anions or neutral ligands and pH dependence due to hydrolysis do affect the actual or formal redox potentials. For example, redox potentials have been measured for $TlCl/TlCl_3 = +0.77$ V in 1 M HCl and $TlOH/Tl(OH)_3 = -0.05$ V in alkaline solution.[1] These formal potentials differ from the standard value for $Tl^{III}/Tl^{I} = +1.25$ V. The difference can be attributed to the substantial difference between the complex forming abilities of Tl^{I} and Tl^{III}, which will be discussed in detail later. The Tl^{III} is thermodynamically stable in the presence of strong complexing agents, even in acidic solutions, though in the absence of these ligands Tl^{+} can only be oxidized by strong oxidizing agents such as MnO_4^{-} or BrO_3^{-}. In contrast, Tl^{+} is a powerful reducing agent in alkaline media.

It is interesting to note that Tl^{I} is more stable than the monovalent oxidation states of the other three metallic elements of group 13, Al, Ga, and In. The occurrence of an oxidation state two units below the group valence is often known as the *Inert Pair Effect* (see, e.g. Hg, Sn, Pb, and Bi). This effect implies a resistance of a pair of s electrons (i.e. $6s^2$ for Tl) to be lost or to form covalent bonds. The reason for the stability of the lower oxidation state cannot be attributed to its unusually high ionization potential for this pair of s electrons. The sum of the second and third ionization enthalpies for Tl (4820 $kJ\,mol^{-1}$) is slightly higher than the same value for In (4501 $kJ\,mol^{-1}$), but lower when compared to Ga (4916 $kJ\,mol^{-1}$). On the other hand, the mean bond energies of the trichlorides are 242, 206, and 153 $kJ\,mol^{-1}$ for Ga, In, and Tl respectively. There is a substantial decrease in the bond strengths and this is the reason why the formation of $TlCl_3$ is less favored in comparison with $GaCl_3$ or $InCl_3$. The relativistic contribution of the inert pair effect has been appreciated in recent theoretical calculations. An s^2 pair is not stereochemically active because the s orbital is spherically distributed, unlike a 'lone pair' occupying a coordination site in a molecule (see, e.g. $SnCl_3^{-}$).[17]

The Pauling *Electronegativity* (EN) values of the stable oxidation states of thallium are 1.62 and 2.04 for Tl^{I} and Tl^{III} respectively.[9] The latter value is equal to that for boron, and thus Tl and B are the most electronegative elements of group 13. It should be noted that the trend in the electronegativities is not monotonic for this main group, and the values have limited importance in predicting trends even for compounds of elements having the III oxidation state. On the other hand, the concept of 'hard' or class 'a' and 'soft' or class 'b' metal ions and ligands (*see* ***Coordination & Organometallic Chemistry: Principles***) is a useful guideline in the classification of bond strengths and the ionic/covalent character of bonds in thallium compounds. Thallium(III) belongs to the group of 'soft' metal ions, in contrast to Al^{III}, Ga^{III}, and In^{III}, which are classified as 'hard' ions. The 'softness' of Tl^{III} is rationalized in terms of its strong interactions with 'soft' donor ligands such as sulfur or the halides, with the exception of F^{-}. One can find similarities in the chemistries of Au^{I}, Hg^{II}, and Tl^{III}. On the other hand, Tl^{I} is classified as a borderline ion, having similarities both with the alkali metal ions, which have comparable ionic radii, and also with Ag^{+}. Thallium(I) forms ionic crystals; however, the non-Coulombic interaction increases on moving from TlF to TlI. Furthermore, complexes of Tl^{I} are quite weak due to the s^2 electrons, which are σ-antibonding in all stereochemistries. The greater polarizability of Tl^{I} in comparison with the alkali metal ions may explain its pronounced similarity to Ag^{I}. The geochemical diversity of thallium might also be related to this character.

The TlX_3 compounds, like their Al, Ga, and In analogs, are found to behave as Lewis acids (*see Lewis Acids & Bases*) and accept ligands to form tetrahedral complexes. The position of Tl is uncertain in the Al > Ga > In order. The polymerization of these compounds is extensive in order to achieve coordination saturation.[17]

Before discussing the compounds of thallium in detail, the chemical behavior of the metal will be illustrated by its reactions with some common reagents.

Freshly prepared thallium readily loses its bluish-gray tinge in air. The metal is slowly oxidized by dry air or oxygen

at room temperature, forming Tl_2O, and reacts gradually with water or steam even in the absence of oxygen to form TlOH. Dissolution of thallium in hydrofluoric acid is fast. The decreased reactivity with other hydrogen halides is purely a result of the formation of a layer of insoluble thallium(I) halide. Thallium dissolves in oxidizing acids. Thallium is not soluble in sodium hydroxide, in contrast to the amphoteric metals Al and Ga. A remarkable reaction of the metal is with alcohols forming $Tl(OR)_3$ and H_2. The metal is fairly reactive with the halogens and also reacts with sulfur at elevated temperatures.

3 THALLIUM COMPOUNDS

3.1 Thallium Hydrides

The hydrides of thallium, like those of lead and bismuth, are unstable. However, the compound $LiTlH_4$ has claimed to be a relatively stable thallium hydride. Solid $LiTlH_4$ is easily prepared from $TlCl_3$ using lithium hydride[20] (equation 1):

$$TlCl_3 + 4LiH \xrightarrow[-15\,^{\circ}C]{Et_2O} LiTlH_4 + 3LiCl \qquad (1)$$

The compound readily decomposes to Tl, LiH, and H_2 above 30 °C, whereas in ether solutions a polymeric hydride is formed after a few hours at 0 °C (equation 2):

$$LiTlH_4 \xrightarrow[0\,^{\circ}C,\ -LiH]{Et_2O} TlH_3{\cdot}nEt_2O \longrightarrow (TlH_3)_x \qquad (2)$$

$(TlH_3)_x$ is thermally unstable and loses H_2 at 150 °C giving the stable polymeric Tl^I hydride $(TlH)_x$. This compound has also been prepared by the thermal decomposition of $TlBH_4$, or from TlOEt by addition of B_2H_6 in ether solution. The chemical properties of these compounds reported in the 1950s by Wiberg should be treated with some reservation; for example, the thermal stabilities of TlH_3 and $(TlH_3)_x$ published at that time are not in agreement with recent reports concerning other hydrides of the group 13 elements.[21] Wiberg's report on the stability of $(TlH_3)_x$ seems to be dubious on the basis of theoretical calculations also.[22] Recent ab initio calculations show the thermodynamic instability of Tl_2H_6 both in gas and solid phases, although kinetic stability has been predicted, that is, a local minimum has been found at the MP2 level. However, the isolation of $(TlH_3)_x$ still remains intricate.[23]

No experimental results appear to have been published since the late 1950s, except for the preparation of $TlHI_2$ (from TlI_3, Al, and H_2)[24] and also of HTl_2OH.[25] The latter species are hydrogen bonded and may be formed from Tl vapor with H_2O in an argon matrix by UV irradiation. TlH species have been detected and characterized by spectroscopy in the gas phase.[26] Moreover, a large body of theoretical calculations have been published dealing with the stability and bonding of the thallium hydrides.[23] It is worth mentioning a dimeric compound, Tl_2H_2, which is often used as a model in theoretical studies dealing with the stability of the Tl–Tl bond,[22] and the monohalide-thallanes (TlH_2X) as model systems for calculation of thermodynamic stability and the role of the π-back donation of the halogeno ligand.[27]

3.2 Halides and Pseudohalides

3.2.1 Halides and Halide Complexes

The series of compounds Tl^IX and $Tl^{III}X_3$, except for $Tl^{III}I_3$, are well characterized. The relative weakness of the Tl^{III}-halide bond has been previously discussed in connection with the 'inert pair effect' (see Section 2).

The Tl^I halides are similar to the silver halides in that they are sensitive to light. The yellow compound TlI has a curious orthorhombic layer structure, which is transformed to a red metastable cubic form (CsCl type) at 4.7 kbar or 175 °C, becoming a metallic conductor at about 160 kbar.[28] If a small quantity of a Tl^I halide is added to an aqueous solution of an alkali halide, a blue ***Luminescence*** is emitted; furthermore, TlCl doped KCl behaves as a thallium–alkali halide phosphor. In both cases, $TlCl_2^-$ is believed to be the active species.[1]

Thallium(I) halides are predominantly ionic, although there is a tendency toward increasing covalent character in the series of compounds TlCl (17%), TlBr (20%), and TlI (28%). This increased degree of covalency results in decreased solubility; for example, TlF is soluble in water whilst the other Tl^I halides are only sparingly soluble. The thallium(I) halides are classical examples of 'incompletely dissociated' 1:1 electrolytes. The stability of halide complexes of Tl^I is low and follows the order TlF < TlCl < TlBr < TlI, where for the series of halides, $K_1 = -$, 0.8, 2.1, 5.0 and $K_2 = -$, 0.2, 0.7, 1.5 respectively.[1] The fluoride ion F^- is preferred to perchlorate as a 'noncomplexing' counterion. Claims have been made for $TlX_n^{\,1-n}$ species with $n = 3$ and 4; however, the formation of complexes in aqueous solution with $n > 2$ seems unlikely.

The covalent trihalides of thallium(III) are less stable than the trihalides of the lighter metals of group 13. Aqueous solutions of these compounds are acidic because of their extensive hydrolysis. The compound $TlCl_3$ is an important starting material for the preparation of Tl^{III} organometallic compounds.

The white compound TlF_3 has been prepared by the direct fluorination of Tl_2O_3 with F_2, BrF_3, or SF_4 at 300 °C. TlF_3 decomposes at 500 °C before melting, it does not form hydrates, and it hydrolyzes in water; no complexes of type Tl^{III}–F^- have been detected. The solids $MTlF_4$, where M = Li or Na, are true double salts. The complexes M_3TlF_6 (M = Na, K, Rb, Cs) have been prepared by fluorination of a mixture of $TlCl_3$ and the appropriate alkali chloride. These compounds contain discrete octahedral TlF_6^{3-} anions.[21]

Concentrated solutions of $TlCl_3$ and $TlBr_3$ can easily be prepared by oxidation of Tl^I halides with the appropriate halogen.[29] $TlCl_3{\cdot}4H_2O$ (mp = ca. 43 °C) and $TlBr_3{\cdot}4H_2O$ (decomposes at ca. 30 °C) may be crystallized from aqueous solutions; attempts at thermal dehydration lead to the formation of TlCl or TlBr. However, $SOCl_2$ may be used to dehydrate these compounds giving, for example, anhydrous $TlCl_3$ (mp = 115 °C). Solutions of anhydrous $TlCl_3$ or $TlBr_3$ in MeCN can be prepared by simply treating the solution of the monohalide with Cl_2 or Br_2. Solid $TlCl_3$ can be prepared as shown in equation (3):[17]

$$\text{Tl or TlCl or Tl}_2\text{CO}_3 \xrightarrow{\text{NOCl}} \text{TlCl}_3{\cdot}\text{NOCl} \xrightarrow{\text{heat}} \text{TlCl}_3 \qquad (3)$$

$TlCl_3$ is very hygroscopic and is soluble in water, acetonitrile, ether, and alcohols. In addition to $TlCl_3$, $TlCl_2^+$ and $TlCl_4^-$ species may coexist in solution. However, $TlCl_3$ reacts with ketones, yielding α-chloro ketones.[30]

As is to be expected from the 'soft' character of Tl^{III}, strong chloride and bromide complexes of type TlX_n^{3-n} are formed in solution, where n is less than or equal to 4. These species are more stable in aqueous solution than the analogous Al^{III}, Ga^{III}, and In^{III} halides. Some of these halides have been thoroughly characterized both in the solid state and in solution by means of X-ray crystallography, solution X-ray diffraction, and NMR. These complexes are among the most stable metal–halide complexes known, particular stability having been claimed for the TlX_2^+ complexes with chloride (see e.g. the overall stability constants, $\beta_n = 10^{7.16}$; $10^{12.60}$; $10^{16.15}$; $10^{18.32}$; and $\sim 10^{18.02}$; $n = 1$–5, respectively for X = Cl in 3 M $HClO_4$) and bromide ligands.[1,7] In addition, the formation of weaker species with $n > 4$ has been demonstrated.[31] In a detailed study of ligand exchange reactions between Tl^{III}–X^- complexes, where X = Cl, Br, and CN, the authors claim a preference for a bimolecular reaction between the lower complexes, as opposed to a direct reaction between the complexes and the free halide, which is present only at very low concentrations. The direct path becomes dominant only for the higher complexes.[32]

There is a systematic change in the coordination geometry of the Tl^{III} complexes TlX_n^{3-n} (X = Cl, Br). The $Tl(H_2O)_6^{3+}$ cation has a regular octahedral geometry, which appears to be retained in the first and second complexes, $TlX(H_2O)_5^{2+}$ and $TlX_2(H_2O)_4^+$, the TlX_2^+ unit being linear in aqueous solution. The solids $TlCl_3{\cdot}4H_2O$ and $TlBr_3{\cdot}4H_2O$ are isomorphous, having a trigonal bipyramidal coordination around Tl^{III}. X-ray diffraction studies indicate that the three halide ligands are coordinated in a trigonal arrangement with two water molecules completing the coordination sphere. In aqueous solution, the geometry is essentially the same for $TlBr_3(H_2O)_2$, but for the chloride complex the coordination is probably a distorted tetrahedral.[7,33] In the TlX_4^- complexes where X = Cl, Br, or I, the coordination sphere is tetrahedral with no water molecules in the inner sphere, either in solution or in the solid phase.[34] The complexes $TlX_5(H_2O)^{2-}$ (X = Cl, Br) occur in the crystal structures of $K_3TlCl_6{\cdot}\frac{13}{7}H_2O$ and $Rb_3TlBr_6{\cdot}\frac{13}{7}H_2O$ and also in solution for X = Cl; a distorted octahedral geometry has been found in the solids. The complexes of type TlX_6^{3-}, where X = Cl or Br, have a distorted octahedral geometry in the solid state. Numerous alkali, tetraalkyl, and arsonium salts of the tetra-, penta-, and hexahalides of thallium(III) have been prepared. $Cs_3Tl_2Cl_9$ is an example of an important structural type having the confacial bioctahedral structure.[3,21,28]

Our knowledge of the Tl^{III}–iodide complexes is relatively limited because redox reactions occur in solution. However, in the presence of a large excess of iodide, the redox reactions are avoided and a stable TlI_4^- complex has been observed; β_4 = ca. 5×10^{35}. Derivatives of TlI_4^- with different cations have been prepared. The anion is clearly tetrahedral in the tetrabutylammonium salt[35] and probably also has the same structure in the other crystals.

Treatment of TlF with I_2, BrCl, ICl, or IBr yields $TlFI_2$, TlFClBr, TlFClI, and TlFBrI, respectively. These products may represent an intermediate between Tl^{III} compounds and molecular adducts of Tl^I.

No mixed Tl^I–Tl^{III} fluorides have been reported. The oxidation of TlCl and TlBr by halogens results, however, in a series of mixed-valence halides. Earlier these compounds were thought to be Tl^{II} salts, but neither magnetic susceptibility measurements nor crystal-structure determinations proved this hypothesis. For example, TlX_2 and Tl_4X_6 (X = Cl or Br) should be correctly formulated as Tl^+ $[TlX_4]^-$ and $(Tl^+)_3[TlX_6]^{3-}$. The mixed Tl^I–Tl^{III}–iodide Tl_3I_4 can be formulated with formulae $(Tl^+)_5[TlI_8]$, but another model involving $(Tl^+)_6I_5(I_3)$ with the triiodide ion cannot be ruled out.[1]

The black crystalline TlI_3 has been known since 1864 and is an intriguing compound. It is obtained by evaporating an equimolar solution of TlI and I_2 in concentrated HI. TlI_3 is isomorphous with CsI_3, and must therefore exist as $Tl^+I_3^-$ in the solid state. However, the absorption spectra of solutions of the compound in methanol do not indicate the presence of the I_3^- ion; indeed, the spectra are similar to those of $KTlI_4$, thus suggesting a tandem redox and complex formation equilibrium (equation 4):

$$4\text{TlI}_3 \rightleftharpoons \text{Tl[TlI}_4]_3 \qquad (4)$$

Solutions of TlI_3 yield Tl_2O_3 when shaken with sodium carbonate.[1] In order to understand these fairly complicated redox reactions in the chemistry of TlI_3, it is important to remember how the formal redox potentials vary with the experimental conditions such as solvent, pH, solubility, and complex formation (see Section 2).

The thallium(III) halides, TlX_3 (X = Cl, Br, I), form complexes with amines (L) with formulas $TlX_3{\cdot}L_n$, where $n = 1$–3. Among the most studied complexes with this ligand stoichiometry are the neutral monomeric species $TlX_3{\cdot}L_2$, where X = Cl or Br, the halide-bridged dimers

$L_2X_2TlX_2TlX_2L_2$, ionic monomers $[TlX_2L_2]X$, and dimer complexes of type $[TlX_2L_4][TlX_4]$.[3] Recently, $TlClBrI{\cdot}L_2$ complexes have also been prepared.

Our knowledge about the Lewis acid behavior of Tl^{III}-halides is scarce. A recent theoretical study claims that the π-donor ability of the halogens (X) increases with $F < Cl < Br < I$ both in TlX_3 and BX_3, and the $p(\pi)$ population at the central atom in TlX_3 is smaller than that is in BX_3. However, the hydride affinity of TlX_3 relative to TlH_3 is substantially higher compared to the hydride affinity of BX_3 relative to BH_3.[27]

3.2.2 Pseudohalides and Pseudohalide Complexes

Thallium(I) forms salts with cyanide (CN^-), cyanamide (NCN^{2-}), azide (N_3^-), cyanate (OCN^-), isocyanate (CNO^-), thiocyanate (SCN^-), and selenocyanate ($SeCN^-$); however, complexes with these ligands, like the Tl^I-halide complexes, are very weak. In contrast, the neutral $Tl^{III}X_3$ species are not well known, although the Tl^{III}-pseudohalide complexes are more or less stable.

Tl^I pseudohalides can be prepared from aqueous solutions of soluble Tl^I salts, usually the sulfate or nitrate, by adding the appropriate anion, thus precipitating the sparingly soluble Tl^I pseudohalide compounds. Thallium(I) azide has been prepared from Tl^I acetate, TlOAc, with NaN_3 in ethanol. TlN_3 is isomorphous with NaN_3 and RbN_3, but its physical properties suggest a somewhat more covalent Tl–N bond in the solid. The azide decomposes slowly at temperatures near the melting point (374 °C) and the liquid is explosive. Tl^I isocyanate, TlCNO, also explodes on heating to 105 °C.[3,21] K_1 has been determined as about 2.5 for TlN_3, but no cyano complexes of Tl^I, unlike Ag^+, have been detected. Weak complexes ($K_1 = 1.7$, $K_2 = 0.6$)[36] have been reported in the Tl^I–SCN^- system at high concentrations of the anion.

Tl^{III} azide complexes have been observed in solution, though the species are not well characterized. The solid complexes $[Ph_4As][Tl(N_3)_4Cl_2]$[1] and $H_3[Tl(N_3)_6]$ have been isolated, the latter being an explosive yellow compound.

The existence of Tl^{III} cyanide complexes has been mentioned previously; however, on the basis of the analogy with other Tl^{III}–pseudohalide redox reactions, and by analysis of the redox potentials, the existence of the $Tl(CN)_n^{3-n}$ complexes was not widely accepted for a time. However, a detailed investigation of this system using ^{205}Tl and ^{13}C NMR spectroscopy has indicated that Tl^{III} indeed forms very stable cyanide complexes (the overall formation constants, $\beta_n = 10^{13.2}$, $10^{26.5}$, $10^{35.2}$ and $10^{42.6}$ in 4 M ionic strength for $n = 1$, 2, 3 and 4 respectively).[37] These species are in fact the most stable complexes of Tl^{III} formed with monodentate ligands. The extra stability of the $Tl(CN)_2^+$ species is worth mentioning. It is certainly not a coincidence that the diorganothallium(III) compounds containing the linear C–Tl–C group (like doing the (N)C–Tl–C(N)) are also very stable. A number of mixed cyanide-halide complexes exist in aqueous solution.[7]

The lack of success encountered by attempts to prepare Tl^{III} pseudohalides might be related to the redox reaction between Tl^{III} and reducing ligands, as in the Tl^{III}–I^- system. In the case of the Tl^{III}–SCN^- system, the reaction stoichiometry appears to be as shown in equation (5):

$$4SCN^- + 3Tl^{3+} + 4H_2O \longrightarrow 3TlSCN + HCN + SO_4^{2-} + 7H^+ \quad (5)$$

Recently, a quite stable $Tl(SCN)^{2+}$ complex was characterized by ^{205}Tl NMR, and may be the predominant intermediate in the course of the above redox reaction.[38] Stable complexes of $Tl(SCN)_3$ with 2,2′-bipyridyl and 1,10-phenanthroline have been prepared in the solid form.[1]

Mixed-valence Tl^I–Tl^{III} pseudohalides, such as $Tl(CN)_2$ and $Tl(N_3)_2$, were first prepared more than 100 years ago. Like the analogous halides, these compounds do not contain Tl^{II}, but instead can be formulated as $Tl[Tl(CN)_4]$ and $Tl[Tl(N_3)_4]$, respectively. The former compound can be isolated from both organic and aqueous solutions. As is expected, the Tl(III) is tetrahedrally coordinated.[39] The redox stability of the TlX_4^- complex might be explained in a similar manner to that of TlI_4^-.

3.3 Oxides

3.3.1 Thallium(I) and Thallium(III) Oxides and Hydroxides

The two well-defined oxides of thallium are Tl_2O and Tl_2O_3. In addition, there are some poorly defined oxides such as the Tl^IO_2 (violet), a mixed oxide Tl_4O_3 or $Tl_2O{\cdot}Tl_2O_3$ (black), and some nonstoichiometric oxides with formulas $TlO_{1.5}$–$TlO_{1.75}$.

Black platelets of thallium(I) oxide are formed when thallium is oxidized in air at moderate temperatures, or from TlOH or Tl_2CO_3 by heating to 100 or 700 °C, respectively, in the absence of air. Tl_2O melts at 596 °C, indicating that the solid has an ionic nature; however, it is also rather volatile and very hygroscopic, forming the yellow solid TlOH on contact with water. Solutions of TlOH are basic, its dissociation constant is about $10^{-0.3}$ at 25 °C, and its basic strength is about 10^5 times greater than that of NH_3 and 10 times greater than for $Ca(OH)_2$.[36] Chemical shift of the ^{205}Tl NMR signal, affected by the equilibrium $Tl^+ + OH^- \rightleftharpoons TlOH$, can be used to monitor the alkalinity of concentrated aluminate solutions.[40] Tl_2O dissolves in ethanol to form TlOEt.

The brown–black thallium(III) oxide can be synthesized from elemental thallium by heating it to dull redness in the presence of oxygen, but is more conveniently prepared from Tl^I salts in alkaline solution by adding hydrogen peroxide or Cl_2. Tl_2O_3 is easily precipitated and can be dried at 500 °C. It is insoluble in water but can be dissolved in acids, giving the corresponding Tl^{III} salts (see Section 3.6). The oxide has

a remarkably low electrical resistance at room temperature (about $7 \times 10^{-5} \Omega$ cm).[28] At elevated temperatures, Tl_2O_3 vaporizes and decomposes to Tl_2O and O_2.

The appearance of the brown color of Tl_2O_3 at higher pH is very common in solutions containing inorganic Tl^{III} species. Stepwise replacement of the L ligands in $Tl^{III}L_x$ may result in mixed hydroxo complexes, such as oxohalides. Previously the aqua ion, $[Tl(H_2O)_6]^{3+}$, has been claimed to have a distorted octahedral structure in which two of the water molecules are more strongly bound than the others. However, structural investigations, both in solution and in the solid state by X-ray diffraction, indicate a regular octahedral geometry for this cation.[41] The aqua ligands of the hexaaquathallium(III) ion are quite labile; the pseudo first-order rate constant for the exchange of water ligands has been estimated to 5×10^7 s^{-1}.[32] The $Tl^{III} \cdot$ aq ion is very acidic, the acid constants $K_{a,1}$ and $K_{a,2}$ having values of $10^{-0.5}$ and $10^{-1.2}$ in 1 mol dm^{-3} $NaClO_4$, respectively.[36] In other words, $Tl(OH)^{2+}$ and $Tl(OH)_2{}^+$ are among some of the most stable metal–hydroxo species. On the other hand, in contrast to Al^{III}, Ga^{III}, and In^{III}, no polynuclear species of type $M_x(OH)_y{}^{(+3x-y)}$ have been characterized for Tl^{III}. Even the formation of $Tl(OH)_3$ and its hydrates is not clearly proven.

3.3.2 *Ternary and More Complex Oxides*

Extensive studies of these compounds are in progress as a result of their potential applications in solid-state electronics. The electrical and magnetic properties of these compounds show a particular sensitivity to their composition and even to the often 'secret' methods used for their preparation. Selected topics will be briefly discussed here (*see also* ***Oxides: Solid-state Chemistry***).

In spite of the nonamphoteric character of thallium(I), the Tl–alkali metal oxides are often called oxythallates.[1] Red crystals, KTl^IO, and $RbTl^IO$ have been prepared by heating Tl_2O and an alkali oxide. Oxythallate(III) derivatives, $MTlO_2$ (formally metathallates), can be prepared in the same way as those of the alkali metals. The majority of these compounds have the α-$NaFeO_2$ structure: M^+ and Tl^{3+} cations lie in alternate layers in the octahedral interstices of the oxygen array. The solid-state electrolyte Tl^I β-alumina, $TlAl_{11}O_{17}$, can be prepared from sodium β-alumina by heating with a molten Tl^I salt (*see* ***Aluminum: Inorganic Chemistry***). The Tl^I based ferrites (*see Ferrite*) have the idealized formula $TlFe_{11}O_{17}$ and are structurally closely related to ionic conductors.[42]

The recently discovered thallium-based high-temperature superconductors[13,14] received extraordinary attention because their transition temperature is above that of liquid nitrogen, 100–120 K, and these materials seem to be both stable in air and resistant to moisture. Different thallium cuprates are prepared by melting (920–950 °C) appropriate amounts of mixed powders of Tl_2O_3, BaO/SrO, CaO, and CuO.[43] The oxides have the idealized formulas $TlA_2Ca_{m-1}Cu_mO_{2m+3}$ (A = Sr, Ba) and $Tl_2Ba_2Ca_{m-1}Cu_mO_{2m+4}$. No deviation from the ideal oxygen stoichiometry, 'O_{2m+3}' and 'O_{2m+4}', has been found, and the mixed oxidation state of Cu can be explained by the thallium deficiency in the lattice. The oxidation state of Cu and Tl in these materials has been investigated since this might be important for the superconducting properties: Cu^{II} and Cu^{III} have been proposed from X-ray absorption measurements, whilst Tl^{III} is clearly dominant. Both X-ray and ^{205}Tl NMR results show the existence of some Tl^I,[44] but the 'issue of the competition between the systems Tl^I–Tl^{III} and Cu^{II}–Cu^{III} still remains open'.[45]

3.4 Chalcogenides

Chalcogenides of Tl, like those of Ga and In, are numerous and have been extensively studied since many of them are ***Semiconductors*** (*see* ***Semiconductor Interfaces***), semimetals (*see Semimetal*), photoconductors (*see Photoconductivity*), or light emitters. The compounds are covalent, and the formal oxidation states can be determined by checking the overall charge balance. However, this is somewhat arbitrary in such systems: Tl has two stable oxidation states and sulfur, especially, has a great propensity for *Catenation*. Existence of Tl^{III} sesquichalcogenides, Tl_2X_3, has been tentatively proposed; Tl^{III} may be reduced to Tl^I by chalcogenides. Well-characterized compounds include, for example, the black Tl_2S (distorted CdI_2 layer lattice), Tl_4S_3 ($Tl^I{}_3[Tl^{III}S_3]$), the black TlS ($Tl^I[Tl^{III}S_2]$), TlS_2, the red and black forms of Tl_2S_5 and Tl_2S_9 (Tl^I polysulfides), Tl_5X_3, TlX, and Tl_2X_3, where X = Se, Te.[28]

A large number of mixed chalcogenides and ternary or more complex thallium–chalcogenide complexes have been prepared and characterized (*see* ***Chalcogenides: Solid-state Chemistry***).

3.5 Thallium Salts with Oxoanions

Both Tl^I and Tl^{III} form salts with many oxoanions. Thallium(I) salts have no direct uses, except perhaps as starting materials for other reactions. Thallium(III) salts, however, especially thallium(III) nitrate, have been widely used in modern organic synthesis.

The following list gives some standard methods[1,3,29] for the preparation of Tl^I salts (examples shown in brackets):

1. dissolution of thallium metal in acid (Tl_2SO_4, $TlNO_3$)
2. neutralization of TlOH or Tl_2CO_3 with acid ($TlNO_3$, TlOAc, $TlClO_4$)
3. metathesis of Tl_2SO_4 with a barium salt ($TlNO_2$, $TlClO_3$, $TlBrO_3$, $TlIO_3$)
4. treatment of $TlNO_3$ with a nonvolatile acid ($TlClO_3$, Tl_3PO_4)
5. direct precipitation from aqueous solution ($TlIO_3$, Tl_2CrO_4).

Since TlOH and Tl_2CO_3 are commercially available, method 2 is a universal method for almost all salts. Thallium(I)

salts of carbonic acids can be prepared in nonaqueous solvents (ethanol or ether) by the reaction of Tl^IOEt with the appropriate acid.

Some weak interactions of Tl^I with certain oxoanions have been claimed and the following stability constants (K_1) measured: $TlCO_3^-$, 3.2; TlOAc, 0.8; $TlNO_3$, 0.3–0.7; $TlSO_4^-$, 0.3; $TlClO_4$, 0.3.[1]

Oxidation of Tl^I salts by bromine may yield stable mixed Tl^I-Tl^{III} or Tl^{III} salts. $Tl_2Br_2SO_4$ has been prepared from Tl_2SO_4; it can be formulated as $Tl^I[Tl^{III}Br_2SO_4]$. The reaction of bromine with TlOAc gave $Tl(OAc)Br_2$.[1]

The preparation of Tl^{III} salts, including the nitrate, sulfate, phosphate, halogenates, acetate, and trifluoroacetate is based on the dissolution of Tl_2O_3 in the appropriate acid. Thallium(III) phosphate has also been prepared from $Tl(NO_3)_3$ by treatment with H_3PO_4. Solution of $Tl(ClO_4)_3$ can be prepared by the anodic oxidation of $TlClO_4$ in perchloric acid or by the reaction of $TlCl_3$ with $AgClO_4$.[7] Thallium(III) carboxylates are generated by the simple metathesis of $Tl(OAc)_3$ and a carboxylic acid.

Complexes of Tl^{III} with the oxoanions are much more stable than those of Tl^I. The coordination of perchlorate to Tl^{III} cannot be ruled out; however, ClO_4^- is considered to be the best noncoordinating counter anion for equilibrium studies. Related stability constant values (K_1) are: $Tl(NO_3)^{2+}$, $10^{0.9}$; $TlSO_4^+$, $10^{1.95}$; $TlHSO_4^{2+}$, $10^{1.2}$; $Tl(OAc)^{2+}$, $10^{6.2}$. The overall stability constant $\beta_3 = 10^{15.1}$ for $Tl(OAc)_3$. Some mixed hydroxo complexes have also been detected, including $Tl(OH)_2NO_3$ and $Tl(OH)(OAc)^+$. Numerous complexes have also been isolated in the solid state, such as $MTl(SO_4)_2$ (M = Li–Cs, NH_4), $K_2Tl(NO_3)_5 \cdot H_2O$, and $[NO]^+ [Tl(NO_3)_4]^-$; the last-named is produced by oxidizing $TlNO_3$ with N_2O_5. It is interesting that in the $Tl^{III}A_3 \cdot L_n$ complexes ($n = 2$, 3; L = bidentate N-donor ligands like 2,2′-bipyridyl or 1,10-phenanthroline), mentioned in Section 3.2.2 for A = SCN^-, A can also be NO_3^- or ClO_4^-, and the oxoanions might behave as inner-sphere ligands in the complexes.[3,21]

$Tl(OAc)_3$ is a strong Lewis acid and an effective Friedel–Crafts catalyst. The complex has been used in organic synthesis as the electrophilic agent for oxythallation reactions (*see* ***Thallium: Organometallic Chemistry***). In fact, $Tl(OAc)_3$ is only a weak electrophile, having mild oxidizing properties, because it is a stable complex. By contrast, thallium(III) nitrate (TTN) is highly ionic and thus a good electrophile. $Tl(NO_3)_3 \cdot 3H_2O$ now has a dominant role in oxythallation reactions.[46] It is soluble in a wide range of solvents, both organic and inorganic, and can be used as a solid supported catalyst. The water of crystallization cannot be removed by heating in vacuum or by treating with $SOCl_2$; indeed, Tl^I salts are formed. Dehydration has been achieved using methyl orthoformate[46] (equation 6):

$$Tl(NO_3)_3 \cdot 3H_2O + 3HC(OMe)_3 \longrightarrow Tl(NO_3)_3 + 6MeOH + 3HCO_2Me \quad (6)$$

3.6 Complexes with Multidentate Organic Ligands

Thallium(I) acts as a weak Lewis acid and behaves similarly to the alkali metal ions, forming only weak complexes even with complexones such as edta and its analogs. The Macrocyclic Ligands (L), (*see* ***Macrocyclic Ligands***) and in particular the *Crown Ethers* containing 18-membered rings, such as 18-crown-6, do however form strong complexes. As is the case for other M^+ cations, the size of the macrocyclic cavity is critical for the formation of stable complexes. Unsymmetric benzo-type crown ethers possess high thallium(I) selectivity especially against potassium and rubidium ions.[47] Thallium can be immobilized as a thallium-rich mixed-valence solid, $[\{Tl(18\text{-crown-}6)Z\}_4CuCl_4][TlCl_4]_2 \cdot nH_2O$.[48] In addition to the Tl^ILX compounds, Tl^IL_2X sandwich complexes (*see Sandwich Compound*) are also known.[21]

Our knowledge of Tl^{III}–organic ligand systems is rather limited. Two important 'side reactions' must be mentioned: first, that $Tl(H_2O)_6{}^{3+}$ is easily hydrolyzed, leading to Tl_2O_3 even at pH = 2–3, and, secondly, that it is a strong oxidant. Both these effects prevent the formation and study of many such complexes. On the other hand, the interaction of Tl^{III} with multidentate ligands can stabilize the cation against both hydrolysis and reduction. These effects are exemplified by the $[Tl^{III}(edta)]^-$ complex, which is one of the most stable metal–edta species known ($K = 10^{37.8}$); only $[Co^{III}(edta)]^-$ is more stable.[49] The Tl^{III}–edta complex is stable up to pH = 12; $Tl(edta)(OH)^{2-}$ is formed in alkaline solutions. The structure of the Tl^{III}–edta complex in the solid phase is not known, but it could well be seven coordinate with one water molecule in the inner sphere since it readily forms $Tl(edta)X^{2-}$ mixed complexes with unidentate ligands, halides, and pseudohalides (including S-bonded SCN^-) without reduction of Tl^{III}. In solid $Na_2Tl(edta)CN \cdot 3H_2O$, the thallium(III) ion is hemispherically surrounded by the hexadentate edta, and there is also one strongly bound CN^- in the inner coordination sphere.[50]

However, the coordination number of thallium(III) is found to be eight in the bis(nitrilotriacetato) complex, $[Tl^{III}(nta)_2]^{3-}$ in solid by X-ray.[51] Stepwise formation of three $[Tl(en)_n]^{3+}$ complexes (en = ethylenediamine, $n = 1-3$) has been established by ^{205}Tl and ^1H NMR in a pyridine solvent. The $Tl^{III}$is octahedrally coordinated in the $[Tl(en)_3](ClO_4)_3$ solid.[52]

Porphyrin derivatives of Tl^{III} have been prepared; the metal ion lies 0.9 Å above the N_4 plane, with an anion coordinated as the fifth ligand.[21] A $Tl^{III}L_2$ species is formed with 1,4,7-triazacyclononane; two tridentate ligands are coordinated to a Tl^{III} ion in a distorted octahedron. It is an inert species with no additional labile coordination sites, and can therefore only be reduced via an outer-sphere electron-transfer process.[53] Crown ether complexes are known only for R_2Tl salts.[21]

3.7 Metal-metal bonded Tl-complexes

Recently the metallophilic interaction between heavy elements[54] has earned considerable interest (*see* ***Polynuclear***

Organometallic Cluster Complexes), and seems to be the most active research field of thallium coordination chemistry.

Although Tl(I) is often used as a large size counter cation in order to crystallize anionic metal complexes, its role might be more sophisticated as exemplified in the $Tl_2Pt(CN)_4$. This solid compound does not show the usual Pt–Pt 'linked' columnar structure of other $M_2Pt(CN)_4$ salts, but involves two Pt–Tl bonds with a weakly covalent character. The strong luminescence of the compound attributed to these bonds is not retained in solution.[55,56] On the contrary, the ligand supported metal–metal bond in the complex $[Tl^{I}(crown\text{-}P_2)Pt^{II}(CN)_2]NO_3$ ($P = -CH_2PPh_2$) is intact in solution.[57]

Recently, the formation,[58] structure,[59–61] equilibrium,[62] and kinetics[63] of a family of cyano compounds containing a direct and not supported by ligands platinum–thallium metal–metal bond have been reported. The complexes are synthesized according to the reaction:

$$mPt(CN)_4{}^{2-} + Tl^{3+} + nCN^- \rightleftharpoons [Pt_mTl(CN)_{4+n}]^{(n-1)-} \qquad (7)$$

Four binuclear species represented by a general formula $[(NC)_5Pt{-}Tl(CN)_{n-1}]^{(n-1)-}$ ($n = 1$–4) and a trinuclear complex $[(NC)_5Pt{-}Tl{-}Pt(CN)_5]^{3-}$ are formed in aqueous solution. The complexes exist in an equilibrium, which also includes the parent complexes $Pt(CN)_4{}^{2-}$ and $Tl(CN)_n{}^{3-n}$ ($n = 0$–4), and can be controlled by varying the cyanide concentration and/or pH of the solution.

Multinuclear NMR- (^{13}C, ^{195}Pt, ^{205}Tl), IR-, Raman-spectroscopy, Electron Spectroscopy for Chemical Analysis (ESCA), X-ray, and Extended X-ray Absorption Fine Structure (EXAFS) studies confirm direct, short (2.60–2.64 Å) Pt–Tl bonds. Figure 1. shows a typical ^{205}Tl NMR spectrum of $[(N^{13}C)_5Pt{-}Tl(^{13}CN)]^-$ together with the structure determined by EXAFS. The spin-spin coupling pattern is consistent with 4 + 1 + 1 equivalent $^{13}CN^-$ ligands ($I = 1/2$), respectively and one ^{195}Pt nucleus (natural abundance 33.8%, $I = 1/2$). The spectrum has been selected to illustrate the usefulness of Tl NMR spectroscopy in studies of the inorganic chemistry of thallium. The compounds are diamagnetic, and

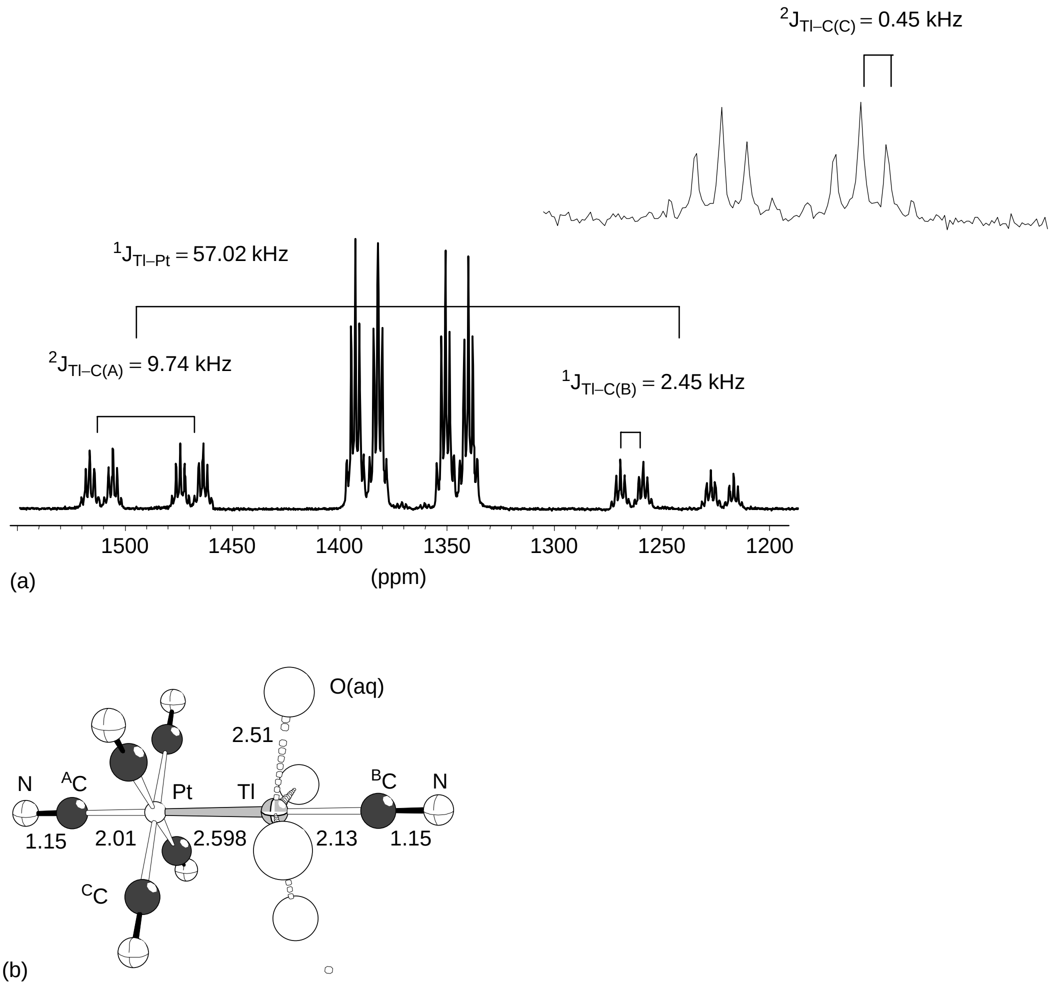

Figure 1 (a) 230.8 MHz ^{205}Tl NMR spectrum of the $[(^{A}CN)(^{C}CN)_4Pt{-}Tl(^{B}CN)]^-$-complex showing the spin-spin coupling schemes. The sample consists of 50 mM Tl^{3+}, 50 mM $Pt(^{13}CN)_4{}^{2-}$ and 150 mM $Na^{13}CN$, pH = 1.04. (b) Structural model based on Pt and Tl L_{III} EXAFS data

the electronic states and the nature of the Pt–Tl bonds have been elucidated by Density Function Theory (DFT) calculation.[64]

Selected crystal structures that contain platinum–thallium bonds can be divided into four groups depending on the formal oxidation states of the metal ions: Pt^{0}–Tl^{I} (2.86–3.05 Å),[65–67] Pt^{II}–Tl^{I} (2.88–3.15 Å),[54,57,68–73] Pt^{II}–Tl^{II} (2.70–2.71 Å),[18] and Pt^{II}–Tl^{III} (2.570–2.628 Å).[59–61,73]

4 TOXICITY[16]

The toxic effects of thallium are attributed to its ability to interfere with potassium-dependent biological reactions in a range of life forms extending from humans to plants and microorganisms.

The lethal dose of thallium is in the range of 10–50 mg kg^{-1}. In humans, 600 mg is often fatal. It should be noted that this dose is much larger than the lethal dose of many synthetic or naturally occurring organic poisons! The route of exposure and the chemical form seem to be insignificant for thallium's toxicity. Thallium is a cumulative poison that may be absorbed through the skin. Evidence of poisoning appears in 1–5 days. Acute thallium intoxication causes death by respiratory failure, preceded by paresthesia of the extremities, hypersecretion, loss of hair, uncontrolled muscle movements, convulsions, delirium, and coma. The most effective known antidote is colloidal Prussian Blue, $KFe^{III}[Fe^{II}(CN)_6]\cdot nH_2O$. Prussian Blue (prepared from $K_4[Fe^{II}(CN)_6]$) acts as an ion exchanger for Tl^{+} in the intestines and accelerates the fecal elimination of Tl; 250 mg kg^{-1} body mass is administered daily. The use of activated charcoal or KCl as an antidote is recommended if Prussian Blue is not available.

5 ANALYTICAL CHEMISTRY OF THALLIUM

The qualitative detection of thallium is easily achieved by emission spectroscopy, thallium giving a green flame color. Thallium(I) iodide is a yellow precipitate that is insoluble in water, nonoxidizing acids, ammonia, and potassium cyanide, but that can be dissolved in sodium thiosulfate. Traces of thallium can be detected by dyes such as Brilliant Blue or Rhodamine B. Tl^{I} (or Tl^{III} after reduction by SO_2) can be determined by BrO_3^{-} or IO_3^{-} titrant. A gravimetric method uses Tl^{I} chromate.[3]

Instrumental analytical methods for thallium have been recently reviewed.[74] The low-detection limits of some methods allow the direct determination of thallium in environmental or biological samples, but preconcentration procedures may be necessary in order to achieve sufficient accuracy. A detection limit of 0.1 ppb (0.1 μg dm^{-3}) has been reported for electrothermal atomic absorption spectroscopy (ET-AAS) and for neutron activation analysis. Analytical methods including pulse voltammetry, isotope dilution and field desorption mass spectroscopy, X-ray fluorescence analysis, and some flame and plasma emission spectroscopic methods have been mentioned in a recent paper related to the environmental aspects of thallium chemistry.[10] Some photometric methods exist, though the detection limits are usually much higher than those of more sophisticated instrumental methods.

1 INTRODUCTION

Although organothallium compounds were synthesized as early as 1870, only nine years after the discovery of the element thallium, for a long time organothallium chemistry received little attention compared to many other areas of organometallic chemistry. However, as the result of a discovery made in the late 1960s that certain thallium derivatives are remarkably efficient reagents or intermediates in organic syntheses, chemists have found an increasing interest in the organometallic chemistry of thallium. This interest has been stimulated further in recent years due to the discovery that certain thallium-containing superconducting metal oxides (SMO) possess among the highest critical temperatures identified so far (*see* ***Superconductivity***).

Organothallium compounds are now known in oxidation states +1, +2 (silyl ligands), and +3. Several review articles dealing with the organometallic chemistry of thallium are available.[1–8] This article is essentially limited to organothallium compounds that contain at least one Tl–C bond.

2 THALLIUM(I) COMPOUNDS

The calculated bond dissociation energy for Tl–C in the unknown MeTl is 59 kJ mol^{-1}, suggesting only limited stability for alkylthalliums (*see* ***Bonding Energetics of Organometallic Compounds***).[9] Known organothallium(I) compounds are almost strictly limited to π bonded species such as cyclopentadienylthallium, CpTl. The most likely reason for the dearth of RTl compounds stems from the combination of weak bonding and unsaturation. In fact, even the members of the Cp′Tl series show effects of coordinative unsaturation, as indicated by polymerization and Tl···Tl interactions commonly observed in the solid state (see Section 2.1.1). The low-valent organometallic chemistry of thallium has been reviewed.[6]

2.1 Cyclopentadienylthallium(I) Complexes

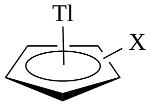
2.1.1 Preparation and Properties

Cyclopentadienylthallium (**1**, X = H) first was described by Meister in 1957.[10] It can conveniently be prepared by the reaction of cyclopentadiene with thallium(I) salts in the presence of sodium hydroxide in aqueous solution (equation 1). Since this initial synthesis, a wide variety of Cp′Tl compounds have been prepared, largely for the purpose of acting as cyclopentadienide transfer reagents in transition metal organometallic chemistry (see Section *Reactions of Cyclopentadienylthallium with Transition Metal Compounds*). The range of ring-substituted Cp′Tl compounds known and the methods used to make them have been reviewed.[6,11] Although transmetallation reactions (equation 2) are often successful, the preferred preparation method is usually the acid–base reaction (equation 3), which sidesteps the need for premetallation and produces no salt by-products.

$$C_5H_6 + TlX \xrightarrow[-NaX]{NaOH/H_2O} C_5H_5Tl \qquad (1)$$

$$Cp'Li + TlX \xrightarrow{-LiX} Cp'Tl \qquad (2)$$

$$Cp'H + TlOEt \xrightarrow{-EtOH} Cp'Tl \qquad (3)$$



(**1**)

Neutral Cp′Tl species are usually polymeric in the solid state, showing a zigzag chain of alternating Tl(I) centers and bridging Cp′ units (e.g. see **2**, below).[6] However, several Cp′Tl monomers[12,13] and dimers[14,15] have been identified using X-ray diffraction (*see* ***Diffraction Methods in Inorganic Chemistry***). The compound 1,3-$(SiMe_3)_2C_5H_3Tl$[16] is a Cp′-bridged

Table 1 Thallium(I) cyclopentadienide compounds characterized by X-ray diffraction

Compound	Tl–Cp[a] (pm)	Cp–Tl–Cp (°)

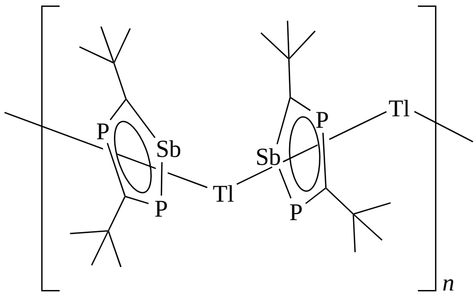
$[Cp_2Tl_3]^+$ $[CpMo(CO)_3]^-$[19]	258, 281, 285, 262, (320)[e]	114.9[b]

[a]Cp = cyclopentadienide centroid. [b]Tl···Tl···Tl. [c]Average value from different molecules in the asymmetric unit. [d]Two crystal modifications known. [e]Distance to Cp associated with anion unit. [f]pmdeta = pentamethyldiethylenetriamine.

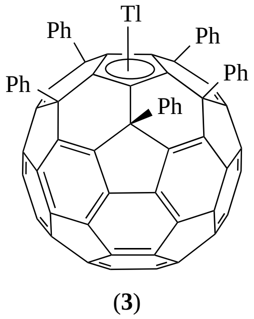
hexamer. Also known are Cp-bridged ionic species, for example, Cp_2Tl^-, $Cp_3Tl_2{}^-$, and $Cp_2Tl_3{}^+$.[17–19] A list of structurally characterized Cp′Tl compounds is provided in Table 1.

Several oligomeric Cp′Tl species reveal weak metal–metal interactions, with Tl···Tl distances 363–400 pm.[14–16] Similar Tl···Tl interactions can be seen between chains in CpTl itself.[20,21] Theoretical calculations show that such short metal–metal contacts are on the borderline for weak bonding.[32–34] Homometallic interactions are expected to be weaker for thallium than for the other group 13 metals due to spin-orbit coupling and inert pair effects.[9,35]

The heteroatom cyclopentadienyl analog 1,4,2-$P_2SbC_2Bu^t{}_2$ has been coordinated to Tl(I) via equation (2), producing zigzag polymer (**2**).[29] Thallium coordination has played an important role in crystallographic characterization of metal–fullerene complexes, providing the first structurally characterized pentahapto metal complexes of C_{60} (**3**) and C_{70} (**4**).[30,36] The key to the formation of these monothallium(I) compounds was the arylation of the fullerenes. Methylated C_{60} forms a thallium complex as well.[37]



(**2**)

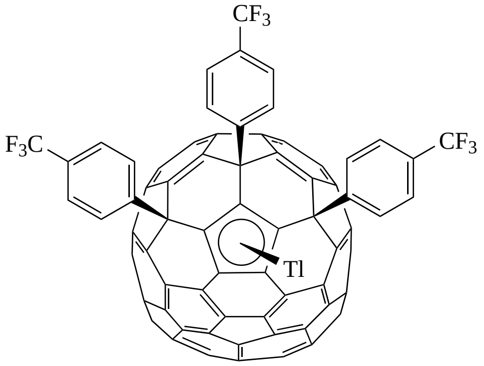


(**3**)

2.1.2 *Reactions of Thallium Cyclopentadienides*

Cyclopentadienylthallium compounds have demonstrated tremendous preparative potential as mild reagents for the synthesis of cyclopentadienyl derivatives of *Main Group Elements, Transition Metals*, and *Rare Earth Elements*. In fact, some alkyl-substituted cyclopentadienyl metal complexes can be obtained only from the analogous Tl(I) compounds. Reactions involving Cp′Tl compounds often are characterized by manipulative simplicity and high yields.

Reactions of Cyclopentadienylthallium with Transition Metal Compounds. Numerous *Metallocene Complexes* have been prepared using CpTl as a Cp-transfer reagent, including *Ferrocene, Cobaltocene*, and *Nickelocene*, as well



(**4**)

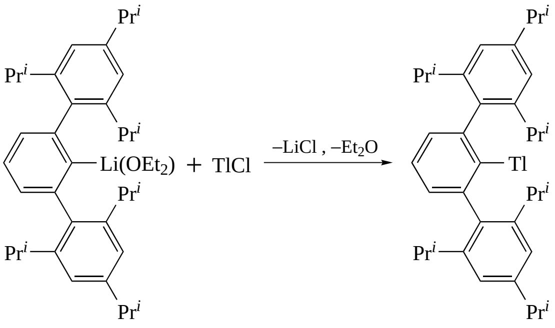
as dicyclopentadienylmercury.[1,38] The reaction of CpTl with transition metal–halide complexes containing carbonyl ligands gives the corresponding cyclopentadienyl metal carbonyls.[1,38,39] Ring-substituted cyclopentadienylthallium derivatives also have been used to prepare the corresponding Cp′ complexes of transition metals by substitution of a halide or Cp ligand.[40–46]

Reactions of Cyclopentadienylthallium with Main Group Compounds and Rare Earth Elements. Cyclopentadienylthallium has found great utility in the formation of cyclopentadienyl derivatives of main group elements. Germanium dibromide reacts with CpTl to give germanocene.[47] Cyclopentadienylphosphines, $CpPX_2$, and dicyclopentadienylphosphines, Cp_2PX, can be produced through the reaction of X_2PCl, and $XPCl_2$ with CpTl (X = R, F).[48,49] Cyclopentadienylthallium compounds react directly with rare earth metals to produce Cp_2M and Cp_3M complexes and elemental thallium.[50]

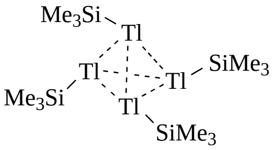
2.2 Alkylthallium(I) Complexes

Only two isolable σ-bound organothallium(I) compounds are known: $[(Me_3Si)_3C]Tl$[51] and $(2,6\text{-}Trip_2C_6H_3)Tl$ (Trip = 2,4,6-triisopropylphenyl).[52] Prepared by metathesis reaction (equation 4), $[(Me_3Si)_3C]Tl$ is of low thermal stability. X-ray diffraction analysis showed the compound to be tetrameric in the solid state (structure **5**) while cryoscopy indicated it to be monomeric in solution. The Tl···Tl distances in $\{[(Me_3Si)_3C]Tl\}_4$ range from 332 to 364 pm, suggesting relatively weak interactions, such as are found for Cp′Tl oligomers. Also thermally unstable, $(2,6\text{-}Trip_2C_6H_3)Tl$ is prepared by simple metathesis of TlCl and the aryllithium (equation 5). X-ray diffraction reveals it to be monomeric in the solid state. Other attempts to prepare Tl(I) σ-alkyls and -aryls via reactions of thallium(I) halides with lithium organyls or *Grignard Reagents* has lead to the formation of either organothallium(III) compounds or organic products.[1] Nevertheless, the proposed mechanism for these reactions involves the formation of organothallium(I) compounds as intermediates.[1,6]

$$CpTl + [(Me_3Si)_3]CLi{\cdot}2THF \xrightarrow{-CpLi,\ -2THF} [(Me_3Si)_3C]Tl \qquad (4)$$



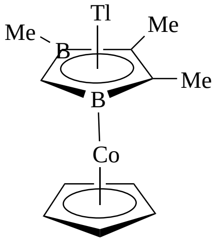
(5)



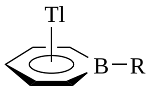
(**5**)

2.3 Complexes of Thallium(I) with Other Anionic Ligands

Several thallium(I) complexes with dicarbollide ligands (*see* ***Boron: Metallacarbaboranes***) have been prepared.[12,53] These compounds of the general formula $Tl_2C_2RR'B_9H_9$ usually are oxygen stable, and one of the thallium atoms can be readily replaced by a Ph_4As^+, Ph_3MeP^+, or PPN^+ cation.[54] The crystal structures of the resulting Ph_3MeP^+[54] and PPN^+ salts (Figure 1)[55] have been reported. Thallium dicarbollides react with aluminum alkyl derivatives and gallium trichloride, forming compounds of the general formula $Tl[M(C_2B_9H_{11})_2]$ (M = Al, Ga).[56] A complex between a cobalt-containing sandwich π-ligand and thallium(I) has been reported.[57] The resulting compound (**6**) is a monomer in the solid state and highly soluble in organic solvents. Thallium(I) also forms a complex (**7**) with the borabenzene anion.[58] (*see* ***Boron: Organoboranes***).



(**6**)



(**7**)

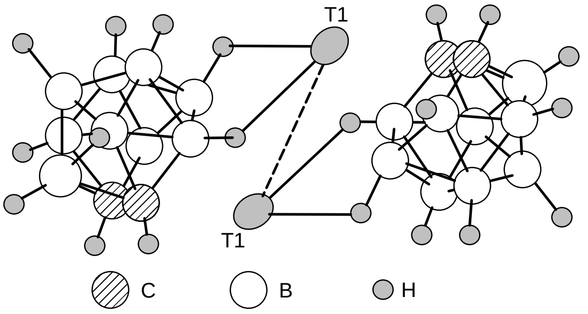


Figure 1 The structure of $[closo\text{-}3,1,2\text{-}TlC_2B_9H_{11}]^-$. (Reprinted with permission from Ref. 55. © 1991 American Chemical Society)

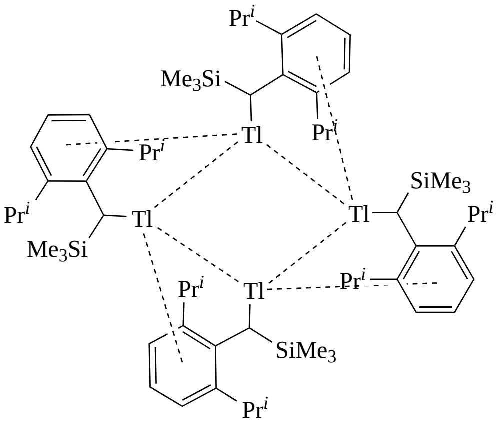
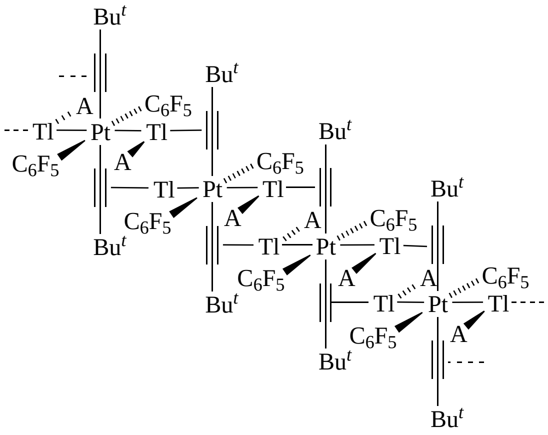
2.4 Complexes of Thallium(I) with Neutral π-Ligands

Structurally uncharacterized π-arene Tl(I) compounds of the composition $C_6H_62\cdot TlAlCl_4$, $C_6H_6\cdot TlAlCl_4$,[59] and $[Tl\cdot 2PhMe]^+$ $[C_5Cl_5]^-$[60] were described in the literature as early as 1968. Complexes of Tl(I) with toluene, 1,2,4- and 1,3,5-trimethylbenzene, and [2.2]paracyclophane have been isolated and structurally characterized.[60–64] These (η^6-arene)Tl complexes are little more than arene solvates, the Tl cations always being additionally coordinated to halide-bearing anions. Secondary π-interactions have been noted in the structures of the two crystal modifications of $[C_5H_4CMe_2$(9-fluorenyl)]Tl[65] (Figure 2). Thallium coordination to the six-membered ring in these structures showed ring slippage to η^2- and η^3-arene. Very weak (η^6-phenyl)Tl interactions result in polymerization of (3,5-diphenylpyrazoyl)Tl[66] and tetramer formation for $[2,6\text{-}Pr^i_2C_6H_3(Me_3Si)N]Tl$ (**8**).[67] Olefin coordination of Tl(I) is virtually unknown. The complex $Tl_2[Pt(C_6F_5)_2(C{\equiv}CBu^t)_2](acetone)_2$ (**9**) exhibits thallium–platinum bonds and Tl–η^2-alkyne interactions.[68]



(**8**)



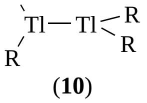
(**9**), A = acetone; Tl···F omitted for clarity

3 THALLIUM(II) COMPOUNDS

True organothallium(II) compounds are unknown. Nevertheless, low-temperature disproportionation reactions (6) and (7) have produced a pair of silylthallium(II) dimers, (**10**), $R = Si(SiMe_3)_3$[69] and $R = SiBu^t{}_3$.[70] Both products were examined by X-ray crystallography, however, $(Bu^t{}_3Si)_4Tl_2$ underwent decomposition in the X-ray beam, yielding only limited data. True Tl–Tl bonding distances of 291.4 and 296.6 pm were found for $[(Me_3Si)_3Si]_4Tl_2$ and $(Bu^t{}_3Si)_4Tl_2$ respectively.

$$4(Me_3Si)_2NTl + 4(Me_3Si)_3SiRb \xrightarrow[-2Tl]{-4RbN(SiMe_3)_2,} [(Me_3Si)_3Si]_4Tl_2 \tag{6}$$

$$4TlBr + 4NaSiBu^t{}_3 \xrightarrow{-4NaBr,\ -2Tl} (Bu^t{}_3Si)_4Tl_2 \tag{7}$$



(**10**)

4 THALLIUM(III) COMPOUNDS

Thallium(III) compounds dominate the known organometallic chemistry of thallium. The structural chemistry organothallium(III) compounds has been reviewed.[7]

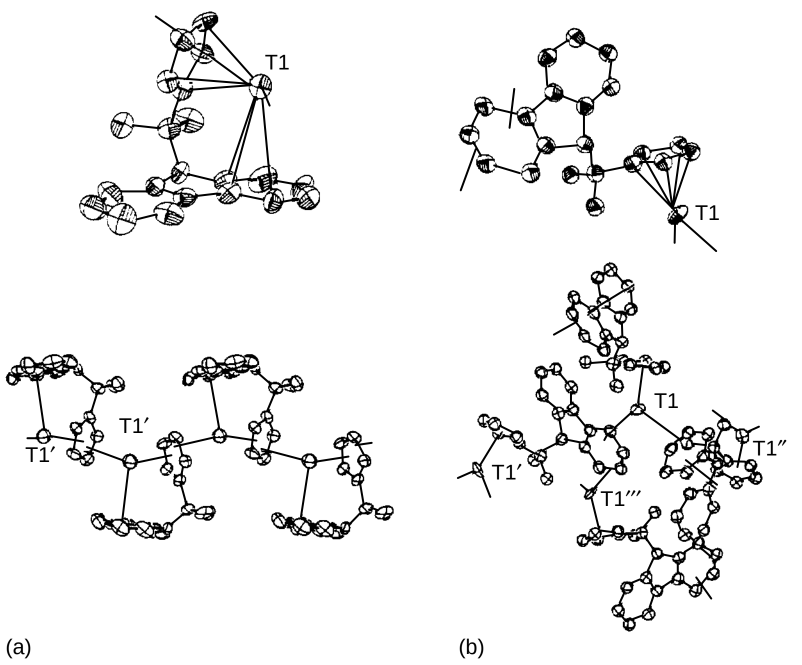


Figure 2 The structure of [$C_5H_4CMe_2$(9-fluorenyl)]Tl: (a) modification 1; (b) modification 2. (Ref. 65. Reproduced by permission of the John Wiley and Sons)

4.1 Triorgano-, tetraorgano-, and hexorganothallium Compounds

4.1.1 Preparation and Properties

Triorganothallium and the related compounds are usually prepared through the reaction of dialkyl- or diarylthallium(III) halides with organolithium compounds or, in some cases, Grignard reagents.[3] Aryllithium reagents have been used to effect conversion of $TlCl_3$, to Ar_3Tl.[71] Reactions involving excess carbanion source can produce peralkyl- or perarylthallium(III) anions, $[R_4Tl]^-$ and $[R_6Tl]^{3-}$.[71–74] To date, trimethylthallium and trimesitylthallium are the only structurally characterized R_3Tl species (see Table 2).[75–77] Trimethylthallium can be prepared conveniently by the reaction of methyllithium and thallium(I) iodide in the presence of methyl iodide (equation 8).[3] This reaction most likely involves the formation of methylthallium(I) as an intermediate. The reaction of dimethylthallium amide or trimethylthallium with R–C≡CH (R = H, Me, Ph) affords dimethyl(ethynyl)thallium compounds.[3]

$$2MeLi + MeI + TlI \xrightarrow{-2LiI} Me_3Tl \qquad (8)$$

Trimethylthallium is monomeric in the gas phase, in the melt, and in solution.[78] However, it forms a polymeric framework, with weakly bridging methyls, in the solid state.[75,77] Bonded Tl–C lengths are 219.6–221.6 pm and nonbonded Tl···C distances are 324.3–336.4 pm. The dissociation energy of the first Tl–C bond in trimethylthallium has been estimated as 152 kJ mol^{-1}.[79] The presence of this rather weak bond (compared to the corresponding values in Me_3Ga (249 kJ mol^{-1}) and Me_3In (197 kJ mol^{-1})) is the fundamental reason for the observed high reactivity of trimethylthallium and triorganothallium compounds in general. Triorganothallium compounds are oxygen and water sensitive. A word of caution is warranted about these compounds, as some have been known to decompose explosively upon heating.

Although triorganothallium compounds are much weaker electron-pair acceptors than the corresponding indium and gallium compounds, some adducts of R_3Tl with Lewis bases have been isolated.[3,71,74,80–86] Several such adducts have been examined using X-ray crystallography (Table 2). Two of these are chelates in which the bond lengths and angles are no doubt influenced by metallocycle formation. However, the simple Lewis base adducts $(Me_3SiCH_2)_3TlP(SiMe_3)_3$[84] and $(C_6F_5)_3TlOPPh_3$[74] show C-Tl-C bond angles of nearly 120°, suggesting fairly weak donor–acceptor bonding.

4.1.2 Reactions of Triorganothallium Compounds

Owing to the weakness of the Tl–C bonds, triorganothallium derivatives are highly reactive compounds. Trimethyl- and triphenylthallium react with mercury to form the corresponding diorganomercury derivatives and elemental thallium (equation 9).[2]

$$2R_3Tl + 3Hg \longrightarrow 3R_2Hg + 2Tl \qquad (9)$$

Table 2 Triorganothallium(III) compounds characterized by X-ray diffraction

Compound	Tl–C (pm)	C–Tl–C (°)	E, Tl–E (pm)
Me_3Tl[77]	219.6, 220.6, 221.6	115.1, 120.7, 124.1	–
$(Mesityl)_3Tl$[76]	222, 218, 216.9	116.9, 120.3, 122.8	–
$(Me_3SiCH_2)_3TlP(SiMe_3)_3$[84]	223, 224, 225	116.2, 116.5, 121.1	P, 292.2
$(C_6F_5)_3TlOPPh_3$[74]	218.0, 219.0, 219.2	116.9, 118.5, 122.2	O, 230.0
$(Me_2NFc)_3Tl$[85]	217.6, 218.1, 220.2	114.0, 118.5, 125.9	N, 252.3
$(2\text{-}Ph_2PCH_2C_6H_4)_3Tl$[86]	221.0, 221.4, 222.6	108.1, 122.5, 124.2	P, 279.5; P, 355.8

In the presence of acids, halogens, or pseudohalogens, one of the organic groups in R_3Tl is displaced and compounds of the general formula R_2TlX are formed (equations 10–12).[2] Insertion into the Tl–C bond occurs when trimethylthallium is reacted with either SO_2 or SO_3 (equation 13 and 14).[3]

$$2R_3Tl + ClN_3 \xrightarrow{-RCl} R_2TlN_3 \quad (10)$$

$$R_3Tl + HCl \xrightarrow{-RH} R_2TlCl \quad (11)$$

$$Ph_3Tl + Se(SeCN)_2 \xrightarrow{-PhSeCN,\ -Se} Ph_2TlSeCN \quad (12)$$

$$Me_3Tl + SO_2 \longrightarrow Me_2TlOS(O)Me \quad (13)$$

$$Me_3Tl + SO_3 \longrightarrow Me_2TlOS(O)_2Me \quad (14)$$

The reaction of trimethyl- or triethylthallium with Et_3MH (M = Si, Ge), $B_{10}H_{14}$, or $M'H(CO)_3Cp$ (M′ = Mo, W) leads to the formation of the thallium–metal bonded compounds $Tl(MEt_3)$, $[Me_2Tl][Me_2Tl(B_{10}H_{12})]$, and $Me_2Tl(M'(CO)_3Cp)$, respectively.[3]

4.2 Diorganothallium Compounds

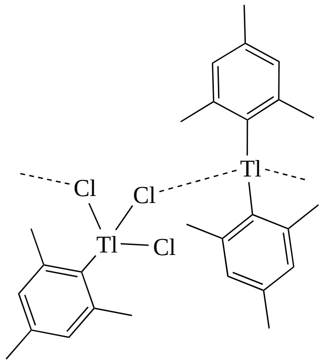
4.2.1 Preparation and Properties

Diorganothallium compounds comprise the most stable class of organothallium(III) derivatives. They usually are prepared via the reaction of $TlCl_3$ with Grignard reagents (equation 15).[2] However, the yields are rather poor, due to the oxidation of the Grignard reagent by $TlCl_3$. Some di(*n*-alkyl)thallium bromides have been prepared in good yields by the reaction of TlBr with RMgBr in a 2:1 molar ratio. Diaryl- and divinylthallium halides can be conveniently synthesized by the reaction of thallium(III) halides with the appropriate organoboronic acid in aqueous solution (equation 16).[2] Arylsilver derivatives (R = mesityl, 2,4,6-$C_6F_3H_2$, C_6F_5) react with $TlCl_3$ to give the corresponding diarylthallium chloride.[87]

$$TlCl_3 + 2RMgX \xrightarrow{-2MgXCl} R_2TlCl \quad (15)$$

$$TlX_3 + 2RB(OH)_2 \xrightarrow[-2HX,\ -2B(OH)_3]{H_2O} R_2TlX \quad (16)$$

Other methods for the preparation of diorganothallium compounds are described in Section 4.1.2. Diorganothallium halides are solids and usually are unaffected by water and atmospheric oxygen. They have high melting and decomposition points and are only sparsely soluble in typical organic solvents. Most salt-type diorganothallium(III) compounds ionize in polar solvents. The dimethylthallium cation $[Me_2Tl^+]$, being isoelectronic with dimethylmercury, is one of the most stable methylated species in aqueous solution reported to date. Many diorganothallium compounds have been characterized by single crystal X-ray diffraction. Table 3 lists some representative diorganothallium compounds and their structural properties. A more complete list is available.[7] The thallium atom reaches coordination numbers between four and eight by both inter- and intramolecular coordination. For most dialkylthallium(III) compounds, an almost linear C–Tl–C arrangement is observed. However, significant deviations are sometimes encountered, usually owing to the steric demand of additional donor ligands and/or oligomerization. Complex (**11**) represents a particularly interesting combination of R_2Tl^+ and $RTlCl_3^-$ (R = mesityl).[87] The diarylthallium(III) cation and aryl(trichloro)thallium(III) anion in (**11**) are weakly associated through a series of long chloride bridges.



(**11**)

4.2.2 Reactions of Diorganothallium Compounds

Although the Tl–C bonds in diorganothallium compounds are considerably more stable than those in either triorgano- or monoorganothallium compounds, reactions that involve the

[a]L = tridecalino-18-crown-6{1,4,15,18,29,32-hexaoxaperhydro[4.4.4](4a,8a)naphthalenophane}. [b]HDaptsc = 2, 6-diacteylpyridine bis(thiosemicarbazone) anion. [c]FcEtsc = ferrocenyl-N-ethylthiosemicarbazone. [d]FcDtsc = ferrocenyl-dimethylthiosemicarbazone. [e]4-CF_3PymS = 4-trifluoromethylpyrimidine-2-thionate. [f]Cptsc = cyclopentanone thiosemicarbazone. [g]Weakly polymeric through ion association, see (**11**); data for $[(Mesityl)_2Tl]^+$; see Table 4 for anion data.

cleavage of M–C bonds in diorganothallium compounds are known. Diorganothallium cations (R_2Tl^+) can be reduced electrochemically, presumably forming R_2Tl *Radicals* as intermediates (equation 17). The radicals then either form elemental Tl and R_3Tl via disproportionation (equation 18), or can be reduced further to afford the corresponding carbanion (equation 19).[3]

$$R_2Tl^+ + e^- \longrightarrow R_2Tl\bullet \quad (17)$$

$$3R_2Tl\bullet \longrightarrow 2R_3Tl + Tl \quad (18)$$

$$R_2Tl\bullet + 2e^- \longrightarrow 2R^- + Tl \quad (19)$$

Diorganothallium compounds are known to undergo disproportionation and alkyl-exchange reactions, as shown in equations (20) and (21).[3] Dialkyl- and diarylthallium carboxylates react with mercury acetate to give monoorganothallium dicarboxylates (equation 22).[3]

$$3Me_2TlY \longrightarrow 2Me_3Tl + TlY_3 \quad (20)$$

$$Y = Co(CO)_4,\ Cr(CO)_3Cp,\ Fe(CO)_2Cp$$

$$Ph^*{}_2Tl^+ + Ph_2Hg \rightleftharpoons Ph_2Tl^+ + Ph^*{}_2Hg \quad (21)$$

$$* = {}^{14}C \text{ labeled}$$

$$R_2TlOAc + Hg(OAc)_2 \longrightarrow RTl(OAc)_2 + RHgOAc \quad (22)$$

4.3 Monoorganothallium Compounds

4.3.1 *Preparation and Properties*

Monoalkylthallium compounds are usually prepared either by the reaction of dialkylthallium carboxylates and mercury(II) carboxylates (equation 22), or by reacting dialkylthallium halides with Br_2 or I_2 (equation 23).[3,104,105] Aryl- and vinylthallium dichlorides are prepared conveniently by the reaction of aryl- and vinylboronic acid, respectively, with excess $TlCl_3$ in aqueous solution (equation 24).[2,3]

$$R_2TlX + Br_2 \xrightarrow{-RBr} RTlXBr \quad (23)$$

$$X = \text{halide, } BF_4$$

$$RB(OH)_2 + TlCl_3 \xrightarrow[-HCl,\ -B(OH)_3]{H_2O} RTlCl_2 \quad (24)$$

$$R = Ar, Vi$$

Another synthetic route to monoorganothallium compounds is the reaction of aryl or vinyl derivatives of mercury(II) or tin(IV) with TlX_3 (X = halide, carboxylate). Monoalkylthallium derivatives are intermediates in the oxidation of alkenes and alkynes by thallium(III) salts (oxythallation) (see Section 7).

Several monoorganothallium(III) compounds have been characterized by single crystal X-ray diffraction. These

[a] BtaPy = 2,6-bis(2-methyl-2-benzothiazolinyl)pyridine. [b] R = 2-exo-bicyclo[2.2.1]hept-exo-3-acetato-5-enyl. [c] Weakly polymeric through ion association, see (**11**); see Table 4 for data on $[(Mesityl)TlCl_3]^-$; see Table 3 for data on $[(Mesityl)_2Tl]^+$. [d] Daptsc = 2,6-diacetylpyridine bis(thiosemicarbazone) dianion. [e] Polymer chain formed through interligand hydrogen-bonding.

are listed in Table 4. With macrocyclic ligands, such as porphyrins, the complexes are monomeric, but with smaller readily bridging ligands, such as halide or carboxylate, oligomers can form.

4.3.2 Reactions of Monoorganothallium Compounds

Monoorganothallium compounds readily undergo reductive cleavage of the thallium–carbon bond. Methylthallium diacetate decomposes slowly in various solvents (e.g. H_2O, methanol, THF, chloroform) at ambient temperature to give methyl acetate and thallium acetate (equation 25).[3] Phenylthallium dichloride is more stable, but the analogous dibromide, $PhTlBr_2$, decomposes rapidly into PhBr and TlBr when heated.[3] If $PhTlX_2$ ($X = Cl$, O_2CCF_3) is treated with KI, the formation of PhI and TlI is observed (equation 26).[3] Cleavage of the Tl–C bond also can be achieved electrochemically (equation 27).[3] Some electrophilic reactions at the Tl–C bond of monoarylthallium compounds are of synthetic interest, for example, the bromination of arylthallium compounds that gives aryl bromides.[3]

$$MeTl(OAc)_2 \xrightarrow{-MeOAc} TlOAc \quad (25)$$

$$PhTlX_2 + 2KI \longrightarrow PhI + TlI + 2KX \quad (26)$$
$$X = Cl,\ O_2CCF_3$$

$$2PhTl^{2+} + 4e^- \xrightarrow{Hg} Ph_2Hg + 2Tl \quad (27)$$

5 THE TOXICITY OF ORGANOTHALLIUM COMPOUNDS

Elemental thallium and its compounds are extremely toxic and must be handled with care (*see* ***Metal Ion Toxicity***). The lethal dose is considered to be 10–12 mg kg^{-1} body weight. The organometallic chemistry of thallium shows similarity to that of Hg^{2+} and Pb^{2+}. Both Hg^{2+} and Pb^{2+} undergo *in vivo* biomethylation, with methylcobalamin ($MeCoB_{12}$) being the biological source of the methyl groups (*see* ***Cobalt: B_{12} Enzymes & Coenzymes***).[112] It has been shown that $MeCoB_{12}$ can be demethylated by Tl^{3+}, but the resulting methylated Tl species has not been isolated.[113,114] Monovalent Tl is not able to demethylate $MeCoB_{12}$, however. Bacteria from an anaerobic lake sediment have been used to convert TlO_2CCH_3 into the water-stable Me_2Tl^+ cation in an atmosphere of N_2 and under the exclusion of light.[115] The formation of Me_2Tl^+ is unsurprising, considering that monomethylthallium(I) compounds are unstable and Me_3Tl decomposes in water. Unlike the organometallic derivatives of Pb^{2+} and Hg^{2+} generated by the biological system, Me_2Tl^+ appears to be less toxic than inorganic thallium compounds and elemental thallium itself. Dimethylthallium(I) has recently been detected in Atlantic Ocean water at levels up to 3.2 ng L^{-1} using isotope dilution mass spectrometry.[116]

Although detailed data about the biological effects of organothallium compounds remain sparse, they should be considered to be extremely toxic, taking into account their chemical similarity to organomercury and -lead compounds (*see* ***Mercury: Organometallic Chemistry*** and *Lead: Organometallic Chemistry*), combined with the known toxicity of inorganic thallium compounds and thallium metal.

6 ORGANOTHALLIUM COMPOUNDS AS PRECURSORS FOR ELECTRONIC MATERIALS

Thallium(III) oxide is a degenerate n-type semiconductor (*see* ***Semiconductors***) with a Band Gap of 1.4 eV, and it shows electronic and optical properties, which make it useful in applications such as solar cells and electrical contacts.[117] The interest in thallium oxide has been further stimulated by the discovery that the system Tl–Ca–Ba–Cu–O represents a

class of superconducting materials with critical temperatures as high as 125 K, coupled with the presence of very high critical current densities.[118] Superconducting metal oxides (SMO) were originally studied as bulk materials;[119] however, it is as thin films that they attract the most interest (*see* ***Thin Film Synthesis of Solids***). One proven technique that provides high-quality films on large area substrates at mild conditions is Metal–Organic Chemical Vapor Deposition (MOCVD).[120,121] This method requires organometallic precursors that are chemically and thermally stable during their evaporation and transport to the substrate, and which decompose on the substrate to form the desired solid-state material and volatile by-products. Suitable organothallium MOCVD precursor compounds are relatively few in number, however, several have been used successfully in the preparation of thallium-containing superconductors and semiconductors by the MOCVD technique. Among them are thallium tris(β-diketonates)[122–124] and cyclopentadienylthallium.[123,125] The most promising precursors to date are CpTl and some of its derivatives. These compounds can be prepared relatively easily and come closest to possessing the necessary volatility.[126]

7 THALLIUM IN ORGANIC SYNTHESIS

7.1 Introduction

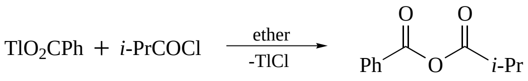
In contrast to the other elements of group 13, thallium is considered a soft acid in Pearson's soft/hard acid classification (*see* ***Hard & Soft Acids and Bases***).[127] This makes the element and its derivatives unique, and leads to its potentially most outstanding feature: the properties of thallium are a subtle blend of some of the most desirable properties of numerous other metals (e.g. heavy alkali metals, silver, mercury, and lead). Thallium compounds are stable in both oxidation states (+1 and +3). The trivalent cation is quite a strong oxidation reagent, since it is reduced to Tl^+ easily (standard redox potential $E°(Tl^{3+} \rightarrow Tl^+) = -1.25$ V). The ease of this reduction is utilized in certain organic reactions.

Numerous transformations in organic chemistry that occur in the presence of thallium reagents have been described. Many of these reactions are unique and are characterized by manipulative simplicity and high yields. Several review articles describe in detail the use of thallium reagents in organic synthesis.[1,127–131] Selected examples are discussed below.

7.2 Selected Examples[1,127–131]

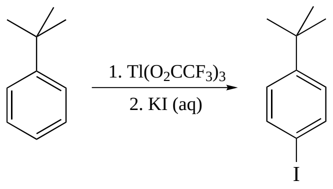
The nonoxidative applications of thallium in organic synthesis are relatively few. Organothallium reagents act as mild nucleophiles. Thus, acid chlorides can be alkylated by R_3Tl, as can α-haloethers. Nucleophilicity is greater for R_4Tl^-. Alkyltrimethylthallate(III) is prepared from Me_3Tl and RLi, and may be used to alkylate α,β-unsaturated ketones.[130]

Symmetrical and unsymmetrical anhydrides can be prepared in quantitative yields by the reaction of Tl(I) carboxylates with carboxylic acid chlorides (equation 28).

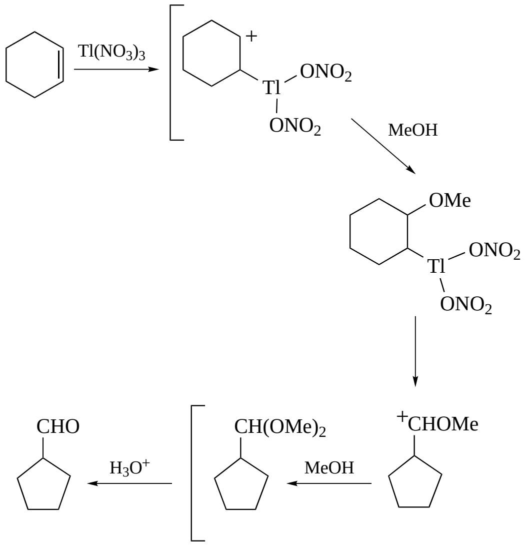


(28)

Thallium(III) reagents are useful for mediating electrophilic substitutions. The resulting arylthallium dications are converted into substituted aromatic compounds easily and in high yields. The new substituent enters the aromatic ring at the position in which the TlX_2 group was attached (equation 29).



(29)



(30)

Thallium(III) salts, especially $Tl(NO_3)_3$, $Tl(O_2CCH_3)_3$, and $Tl(O_2CCF_3)_3$, are widely used as oxidizing reagents for nonaromatic unsaturated compounds.[11,130] This reaction is certainly the most important application of thallium in organic synthesis. The first step in the reaction of a thallium(III) salt with alkenes (oxythallation) takes place rapidly at ambient temperature and leads to the formation of monoalkylthallium(III) compounds. These intermediates are usually unstable under the reaction conditions, and undergo rapid decomposition to give the oxidation product of the organic substrate, while Tl^{3+} is reduced to Tl^+. Cyclic alkenes react with $Tl(NO_3)_3$ in methanol to give the ring-contracted products by oxidative rearrangement (equation 30). This reaction produces very high yields of

ring-contracted products and has been used to great advantage in the conversion of flavanones to flavones, isoflavones, and benzofurans. Similar strategy can be used for ring closures and expansions (equations 31 and 32).[130] Enolizable ketones undergo oxidation at the α position in the presence of Tl(III) salts (equation 33).[130]

Glossary

Laser ablation: light-driven nonequilibrium evaporation of a solid
Thin films: coatings that have thicknesses ranging from a single crystal unit-cell to several microns

Abbreviations

PLD = pulsed laser ablation and deposition; T_c = superconducting transition temperature; RBS = Rutherford backscattering spectrometry; RHEED = reflection high-energy electron diffraction.

1 INTRODUCTION

Inorganic thin films play a central role in many areas of technology and basic research.[1,2] Thin film coatings are essential to the function of numerous mechanical devices. Electronically active thin films have also been central to the discovery of new physical phenomena such as the quantum Hall effect. In general, it is possible to categorize the wide spectrum of inorganic thin films into two categories, passive or active, based simply on their function in a structure or device. Passive thin films are coatings that may be used for cosmetic purposes or to protect a surface from wear or deleterious chemical reactions; however, passive films do not serve a specific electronic or catalytic role. Examples of technologically important passive thin films include: (1) metal nitrides (e.g. TiN) and carbides, which are used as hard, wear-resistant coatings; (2) oxides such as Al_2O_3 and SiO_2, which are used as diffusion barriers and insulators; and (3) metal coatings (e.g. Au), which are used to provide chemically inert, decorative finishes.[1–3] In addition, electronically and chemically active thin films are of great importance to microelectronic devices, sensors, and other key technological areas. For example, alternating thin layers of GaAs and AlGaAs form the basis for optical detectors and semiconductor lasers. On the other hand, ZrO_2 thin films represent the key chemically selective component of oxygen sensors used in many automobile engines.

Central to thin film technology and research are the synthetic methods used to fabricate coatings and new thin film materials. These synthetic methods, which differ significantly from familiar inorganic preparative techniques, can be classified as either chemical or physical in nature. Chemical techniques include *Chemical Vapor Deposition* (CVD),[1] sol–gel techniques (*see* ***Sol–Gel Synthesis of Solids***),[2] and electrochemical plating. In general, chemical techniques rely on the decomposition of molecular precursors (*see* ***Metallic Materials Deposition: Metal-organic Precursors***), where the quality of a resulting thin film depends critically on excluding ligands and other contaminants. Inorganic chemists have made an impact in designing molecular precursors for film growth.

In contrast, physical techniques of thin film synthesis are based upon evaporation or sputtering of elemental or multicomponent sources and subsequent deposition of this material onto a substrate;[3–6] molecular precursors do not play a significant role in thin film synthesis via these techniques. Examples of physical techniques used to prepare thin films include: (1) *Molecular Beam Epitaxy* (MBE);[5] (2) sputtering,[4] and (3) pulsed laser ablation and deposition (PLD).[6] Physical techniques can be extremely powerful methods for fabricating new materials since they allow atomic level control of growth. For example, MBE has revolutionized the fabrication of complex semiconductor superlattices (e.g. GaAs/AlGaAs) that have abrupt variations in composition on an atomic scale. A major limitation of MBE is that it relies on thermal evaporation to generate the elemental components of a film. Equilibrium evaporation will yield films that have a stoichiometry which differs from the bulk starting material when the starting material melts incongruently. Because most chemically interesting complex inorganic materials, such as metal oxides and metal nitrides, melt incongruently, it is not clear whether MBE can contribute greatly to the synthesis of interesting inorganic oxides and nitrides.

On the other hand, we believe there is an emerging body of results which indicate that PLD may revolutionize the synthesis of complex inorganic thin film materials. A unique feature of PLD is that the source material is evaporated (ablated) in a nonequilibrium process such that material is evaporated at the stoichiometry of the bulk. Hence, it is possible to prepare thin films of incongruently melting solids that have a stoichiometry characteristic of the solid phase prior to melting. For example, PLD has been the most effective method for preparation of crystalline $YBa_2Cu_3O_7$

superconductor thin films for both research and commercial applications. Since $YBa_2Cu_3O_7$ melts incongruently, it is difficult to prepare films via conventional thermal evaporation. Furthermore, the PLD technique is a general one for thin film synthesis, and has been used to prepare materials with metallic, insulating, ferroelectric, piezoelectric, magnetic, and superconducting properties.[6] Because PLD can in principle be used to deposit widely varying types of materials and arbitrarily complex stoichiometries, we believe that it is a uniquely powerful approach to the synthesis of inorganic thin films. The remainder of this article will focus on the PLD technique of thin film synthesis, including the fundamental principles of laser ablation and applications of PLD to the synthesis of novel inorganic materials.

2 FUNDAMENTALS OF PLD

The utility of PLD for thin film synthesis is due in large part to the unique characteristics of the laser ablation process. As indicated above, laser ablation is a nonequilibrium process that enables stoichiometric evaporation of elements from a target source. In addition, it is also possible to control the energy of evaporated species in PLD, and thus control film growth on the substrate surface. The underlying basis for these features of laser ablation and their utility in thin film synthesis are described below.

2.1 Laser–Solid Interaction

The interaction of intense laser light with solid surfaces is a complex physical process. This section does not focus on the physics underlying this interaction, but rather reviews the factors that directly influence thin film growth. More detailed explanations of the laser–solid interaction can be found in several reviews of this subject.[7–9]

The interaction of pulsed laser light with a solid surface is shown schematically in Figure 1. Typically, lasers with pulse lengths <50 ns and energies on the order of 1 J cm^{-2} are used for thin film synthesis. Initially, laser light is absorbed by the solid and heats and melts the near-surface region of a target. The depth of the melted region depends upon the power density and rate of thermal diffusion.[7–9] At high power densities, the surface melts during the initial part of the laser pulse, and is then vaporized. In the intense electromagnetic field of the laser light, the vapor is ionized to form a plasma that contains ions, electrons, neutral atoms, and small clusters. The plasma, which is self-regulating,[7–9] is directed perpendicularly away from the target or source surface; this directional vaporization is termed laser ablation. The ions and neutral elements in the plasma can be readily deposited on a substrate located diametrically opposite to the target. During laser ablation it is important to recognize that temperatures in excess of 4000 K are readily achieved, and thus virtually any material can be evaporated. Furthermore, since the target material acts as its own crucible, contamination from a reaction crucible, which is common in conventional solid-state synthesis, is not a problem in PLD synthesis.

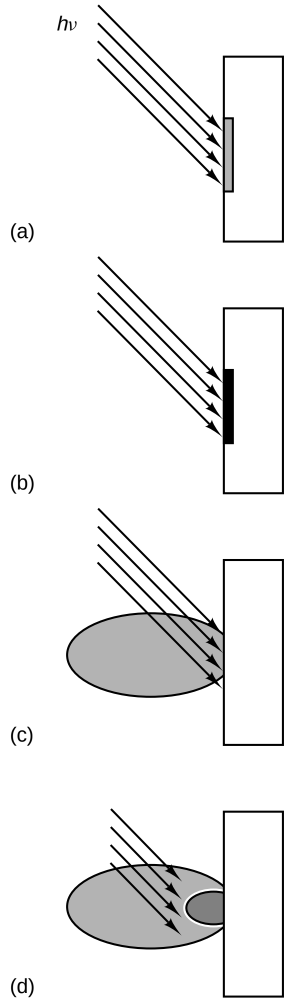

Figure 1 Schematic view of the interaction of laser light with a solid. Initial irradiation heats (a) and then melts (b) the surface. The liquid is then vaporized (c) and ionized (d) to form a plasma that is ejected away from the target surface. The time from (a) to (d) is approximately 30 ns

2.2 Important Laser Parameters

Central to the application of laser ablation in synthesis is the ability to control the rate, energies, and neutral:ion ratio of the evaporated elements through systematic variations in the wavelength, pulse-width, and power density of the laser light. The absorption depth of light by a solid is wavelength dependent, and thus the efficiency of target heating and evaporation will depend on the wavelength of irradiation. The target temperature increase during laser irradiation is inversely proportional to the optical penetration depth for a fixed energy

input, where the penetration depth is directly proportional to wavelength.[10,11] Hence, the surface temperature of a target irradiated with short and long wavelength lasers of equal energy and pulse length will be higher for the former. In addition, the rate of energy input, which is governed by the laser pulse width, is directly related to the temperature increase of the target; i.e. for a shorter pulse length a smaller amount of heat will be transported into the bulk by thermal diffusion. Short wavelength and short pulse length lasers will thus ablate material from a small near-surface volume without segregation of elements from the bulk. That is, regardless of the nature of the equilibrium phase diagram, the evaporated species have the average stoichiometry of the bulk target. Therefore, laser sources that emit short UV pulses (e.g. the excimer laser) are ideal for complex thin film synthesis using PLD.

The laser power density also plays an important role in the evaporation process. First, at very low power densities (not employed typically for PLD) evaporation is nearly an equilibrium thermal process. As the power density increases, however, the process becomes nonequilibrium since heating and evaporation occur more rapidly than thermal and atomic diffusion. Furthermore, as the power density increases, the fraction of ionic to neutral species in the plasma and the kinetic energy of these species increases. Explicit measurement of these dependencies is possible using mass spectrometry.[12–18] Time of flight mass spectrometry measurements have shown that the energy of neutral species can be varied between 3 and 30 eV, while the ions produced in the plasma may have energies from 0.1 to $>$100 eV. These relatively high kinetic energies enhance the chemical reactivity and surface diffusion of the ablated species. Diffusion and reactivity are both important parameters for controlling film growth. Because it is straightforward to change the power density through simply focusing or defocusing of the laser, the synthetic chemist has a powerful variable for controlling thin film growth. Lastly, it is important to reiterate that high power density laser ablation in nearly all cases results in congruent (i.e. stoichiometric) evaporation of the source target. Congruent evaporation has been demonstrated in many important systems which cannot be prepared using conventional thermal evaporation, including ternary semiconductors such as HgCdTe and $Pb_{1-x}Cd_xSe$,[19,20] electronic ceramics,[21,22] and high-temperature copper oxide superconductors.[23] Of even greater importance to the synthesis of new inorganic thin films is the fact that congruent evaporation is also observed for multiphase targets.[24] That is, a thin film of virtually any stoichiometry can be prepared by laser ablation of a target that simply contains elements mixed in the desired stoichiometry.

3 EXPERIMENTAL APPARATUS FOR PLD

A general experimental apparatus for preparing thin films by PLD is shown in Figure 2. The PLD apparatus consists of a vacuum chamber containing a target holder, substrate heater positioned diametrically opposite to the target, optical window, and other components (Figure 2), together with a pulsed laser. Key features and considerations for the deposition apparatus are discussed below.

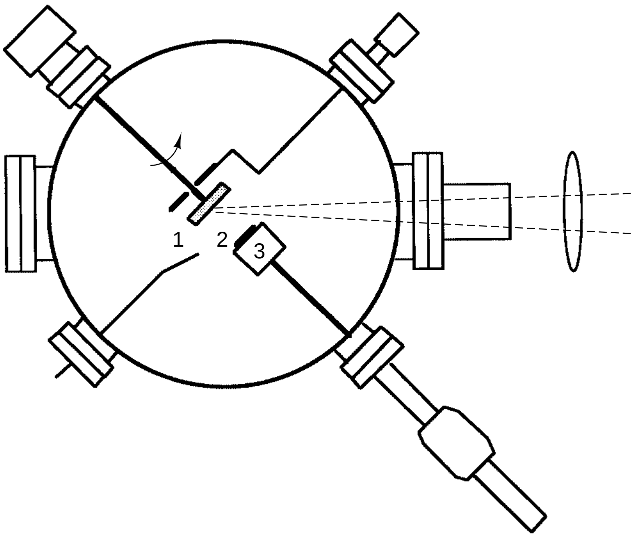

Figure 2 Schematic view of the PLD synthetic chamber. The target (1) is attached to a feedthrough that is rotated during laser irradiation. The growth substrate (2) is attached to a heater (3) that controls the growth temperature between 25 and 900 °C. The dashed lines represent the laser beam (laser not shown); the beam is focused onto the target

Deposition chambers are typically constructed of stainless steel in order to obtain a clean vacuum. Glass chambers can also be used for PLD, although they are generally less versatile than metal chambers. In either case, it is important to minimize the build-up of deposits on the optical window in the chamber since this effectively attenuates the laser power density at the target surface. The build-up of deposits on the optical window can be reduced by locating this window as far away from the target as is possible.

The synthesis of oxide and nitride materials is often carried out with a background pressure in the PLD chamber of 10 to 500 mTorr. This pressure regime can be readily achieved using inexpensive mechanical pumps. However, it is good synthetic procedure to use a turbomolecular pump to establish a high vacuum in the chamber initially, and then to increase the pressure using purified oxygen or nitrogen.

Another key element in the PLD apparatus is the substrate heater. Thin film synthesis of oxide materials may be carried out at temperatures as high as 800 °C in oxygen. These highly oxidizing conditions place severe demands on heating elements, although two general types of heaters, radiant and resistive, have been used successfully. Radiant heaters utilize lamps as a heat source. A simpler solution to this problem is to utilize simple resistance heaters. Resistance heaters are easily

fabricated; however, the metal alloy utilized for the heater element must be chosen with care to ensure reliable heater operation at high temperature in oxygen.

Lastly, it is important to irradiate the target uniformly. If the laser is focused on a stationary target, the ablation process will create a localized depression in the surface. The formation of surface depressions or craters is deleterious to synthesis since it leads to incongruent target evaporation. One method to avoid the formation of localized craters is to rotate the target asynchronously with the laser pulses. Alternatively, when target rotation is not possible, the laser beam itself should be scanned over the surface of the target. Target rotation and beam scanning both lead to uniform (and stoichiometric) removal of material from the target.

4 THIN FILM SYNTHESIS USING PLD

In the remainder of this article specific examples of thin film synthesis using PLD are described. These examples are chosen to illustrate the unique characteristics of PLD that make it a powerful technique for the preparation of complex multicomponent solids and for exploratory synthesis of new materials.

4.1 Preparation of Known Materials

The discovery of high-temperature superconductivity in copper oxide based materials has been a remarkable triumph of inorganic solid-state chemistry (*see* ***Superconductivity*** and ***Oxides: Solid-state Chemistry***). A number of families of copper oxide superconductors are now known, and the transition temperatures (T_c) in many of these solids exceed the boiling point of liquid nitrogen (LN_2). The observation of T_c values above the boiling point of LN_2 has renewed interest in developing superconductor thin films for a variety of electronics devices. For the fabrication of thin film devices it is essential that the thin film material (1) is homogeneous and crystalline, (2) has a high critical current density, and (3) does not react with the substrate on which it is grown. PLD has been by far the most widely used technique for the preparation of these high-T_c thin films.[24–26] These films have been shown to preserve the structure and composition of bulk $YBa_2Cu_3O_7$. Thin films prepared by PLD also exhibit the high critical current densities required for technological applications. In addition, it is possible to grow crystalline, superconducting films of $YBa_2Cu_3O_7$ at temperatures significantly lower than those used to form the bulk phase (700 vs. >900 °C). Low-temperature growth minimizes, and in some cases eliminates, interdiffusion and reaction at the superconductor–substrate interface.

The successful preparation of high-quality $YBa_2Cu_3O_7$ films shows that PLD can readily deposit complex stoichiometry materials in crystalline form at temperatures significantly lower than those required in bulk syntheses. Furthermore, high-quality films have been routinely prepared in many laboratories worldwide. Hence, it is indeed reasonable to consider PLD as a general technique for the synthesis of complex inorganic films.

Another general class of solids that has been prepared as thin films using PLD is ferroelectric materials. A potentially useful characteristic of ferroelectric materials is that they can be polarized by an electric field and retain this polarization when the field is removed. In ferroelectric thin films it may be possible to exploit this polarization phenomenon to make sensors, displays, and memory devices.[27] A number of techniques have been used to prepare ferroelectric thin films. However, it has been difficult to control the stoichiometry (and correspondingly the properties) of these materials using thermal and sputtering techniques. In part, the difficulty in maintaining correct stoichiometry is due to the volatility of a component in the material (e.g. Pb in $PbTiO_3$).

The success of PLD in preparing high-quality superconductor thin films has led to considerable interest in applying this technique to the ferroelectrics. PLD is particularly attractive for the synthesis of ferroelectric materials since it can deposit stoichiometric and crystalline materials at low temperature. Deposition at low temperature (e.g. 300–500 °C) prevents the loss of volatile components from the film. However, simply preparing a film at low temperature using thermal sources would not yield a crystalline thin film since there is insufficient energy for elements to diffuse to the proper crystallographic sites. Laser ablation produces high kinetic energy particles (see Section 2) that can diffuse to the correct crystal sites after deposition and yield highly crystalline thin films at low growth temperatures.

PLD of crystalline and stoichiometric ferroelectric materials has been successful for a number of materials. For example, crystalline $PbTiO_3$ thin films have been deposited at only 350 °C using a KrF excimer laser ($\lambda = 248$ nm).[28] The low deposition temperature makes this a potentially attractive method for directly fabricating ferroelectric/semiconductor hybrid devices. A related solid that is more difficult to prepare in thin film form is $PbZr_{1-x}Ti_xO_3$. To maintain the Pb stoichiometry and ensure random mixing of Ti and Zr requires careful control of film synthesis conditions.[29,30]

Another recent application of PLD thin film synthesis has been in the area of magnetic ferrites. Thin film ferrites are of great technological interest since they could play a key role in high-density magnetic recording devices and in monolithic microwave integrated circuitry. It has been difficult to prepare thin films of ferrites due to their structural and compositional complexity. Attempts to prepare ferrites using sputtering and plasma spraying have not yet achieved high-quality thin films.

In contrast, synthetic investigations using PLD have been quite promising.[31,32] Recent studies of $Mn_xZn_{1-x}Fe_2O_4$ have shown that crystalline films can be prepared on $\langle 100 \rangle$ oriented MgO substrates. Because the physical properties (e.g. resistivity and saturation magnetization) of this ferrite depend

critically on the Mn:Zn:Fe ratio and the oxygen stoichiometry, PLD can be used to readily tune the properties of the films for specific applications. In addition, PLD has been used to grow high-quality epitaxial thin films of $BaFe_{12}O_{19}$ on ⟨0001⟩ sapphire and $Y_3Fe_5O_{12}$ on ⟨111⟩ garnet substrates. These results are quite promising and may lead to practical applications for thin film ferrites produced by PLD. More generally, however, they demonstrate the utility of PLD in the synthesis of complex inorganic thin films.

4.2 Synthesis of New Materials

Conventional synthetic methods for the preparation of inorganic materials involve reaction in the solid state. To facilitate diffusion and reaction in the solid state requires high temperature conditions. Hence, the products obtained from conventional solid-state reactions are typically limited to the ones thermodynamically stable at high temperature. In the past most solid-state synthetic studies have focused on high-temperature chemistry, although there is now a growing interest in the development of low-temperature approaches to inorganic solid-state synthesis.[33] Controlled low-temperature synthesis is a particularly attractive goal since it offers the possibility of obtaining new phases and materials with novel properties. PLD is an especially attractive method to explore the low-temperature synthesis of new materials since (1) stoichiometry can be readily controlled (i.e. laser evaporation is congruent irrespective of the equilibrium phase diagram) and (2) crystalline products can be grown at temperatures much lower than is possible with conventional solid-state reactions. Below, specific examples of the synthesis of several new materials by PLD are described.

The tetragonal infinite-layer phase of $SrCuO_2$, which consists of alternating Sr^{2+} and $CuO_2{}^{2-}$ sheets, represents the parent structure of the high-T_c copper oxide superconductors (Figure 3). In principle, this system is ideally suited for investigating high-T_c superconductivity since it contains only essential copper oxide layers and counterions. It has not been possible, however, to prepare and systematically dope this phase using conventional solid-state methods. Notably, recent studies in our laboratory have shown that it is possible to prepare this phase for a wide range of compositions, $Sr_{1-x}M_xCuO_2$ (M = Nd, Ca, Ba) using PLD.[33–35]

$Sr_{1-x}Ca_xCuO_2$ targets can be prepared using conventional solid-state methods at 900 °C. The $Sr_{1-x}Ca_xCuO_2$ targets are, however, multiphase, except for $SrCuO_2$ which has an orthorhombic structure. Laser ablation of these targets using a KrF laser and deposition onto ⟨100⟩ $SrTiO_3$ substrates at 500 °C yields single-phase materials for all values of x. The films can be structurally characterized using X-ray and electron diffraction. X-Ray diffraction scans ($\theta - 2\theta$) of $Sr_{1-x}Ca_xCuO_2$ films prepared by PLD are shown in Figure 4. These relatively simple diffraction patterns can be indexed as the infinite-layer phase (Figure 3), where the CuO_2 planes

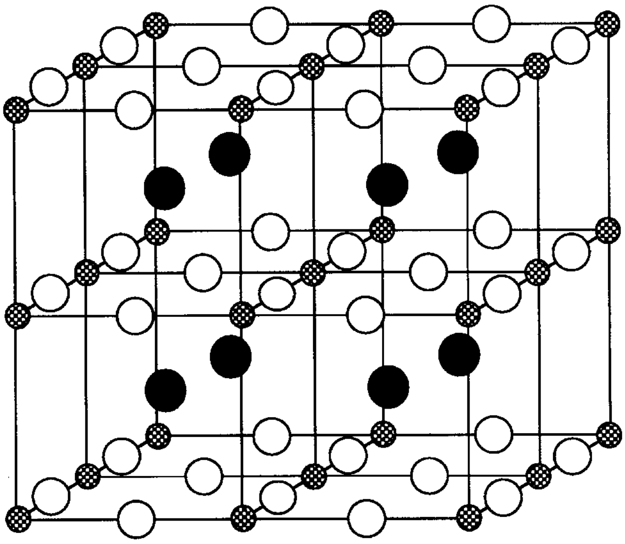

Figure 3 Structural model of the tetragonal infinite layer phase of $SrCuO_2$. The Sr^{2+} ions appear as isolated solid black spheres between the $CuO_2{}^{2-}$ layers. The copper ions are cross-hatched circles and the oxygen ions are open circles

are all oriented parallel to the surface of the ⟨100⟩ $SrTiO_3$ substrate. A simulation of the diffraction pattern expected for a thin film with this orientation also agrees quite well with the experimental data.

The $\theta - 2\theta$ diffraction scans elucidate the layered structure of the $Sr_{1-x}Ca_xCuO_2$ materials. Electron diffraction can be used to complete the structural identification of these thin film materials. Electron diffraction patterns recorded along the [001] plane axis characterize the in-plane structure. An example of an electron diffraction pattern recorded on a $Sr_{0.7}Ca_{0.3}CuO_2$ sample is shown in Figure 5. The diffraction peaks exhibit a square symmetry, as expected for the in-plane structure of the tetragonal infinite-layer phase. Simulations have been used to confirm this in-plane structure. Thus, the X-ray and electron diffraction measurements provide an unambiguous identification of the structure of these thin film materials.

It is also possible to characterize accurately the composition of new thin film materials using RBS. RBS analysis of the $Sr_{1-x}Ca_xCuO_2$ materials demonstrates that the single-phase infinite-layer thin films have the same average composition as the multiphase targets from which they were prepared by laser ablation. These compositional analysis results demonstrate that PLD can be used to prepare readily a specific stoichiometry material even when the target is not single phase.

Since it was not possible to prepare the infinite-layer $Sr_{1-}Ca_xCuO_2$ materials previously using conventional solid-state methods, it is important to clarify what features of PLD enable the general synthesis of this new phase. Structural studies of the $Sr_{1-x}Ca_xCuO_2$ products obtained from PLD

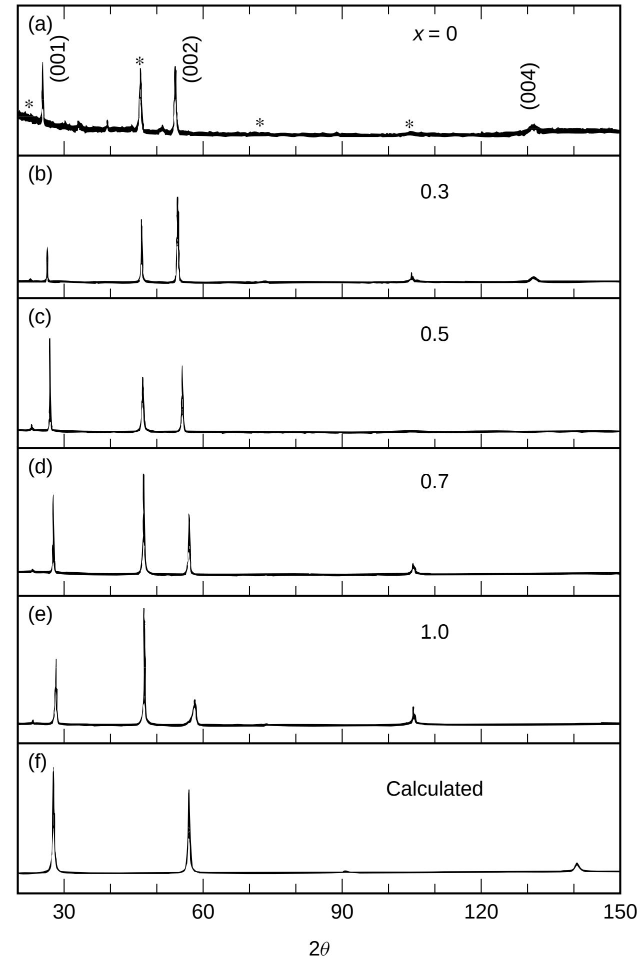

Figure 4 X-Ray diffraction patterns recorded on (a) $SrCuO_2$, (b) $Sr_{0.7}Ca_{0.3}CuO_2$, (c) $Sr_{0.5}Ca_{0.5}CuO_2$, (d) $Sr_{0.3}Ca_{0.7}CuO_2$, and (e) $CaCuO_2$. A simulation of the diffraction pattern for $SrCuO_2$ is shown in (f)

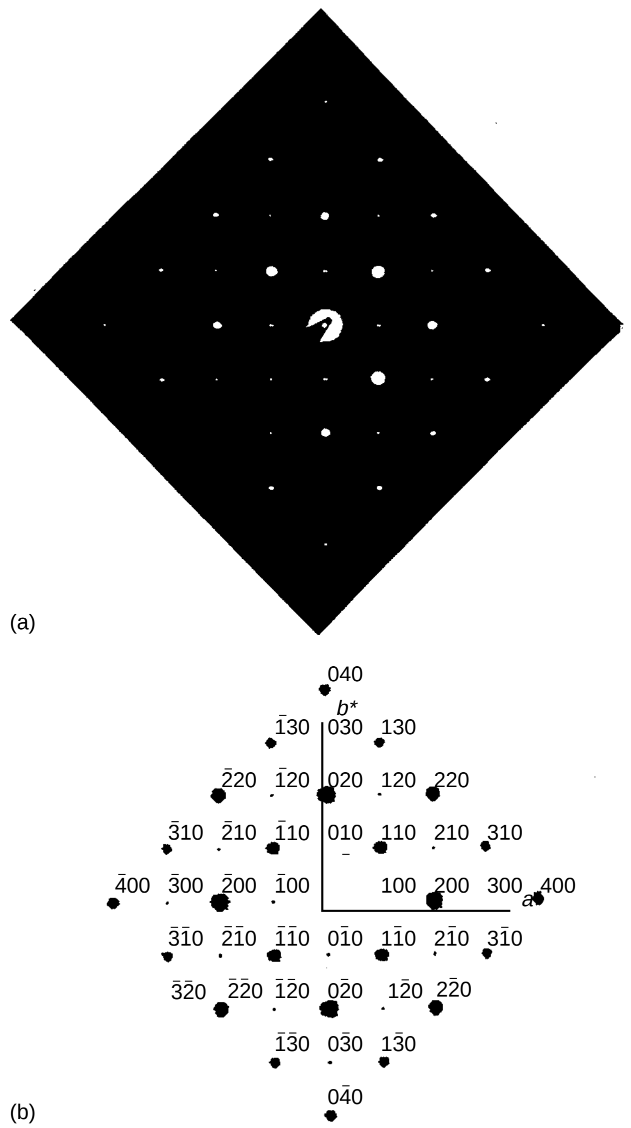

Figure 5 (a) Electron diffraction pattern recorded along the ⟨001⟩ zone axis of a $Sr_{0.7}Ca_{0.3}CuO_2$ sample. (b) Simulation of the diffraction pattern for the infinite-layer phase

growth at different temperatures provide key insight into this question. Temperature-dependent growth studies demonstrate that low-temperature growth is a key factor in stabilizing the infinite layer phase.[33–35] X-Ray diffraction patterns obtained from samples grown at temperatures from 500 to 700 °C (Figure 6) show that the concentration of the orthorhombic phase increases as the growth temperature increases. In the case of $SrCuO_2$, the orthorhombic phase, which is not a layered structure, is the single stable phase at high temperature. These results demonstrate that in the case of $Sr_{1-x}Ca_xCuO_2$, PLD can be used to trap a new metastable phase through low-temperature growth. This idea is expected to be generally useful for inorganic thin film synthesis in the future.

A second distinct example of PLD new materials synthesis involves substitutional doping of $YBa_2Cu_3O_7$.[36–38] It is well known that substitution of Y with other rare earth elements does not affect T_c significantly unless the rare earth is Pr. Indeed, $PrBa_2Cu_3O_7$ is not a superconducting material. To explain the disappearance of superconductivity in the Pr-substituted material it has been suggested that either Pr exists as Pr^{4+} (vs. Y^{3+}) or that the magnetic moment on Pr suppresses T_c. An experimental test of this hypothesis would be to prepare another M^{4+}-substituted compound and a M^{4+}/M^{2+} solid that would have the same average valence as Y^{3+}.

Substitution of Ce^{IV} for Y^{III} would be one possible choice, although it has not been possible to prepare single-phase Ce-doped solids. Nevertheless, PLD syntheses from multiphase $Ce_xY_{1-x}Ba_2Cu_3O_7$ targets yield high-quality single-phase materials. Since T_c is suppressed in the Ce-doped solids, these results indicate that M^{IV} cations may localize or trap

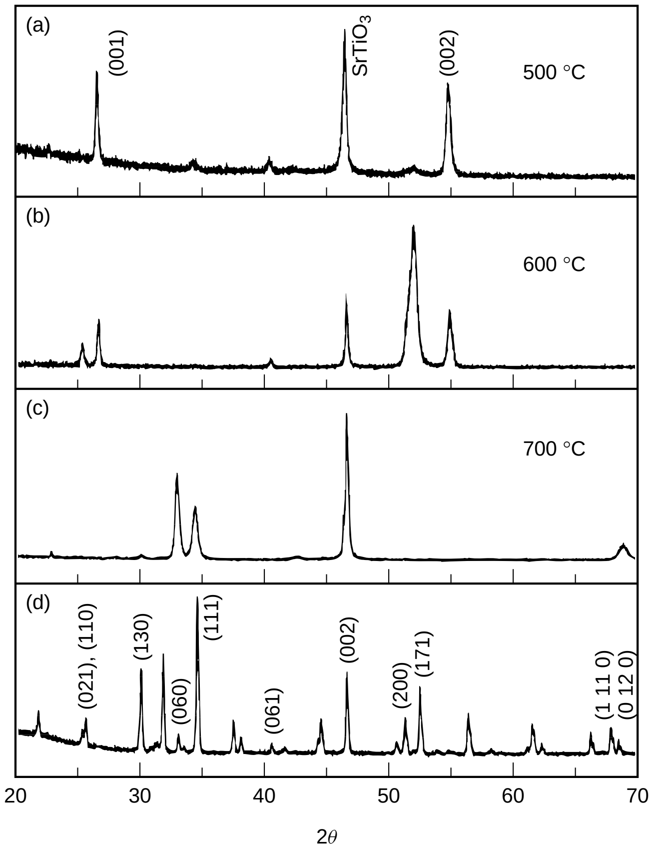

Figure 6 Series of X-ray diffraction patterns recorded on $SrCuO_2$ thin films that were deposited at (a) 500 °C, (b) 600 °C, and (c) 700 °C. The diffraction pattern for orthorhombic $SrCuO_2$ is shown in (d)

carriers in the solid. Similarly, PLD has also been used to synthesize $Pr_{0.5}Ca_{0.5}Ba_2Cu_3O_7$ materials from multiphase targets. Notably, the resulting thin films are single-phase crystalline Pr/Ca solids that exhibit superconductivity. On the basis of the studies of these new materials, which were prepared by PLD, it is apparent that it is the oxidation state of the substituted metal (and not magnetic moment) that is critical to T_c.

4.3 Novel Uses of PLD

As science and technology advances, it becomes increasingly important to integrate different materials with different physical properties into monolithic structures. From the perspective of thin film synthesis, integration requires precise control of the deposition, so that multiple layers can be studied.

One method of meeting this challenge is to use PLD to prepare materials a single layer at a time, so-called layer-by-layer growth.[39–42] To achieve layer-by-layer growth requires careful control of deposition. This can be done by calibrating the rate of thin film growth for ablation of specific targets with controlled laser power densities. Alternatively, growth can be monitored in situ using RHEED.

Kawai and co-workers have used in situ RHEED to synthesize $Bi_2Sr_2CuO_6/Bi_2Sr_2CaCu_2O_8$ superlattices and $Bi_2Sr_2Ca_{n-1}Cu_nO_x$ thin films where n can be as large as 8–10.[39–41] Similar ideas have also been used to carry out band-gap engineering in semiconductor materials. Band-gap engineering is a term coined to describe artificial structures that can be built up atomic layer by atomic layer. For example, Cheung and Shakur have reported the growth of $Hg_{1-x}Cd_xTe$ epitaxial layers with any predetermined composition.[43] The volatility of Hg is a problem in conventional film preparation; however, stoichiometric Hg–Cd–Te thin films can be prepared using low-temperature PLD. These examples of synthesis with atomic layer control represent a unique application of PLD, and suggests that it may be possible to build up very complex architectures in inorganic thin films with novel properties in the future.

5 SUMMARY

In conclusion, this article has introduced the importance of thin films in basic research and technology, and has reviewed thin film synthesis using PLD. From the standpoint of the synthesis of complex and new inorganic materials, PLD can be seen as a simple yet powerful synthetic tool. PLD has many unique features, including congruent target evaporation and low-temperature growth, that make it suitable for thin film preparation. We believe that this technique offers an exciting opportunity for inorganic synthesis in the future.

1 TIN METAL[1]

Tin has been used by man for many centuries; it is mentioned in early books of the Old Testament. The alloying of copper with tin was discovered ca. 3500 BC, although the isolation of the pure metal probably dates much later, from 800 BC or so.

The abundance of tin is 2.1 parts per million and it is about the 48th most abundant element. Tin occurs mainly as cassiterite, SnO_2, with other, and minor, ores containing tin sulfides. Reduction of cassiterite is carried out using carbon in a reverberatory furnace at 1200–1300 °C. The major producers of tin are Malaysia, Indonesia, Thailand, Zaire, China, and Bolivia; Brazil, too, is developing its production of tin.

Tin has two allotropes: the stable modification above 13.2 °C is white, tetragonal, β-Sn. Below 13.2 °C, the thermodynamically stable form is gray α-Sn, which has a cubic diamond structure; however, the transformation is very slow and requires long exposure much below this temperature for extensive transformation. The transformation of β-Sn to α-Sn is also termed tin pest or tin disease and involves a structural distortion along the c-axis, with a density increase of 26%, i.e. the high temperature form is the more dense form.

Tin in the α-form, which has the diamond structure, has four nearest neighbours at 2.80 Å with six Sn–Sn–Sn valency angles of 109.5°. The β-form has a structure in which the Sn–Sn–Sn angles are two at 94° and four at 149.5°, with each tin having four neighbours at 3.02 Å and two at 3.18 Å. The transformation between the two allotropes is accompanied by a redistribution of the valency electrons: Mössbauer isomer shifts are 2.10 mm s^{-1} and 2.65 mm s^{-1} for the α- and β-forms, respectively.

Table 1 lists some properties of elemental tin.

1.1 Reactions of Tin

Tin forms compounds in the +II and +IV oxidation states; in the Sn^{IV} state tin uses all its $5s^25p^2$ valence electrons in bonding, while in the Sn^{II} state normally only the $5p^2$ valence electrons are used.

Potentials for $Sn^0 \rightarrow Sn^{II} \rightarrow Sn^{IV}$ are shown in equations (1) and (2).

$$\text{Acid solution:}\quad Sn \xrightarrow{0.136\,V} Sn^{II} \xrightarrow{-0.15\,V} Sn^{IV} \qquad (1)$$

$$\text{Basic solution:}\quad Sn \xrightarrow{0.91\,V} Sn^{II}(OH)_3^- \xrightarrow{0.93\,V} [Sn^{IV}(OH)_6]^{2-} \qquad (2)$$

The +IV state is more stable than the +II state, but the energy difference between the two states is low. Extensive chemistries for both oxidation states are known.

There are only a few known stable species in the +III oxidation state, e.g. the bulky $\cdot Sn[N(SiMe_3)_2]_3$ has a high kinetic stability; generally compounds in the +III oxidation state are unstable with respect to disproportionation.

Tin, although more reactive than germanium, is inert to water, air, hydrogen, and ammonia at ambient temperatures. However, tin does react with water vapor at temperatures

above 700 °C, and reacts with air or oxygen at 200 °C to give SnO_2. Dilute hydrochloric acid and dilute sulfuric acid have little, if any, reaction with tin, but concentrated acids produce $SnCl_2$ and H_2 (from HCl) and $SnSO_4$ and SO_2 (from H_2SO_4). Dilute nitric acid is reported to give $Sn(NO_3)_2$ and NH_4NO_3. As noted by the above, Sn^{II} compounds are significant products in the reaction with these acids.

Tin metal reacts with chlorine and bromine in the cold and with fluorine and iodine on heating to give tin(IV) tetrahalides. Sulfur and selenium react vigorously with tin on heating to give tin(II) or tin(IV) chalcogenides, depending on the mole ratio of the elements used; reaction with tellurium only provides the tin(II) telluride.

Tin dissolves in hot aqueous alkali solutions to give hydroxystannates, $M_2[Sn^{IV}(OH)_6]$.

The reaction of $N(CH_2CH_2OCH_2CH_2OCH_2CH_2)_3N$ (crypt) with alkali metal–tin alloys in $H_2NCH_2CH_2NH_2$ produces[2] such polytin anionic species as $[K(crypt)]_2{}^+[Sn_4]^{2-}$ (tetrahedral tin), $[Na(crypt)]_2{}^+[Sn_5]^{2-}$ (trigonal bipyramidal tin), and $[Na(crypt)]_4{}^+[Sn_9]^{4-}$ (monocapped square antiprismatic tin) (Figure 1). Mixed zintl anions have also been characterized, including $[Sn_2Bi_2]^{2-}$, $[TlSn_9]^{3-}$, and $[TlSn_8]^{3-}$ (*see* ***Zintl Compounds***).

Some bond distances and energies of Sn–X bonds are given in Table 2.

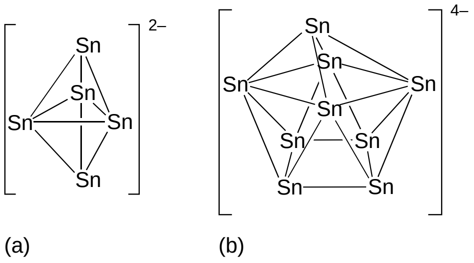

Figure 1 Two types of metallic tin clusters (a) $[Sn_5]^{2-}$, (b) $[Sn_9]^{4-}$

Table 2 Bond distances and energies[1]

2 TIN(II) COMPOUNDS[3,4]

2.1 General Considerations

Bivalent tin, in its compounds, is rarely found with a spherical symmetry. This is a consequence, in the condensed phases, of a ready distortion of the nonbonding pair of electrons (which are $5s^2$ in the free gaseous ion) due, for example, to the adoption of some p character. The lone pair therefore frequently has stereochemical activity. In addition, the nonbonding pair of electrons in tin(II) species can be used in coordination with acceptors or Lewis acids; furthermore, the empty 5p or d orbitals can be used to interact with donors or Lewis bases.

The simplest structural arrangement for tin(II) compounds is the angular geometric array (Figure 2). The ground state structure calculated for SnH_2 is the angular singlet state ($^1A_1$); the triplet ($^3B_1$) state has a higher energy. The tin(II) halides, SnX_2 (X = F, Cl, or Br), have also been shown to have the angular structure in both the vapor phase and in low-temperature inert matrices. Other SnX_2 compounds having an angular structure are those with extremely bulky ligands, X, e.g. X = [2,6-t-Bu_2-4-MeC_6H_2O],[5] $(Me_3Si)_2N$,[6] and 2,4,6-t-$Bu_3C_6H_2S$.[7] Table 3 lists some structural details of compounds having this basic angular geometry.

However, if longer contacts can also be taken into account, different geometries can be assigned, e.g. for $(Me_3Si)_2N$–Sn–NCS in the solid state,[8] as well as the two short Sn–N distances at 2.250(6) and 2.079(5) Å, there are two intermolecular Sn···S contacts at 3.047(2) and 3.316(2) Å. If both the Sn···S distances are considered to be significant,

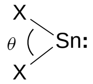

Figure 2 The angle (θ) formed between the substituents in divalent tin compounds

Table 3 Structural data for angular geometric Sn^{II} compounds[4]

Compound	M–X (Å)	X–M–X, θ (°)	Method
SnH_2 ($^1A_1$)	1.756	92.7	Calculation
SnH_2 ($^3B_1$)	1.707, 1.77	118.2, 93	Calculation
SnF_2	–	94(5)	ED
$SnCl_2$	2.347(7)	99(1)	ED
$SnBr_2$	2.55(2)	95	ED
$Sn[N(SiMe_3)_2]_2$	2.096(1), 2.088(6)	104.7(2)	X-ray
	2.09(1)	96	ED
$(SCN)SnN(SiMe_3)_2$	2.079(5), 2.250(6)	94.1(2)	X-ray
$Sn(OC_6H_2Me$-4-t-Bu_2-2,6$)_2$	1.995(4), 2.002(4)	88.8(2)	X-ray
$Sn(SC_6H_2$-t-Bu_3-2,4,6$)_2$	2.435(1)	85.4(1)	X-ray

then a pseudotrigonal bipyramidal geometry, with the tin nonbonding pair in an equatorial site, is realized.

It is generally found that bivalent tin compounds, wherever possible, adopt structures, by means such as bridging, chelation, and coordination, in which tin attains coordination numbers greater than two. Some basic structures found for tin(II) compounds having these higher coordination numbers are given in Table 4.[4] A frequently found tin(II) environment has a trigonal pyramidal arrangement of three short Sn–X distances coupled with three much longer Sn–X contacts, at or near the limits for bonding. The longer interactions can be considered to be a consequence of the hindrance by the nonbonding electron pair to the approach of ligands towards tin. If all six contacts are taken into account, the overall geometry can be deemed to be octahedral or, preferably, distorted octahedral.[3] An example of this structural arrangement is that shown by tin(II) sulfate,[9] in which there are three Sn–O bonds between 2.25 and 2.27 Å and three Sn–O contacts between 2.92 and 2.99 Å. Other compounds having this type of structure are $[NH_4]_2[Sn(O_2POH)_2]$[10] and $K[Sn(O_2CCH{=}CHCO_2)(O_2CCH{=}CHCO_2H)]$[11] (Figure 3).

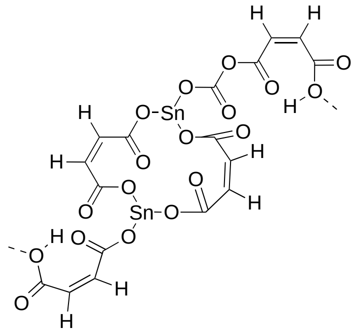

Figure 3 The trigonal pyramidal Sn environments with the three short Sn–O contacts shown

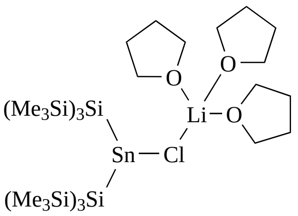
Despite its bulky ligands, $[(Me_3Si)_3Si]_2(Sn(\mu\text{-}Cl)Li(THF)_3]$ (**1**), obtained from $SnCl_2$ and $LiSi(SiMe_3)_3$, has a three-coordinate tin atom with a bridging chloride ion.[12]

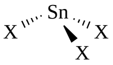


(**1**)

As stated earlier, and as shown in Table 3, very bulky tin(II) amides, $Sn(NR)_2$, alkoxides and aryloxides, $Sn(OR)_2$, and thiolates, $Sn(SR)_2$, can exist as monomeric angular-shaped species, even in the condensed phases. With less bulky groups, there is a strong tendency to form oligomers, e.g. dimers and trimers such as (**2**)–(**4**), and even polymeric species for compounds with small ligands, e.g. $[Sn(OR)_2]_n$ (R = Me or Et). Compounds (**2**)[13] and (**3**)[14] in the solid state have tin atoms with trigonal pyramidal geometries, while in (**4**)[4] the geometry of the terminal atoms is also trigonal (ignoring the lone pair). The geometry of the central tin atom in (**4**) can be considered to be pseudotrigonal bipyramidal with an equatorial lone pair.

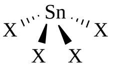
Table 4 Basic structures of Tin(II) compounds having coordination numbers greater than two[4]

Three-coordinate Sn



Pyramidal, e.g. SnS, SnO_4, orthorhombic SnSe

Four-coordinate Sn

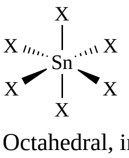


Pseudotrigonal pyramidal, e.g. $Sn(O_2CH_2)$, $[SnCl_4]^{2-}$, $Sn(S_2COMe)_2$

Five-coordinate Sn

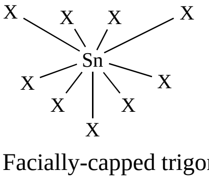
tris(pyrazolyl)boratotin

Six-coordinate Sn

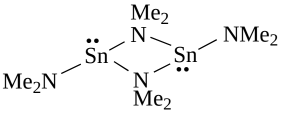


Octahedral, including distorted octahedral, e.g. cubic SnSe, SnTe

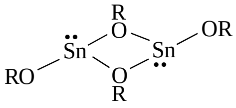
Nine-coordinate Sn



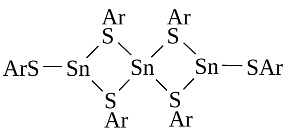
Facially-capped trigonal prismatic, e.g. $Sn(NCS)_2$, $[Sn(SbF_6)_2][AsF_3]_2$, $SnCl_2$ (solid state), $SnBr_2$ (solid state)



(**2**) *d*(Sn–N) = 2.07, 2.67, and 2.67 Å
next Sn..N = 2.98 Å

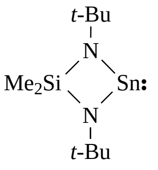


(**3**) R = *t*-Bu or Me_3Si

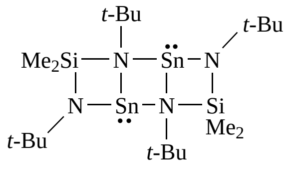


(**4**) Ar = 2,6-*i*-$Pr_2C_6H_3$

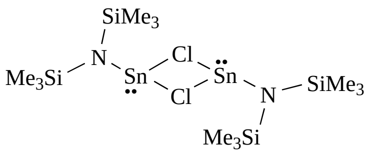
The compound *t*-$BuNSiMe_2N$-*t*-BuSn (**5**) exists in the solid state both as a monomer (**5a**) and a dimer (**5b**); in the gas phase and in benzene solution (**5**) is monomeric.[15] The chloroamides (**6**) and (**7**) are dimeric in the solid state due to chloride bridging; of interest, (**6**) is a *trans* dimer in the



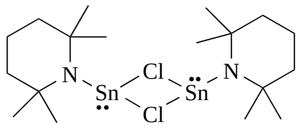
(**5a**)



(**5b**)



(**6**)

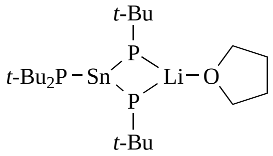


(**7**)

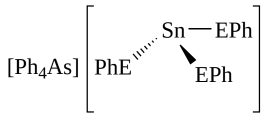
solid state, while (**7**) is a *cis* dimer.[16] In toluene solution, (**7**) undergoes *cis–trans* isomerization.

Also dimeric in the solid state is the series of compounds $[Sn(O\text{-}t\text{-}Bu)X]_2$ (X = Cl, O-*t*-Bu, and $N(SiMe_3)_2$); for this series of compounds, bridging is via the *t*-butoxy group.[17]

Bis(bis-*t*-butylphosphino)tin(II), obtained[18] from KP-*t*-Bu_2 and $SnCl_2$ (2:1 mole ratio), has been reported to be dimeric in benzene solution. The complexes $[LiSn(P\text{-}t\text{-}Bu_2)_3{\cdot}THF]$ (**8**), obtained[19] from LiP-*t*-Bu_2 and $SnCl_2$ (3:1 mole ratio), and $[Ph_4As][Sn(EPh)_3]$ (**9**; E = S or Se)[20] all have three-coordinate trigonal pyramidal tin atoms in the solid state.

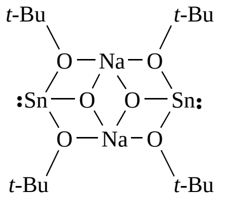


(**8**) *d*(Sn–P) = 2.671–2.814 Å
δ^{119}Sn = −1310 ppm



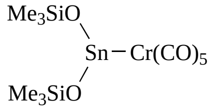
(**9**)
E = S, *d*(Sn–S) = 2.522–2.552 Å
δ^{119}Sn = 146 ppm
E = Se, *d*(Sn–Se) = 2.649–2.671 Å
angle Se–Sn–Se = 88.7–97.3°
δ^{119}Sn = 208 ppm

Monomeric, dimeric, and polymeric metal tin tris(*t*-butoxides) $[M(O\text{-}t\text{-}Bu)_3Sn]$ (**10**; M = In) and (**11**; M = Tl), $[M(O\text{-}t\text{-}Bu)_3Sn]_2$ (**12**; M = Li or Na), and $[M(O\text{-}t\text{-}Bu)_3Sn]_n$ (M = K, Rb, or Cl)[21,22] all contain three-coordinate trigonal bipyramidal tin, e.g. (**12**; M = Na). The indium (**10**) and thallium (**11**) complexes undergo[22] interesting regioselective complexations on reaction with $M(CO)_6$ (M = Cr or Mo); the favored site for coordination in the indium compound (**10**) is at indium, to give (**13**), in contrast to the tin site in the thallium complex (**11**). As shown in Scheme 1, additional complexation of (**13**) can occur at the Sn site; structural isomers of (**14**) have been obtained, e.g. (**14**; M = Mo, M′ = Cr) and (**14**; M = Cr; M′ = Mo). The four metals in (**14**) form a near linear arrangement.

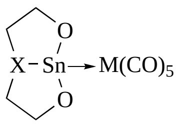


(**12**) M = Na

Tin(II) can act as a donor.[4] Complexation of various divalent tin compounds by Lewis acids has been realized, many in transition metal complexes, e.g. (**15**) and (**16**), but also with main group Lewis acids, e.g. (**16**).

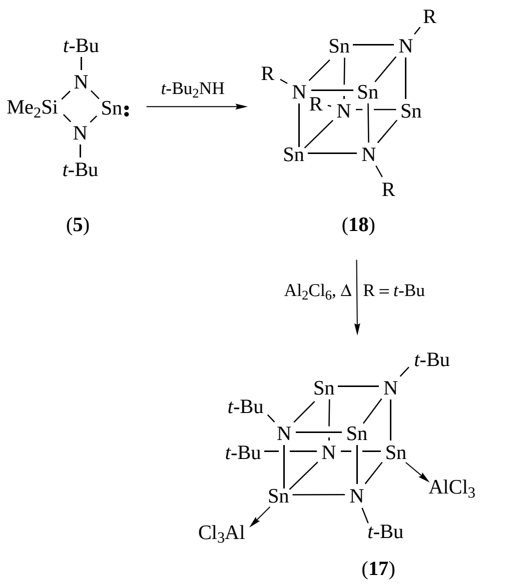


(**15**)



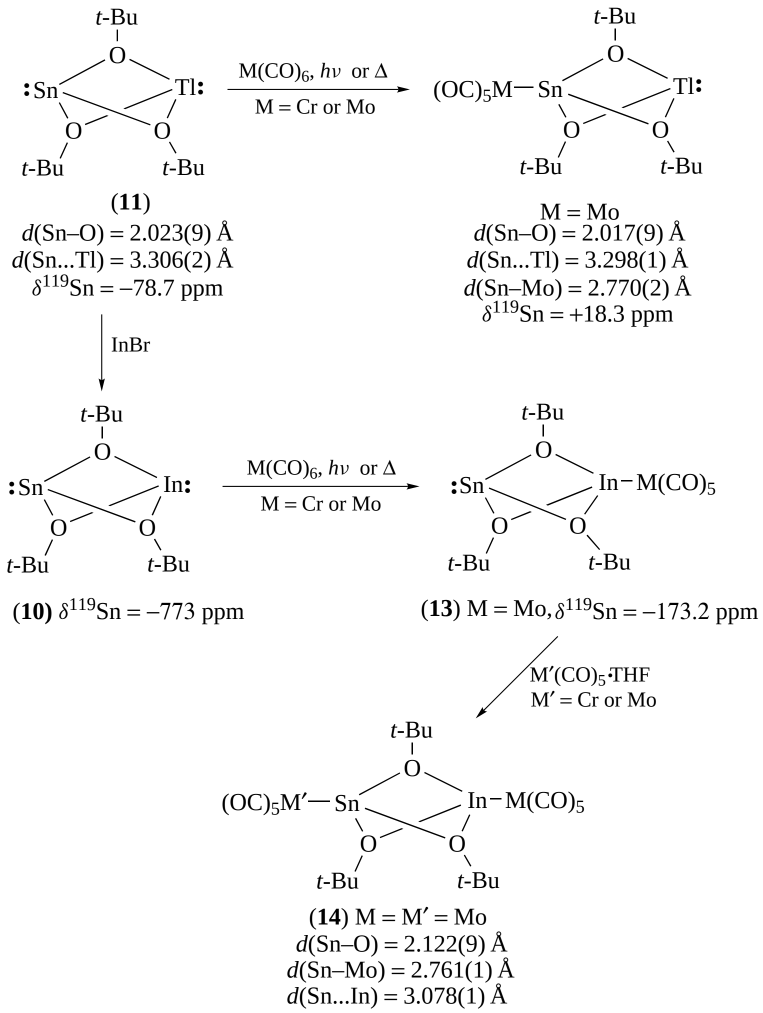
(**16**) M = Cr, Mo, or W;
X = *t*-BuN, PhO, O, or SO

Bivalent tin compounds can act both as donors and as acceptors in the same molecule, as in $F_3B \leftarrow SnX_2 \leftarrow NMe_3$ (X = Cl, Br).[23] The acceptor–donor complex (**17**) was obtained on treatment of the tin–nitrogen cage compound (**18**) with Al_2Cl_6; (**18**) was produced from (**5**) and *t*-Bu_2 NH (equation 3). Various other tin–nitrogen cages have been characterized, e.g. (**19**)–(**22**).[24–26]

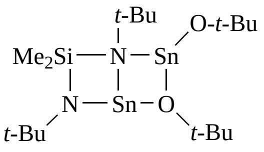


(**5**) (**18**) (**17**)

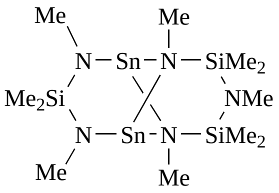
(3)



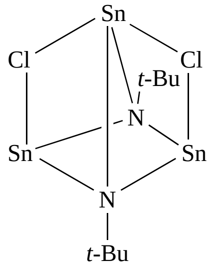
Scheme 1



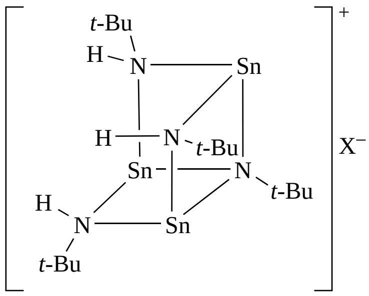
(**19**)



(**20**)



(**21**)



(**22**)

The coordination number at tin can be expanded on chelation, as shown for example in $Sn(S_2COMe)_2$ (**23**),[27] in bis(ethyl cysteinato)tin(II) (**24**),[28] and in the β-diketonato complexes (**25**);[29] compounds (**23**)–(**25**) have pseudotrigonal pyramidal tin atoms, with equatorial lone pairs. Combinations of coordination and chelation, e.g. in (**26**)[30] and (**16**), and chelating and bridging, e.g. in (**27**),[31] further expand the coordination number.

Another common tin geometry in bivalent tin compounds is a distorted four-coordinate pyramidal arrangement; in this array there are two shorter and two longer bonds, e.g. as in sodium bisoxalatostannate(II) $Na_2Sn(C_2O_4)_2$ (**28**)[32] and in $Sn(O_2PH_2)_2$ (two Sn–O at 2.16 Å and two Sn–O at 2.35 Å, with next nearest neighbor at 3.36 Å; O–Sn–O from 79.0 to 151.4°).[3]

Although the majority of bivalent tin(II) compounds contain tin with a lone pair distorted geometry, some

highly symmetric octahedral tin(II) geometries have been found in some compounds, e.g. black $CsSnBr_3$, which has a perovskite lattice,[33] and in the high temperature form of $CsSnCl_3$.[34] In these compounds the high symmetry results from delocalization of the nonbonding electrons into solid-state bands. Tin(II) compounds having higher symmetry geometries have unusual optical and electrical solid-state properties, e.g. $CsSnBr_3$ is an electrical conductor and exhibits photoemission effects. Greatest distortion from symmetric tin(II) environments are realized for compounds with bonds to the lighter elements (e.g. N, O, and F).[3]

A rationale for the bonding in high symmetry bivalent tin(II) compounds is based on the energy levels of ligand (X) and Sn orbitals[3] (Figure 4). For $[SnX_3]^-$ (X = halide) it was argued that the stereochemical activity of the tin lone pair depends on the directional tin $5p_z$ orbital character in the nonbonding tin lone pair orbital. In order to form a strong a_1 bond, the tin 5s and $5p_z$ orbitals mix to give a hybrid orbital of a similar energy to that of the halogen np orbital. Thus for bonding to F the tin a_1 bonding orbital is rich in 5s character, but for I it is rich in $5p_z$ character. Hence the lone pair orbital in $[SnF_3]^-$ has a high $5p_z$ (i.e. directional) component and in $[SnI_3]^-$ it has a high 5s (i.e. nondirectional) component. The increase in the 5s character of the nonbonding pair on tin, from fluoride to iodide, results in more symmetric and less distorted structures. Further reduction in distortion can result from population of empty delocalized bonds in the solids by the nonbonding electron pair. For perovskite $CsSnBr_3$ a delocalized band system arises from the overlap of empty bromide t_2 4d-orbitals; on population of this solid-state band by the tin nonbonding electrons the distortive consequences of the nonbonding orbital are reduced.

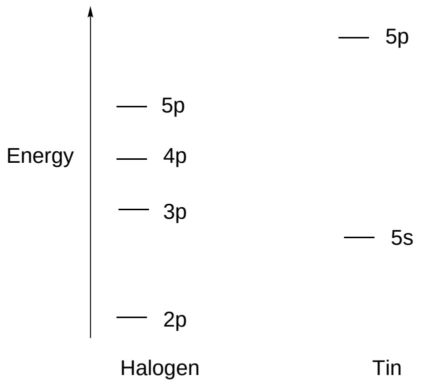

Figure 4 Relative binding energies of tin 5s and 5p and halogen np orbitals

Of interest, black $CsSn^{II}Br_3$ has a similar structure to white $Cs_2Sn^{IV}Br_6$, but $Cs_2Sn^{IV}Br_6$ has none of the optical/electric properties of $CsSnBr_3$. It has been argued that $Cs_2Sn^{IV}Br_6$ has a similar low-energy band to that of $CsSnBr_3$ but, unlike in $CsSnBr_3$, there are no high-energy nonbonding electrons present to populate the empty band.

The high symmetry Sn^{II} solid-state environment is only found in those compounds in which the distorting effect of the lone pair orbitals is reduced by allowing the electrons to populate a low-energy delocalized solid-state band in the structure. Tetragonal tin(II) oxide has short Sn–Sn contacts and in this compound the lone pair orbitals in tin can be used to populate the solid-state band, formed by overlap of the tin empty d-orbitals.

The nonbonding electrons on tin can also be delocalized into cluster molecules such as $K_3Sn_2(SO_4)_3Br$, which has a 3D network structure[35] of tin atoms and bridging sulfates, and also $Cs_2Sn_6Br_3F_{11}$, obtained from CsBr and SnF_2 (1:2 mole ratio).[36] There are three distinct tin sites in $Cs_2Sn_6Br_3F_{11}$, with

strong tin bonding only to fluoride; each site has one short and one long Sn–F bond with additional bonding patterns being made up from Sn–F and cluster interactions involving Br atoms.

2.2 Solution Studies of Tin(II) Compounds

Bivalent tin species in acid solutions are frequently of the pyramidal $[SnX_3]^-$ type, (e.g. X = halide, pseudohalide, or carboxylate group). Increases in the coordination number beyond three are not normally realized. The $[SnF_3]^-$ ion is the stable and dominant ion in solutions containing excess F^-; however, when insufficient F^- is present, species such as $[F_2Sn(\mu\text{-}F)SnF_2]^-$ result.

The major species in alkaline solutions is $[Sn(OH)_3]^-$; however, $[(HO)_2Sn(\mu\text{-}O)Sn(OH)_2]^{2-}$ has also been detected. At high pH the dominant species is $[Sn_3(OH)_4]^-$.

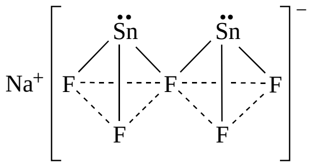
Several bivalent tin compounds have appreciable water solubilities, e.g. the solubility of tin(II) chloride is 83.9 g in 100 mL at 0 °C, that of tin(II) fluoride is 4.1 g in 100 mL at 25 °C, and of tin(II) sulfate is 35.2 g in 100 mL at 10 °C. Aqueous solutions are susceptible to hydrolysis to hydrous tin(II) oxide and oxidation to Sn^{IV} species; the stability of aqueous solutions depends upon the anions present and the pH. The presence of anions that are able to form strong complexes with Sn^{II}, e.g. F^- or OAc^-, enhances resistance to hydrolysis and oxidation. Ease of hydrolysis increases with pH; at very high pH, disproportionation of Sn^{II} to Sn^0 and Sn^{IV} results.

Certain bivalent tin salts have solubilities in nonaqueous solvents, e.g. tin(II) chloride is soluble in many organic solvents, including alcohols, acetone, THF, and pyridine, probably to give rise to three-coordinate pyramidal $[SnCl_2{\cdot}L]$-type complexes. Other selected solubilities are $SnBr_2$ in methanol, pyridine, or THF and tin(II) formate in $HO(CH_2)_3OH$. Bivalent tin species are also soluble in acetonitrile solution, to give $[Sn(MeCN)_n]^{2+}$ (n = 2, 3, or 6), and in liquid ammonia, to give $[Sn(NH_2)_3]^-$.

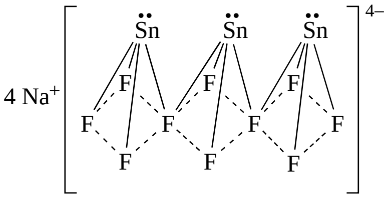
2.3 Tin(II) Halide Species in the Solid State

In both the orthorhombic and monoclinic forms of tin(II) fluoride, the basic structural unit is the $[SnF_3]$ trigonal pyramid; additional fluoride bridging leads to pseudotrigonal, bipyramidal, and distorted octahedral tin geometries, respectively. Discrete $[SnF_3]^-$ anions are found in $[NH_4][SnF_3]$; however, in general the strong tendency for fluorine bridging is realized, e.g. in $Na[Sn_2F_5]$ (**29**), $Na_4[Sn_3F_{10}]$ (**30**) (both obtained from NaF and SnF_2 in aqueous solution), and $K[SnF_3]{\cdot}0.5H_2O$ (**31**).[4]

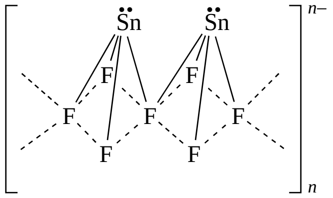
Various mixed halofluorotin(II) species, e.g. Sn_2F_3Cl, Sn_3F_5Br, Sn_2F_3I, and $[Sn_5F_9]BF_4$, contain pyramidal $[SnF_3]$ or distorted pyramidal $[SnF_4]$ units. Additional halide or BF_4 ions occupy holes in the network. Compounds [SnFCl] and [SnF(NCS)] have ribbon-like structures, with tin in pseudotrigonal bipyramidal sites (e.g. **32**).



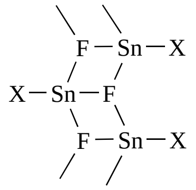
(**29**) Corner-sharing pyramids



(**30**) Edge-sharing square pyramids



(**31**) Anionic arrangement in (**30**)



(**32**) X = Cl or NCS

Tin(II) chloride (mp 246 °C) and tin(II) bromide (mp 216 °C) have the $PbCl_2$-type lattice. In this, tin has nine halide neighbors from three different layers, six at the apexes of a trigonal prism and three in facially capped positions; only three of the tin halide interactions are weak.[37]

Tin(II) iodide (mp 316 °C) (from Sn and I_2 in 2 M hydrochloric acid) has a unique layered structure: tin(II) atoms are in two sites. Two-thirds of the tin atoms are in sites based on the $PbCl_2$-type structure, while the remainder are in $PdCl_2$-type chains, which interlock with the $PbCl_2$-type part of the structure to give almost perfect octahedral coordination.[38]

Many complexes of the types $SnX_2{\cdot}L$ and $SnX_2{\cdot}2L$ have been investigated.[4] The basic unit of crystalline $[SnCl_2{\cdot}2L]$ (L = H_2O or $S{=}C(NH_2)_2$) is a pyramidal $[SnCl_2L]$ unit, which is tightly bound into 3D structures by hydrogen bonding and/or chloride and sulfur bridging. The structure of polymeric $[SnCl_2{\cdot}1,4\text{-dioxane}]_n$ consists of angular $[SnCl_2]$ units bridged

by dioxane ligands to produce pseudotrigonal bipyramidal tin. Different structures arise with $SnCl_2 \cdot L$ (L = phen, bipy); in these chain complexes the tin atoms are chelated by the ligand, L, and have two strong and two weak interactions with chlorine.

The tin(II) bromide hydrates $[(SnBr_2)_2 \cdot H_2O]$, $[(SnBr_2)_3 \cdot H_2O]$, and $[(SnBr_2)_6 \cdot 5H_2O]$ all have structures based on trigonal prismatic geometry, in which the tin atom is surrounded by a trigonal prism of six bromine atoms and further bromines and water (or vacancies) at the facially capped sites.[4]

Discrete isolated $[SnCl_3]^-$ anions occur in $[Co(en)_3][SnCl_3][Cl]_2$. The $[SnCl_4]$ ion in $[Co(NH_3)_6][SnCl_4][Cl]$ has a pseudotrigonal bipyramidal geometry. No interaction occurs between $[SnCl_3]^-$ and $[Cl]^-$ in this complex, unlike the situation in $[NH_4]_2[SnCl_3][Cl] \cdot H_2O$, which has a highly distorted octahedral tin atom. A similar tin environment is found in the low-temperature form of $CsSnCl_3$, i.e. three long and three short Sn–Cl bonds; in contrast, the high-temperature form has a cubic perovskite structure, in which tin has an ideal cubic geometry. Tin also has a regular octahedral geometry in $[MeNH_3][SnBr_xI_{3-x}]$ ($x = 0$–3) and in $CsSnI_3$ compounds.

2.4 Tin(II) Chalcogenide Derivatives[4]

Tin(II) oxide exists in several modifications. The commonest is blue-black tetragonal tin(II) oxide, formed by alkaline hydrolysis of a tin(II) salt; it has a layer lattice with square pyramidal coordination at tin and equal Sn–O distances (Sn···Sn distances between Sn atoms in adjacent layers are 3.70 Å, close to the values in β-Sn). Tin(II) oxide is amphoteric and dissolves in aqueous acid and alkalies. Tin(II) hydroxide, $Sn(OH)_2$, has been obtained from Me_3SnOH and $SnCl_2$. Tin(II) sulfide has a structure with parallel zig-zag – Sn–S– chains, which are connected by short interchain Sn···S contacts; this gives a basic pyramidal $[SnS_3]$ unit. Tin(II) selenide (mp 861 °C) exhibits one phase which is isomorphous with SnS and a second cubic phase with the NaCl lattice; the latter is also taken up by tin(II) telluride.

$Sn_3(PO_4)_2$ and other phosphates, e.g. $Sn[O_2PO(OH)]$, $Sn[OPO(OH)_2]_2$, $Sn_2P_2O_7$, and $Sn(PO_3)_2$, have been reported. The structure of tin(II) sulfate, from tin and aqueous $CuSO_4$, consists of $[SO_4]$ groups linked into a framework of O–Sn–O bonds, and as pointed out in Section X.X, tin has three short oxygen contacts and three longer oxygen contacts.

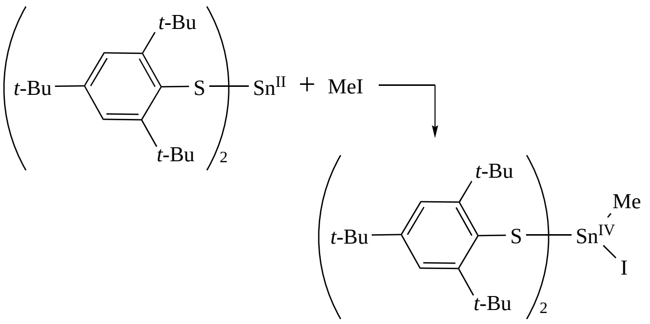
Hydrolysis of tin(II) salts yields various oxotin ions; these species have similar structures, e.g. $Na_2[Sn_2O(OH)_4]$, which contains the $[Sn(OH)_3]^-$ unit, $Na_4[Sn_4O(OH)_{10}]$, which contains the oxo-bridged $[(HO)_2SnOSn(OH)_2]^{2-}$ anion, and $Ba[SnO(OH)]_2$, which contains the one-dimensional $[SnO(OH)]_\infty^{\infty-}$ polyanion.[39] These three oxotin species all have pyramidal coordination at tin.

The discrete cation in $[Sn_3O(OH)_2][SO_4]$ contains one tin atom with a pyramidal geometry and two in distorted square pyramidal (four-coordinate) geometry.[40] The hydrate $3SnO \cdot H_2O$ has an adamantane-like $[Sn_6O_8]$ structure, similar to that found in $[Sn_6O_4(OMe)_4]$; the latter compound was obtained by the controlled hydrolyses of $Sn(OMe)_2$. The tin atoms in $[Sn_6O_4(OMe)_4]$ have a distorted pseudotrigonal bipyramidal geometry.[41]

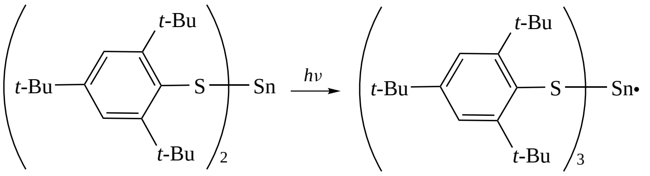
The basic salt $[Sn_3(OH)_4(NO_3)_2]$ has been obtained from hydrous SnO and aqueous HNO_3; anhydrous $Sn(NO_3)_2$ is unknown.

2.5 Other Reactions of Tin(II) Compounds

Inorganic tin(II) compounds can form tetravalent tin compounds on oxidative addition (equation 4).[7] UV irradiation of bivalent tin(II) can provide Sn^{III} radical species (equation 5).[7] Other typical reactions of bivalent tin include substitutions. Examples are shown in Scheme 2.[7]



(4)



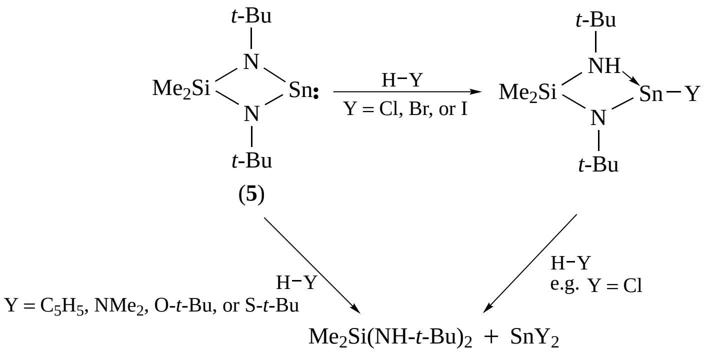
(5)

3 TIN(IV) COMPOUNDS[3]

Tin(IV) oxide is amphoteric and dissolves in aqueous acids or alkali solutions. The predominant tin species in appropriate acid solutions are of the type $[SnX_6]^{2-}$, where X = halide or pseudohalide, and also mixed anions $[SnX_nX'_{6-n}]^{2-}$ (e.g. X, X′ = halides or pseudohalides).

The main species in highly basic solutions is $[Sn(OH)_6]^{2-}$; in less basic solutions $[SnO_3]^{2-}$ is obtained. Tin(IV) sulfide is soluble in aqueous alkaline media, containing sulfide ion, to give $[SnS_3]^{2-}$. All tin(IV) species in aqueous solutions tend to undergo hydrolysis, e.g. to hydrous tin(IV) oxide.

Several tin(IV) compounds are soluble in organic solvents, e.g. $SnCl_4$ and $SnBr_4$ dissolve in acetone, pyridine, and benzene. Compounds such as $SnX_4 \cdot 2L$ can be obtained. Tin(IV) tetraiodide is soluble in chlorocarbon solvents,



Scheme 2

hydrocarbons, and ethers. In liquid ammonia, $[Sn(NH_2)_6]^{2-}$ is obtained.

3.1 General Structures in Tin(IV) Chemistry

Basic structural types for inorganic tin(IV) compounds are given in Table 5; the most common higher coordination numbers are five and six. Thermally unstable, tin(IV) hydride (mp −146 °C), available from $SnCl_4$ and $LiAlH_4$, has tetrahedral geometry. Tin(IV) halides are also tetrahedral in the vapor and liquid phases. However, in the solid state, $SnBr_4$ (mp 31 °C) and SnI_4 (mp 144 °C) have hexagonally close-packed halogen atoms with tin occupying one-eighth of the tetrahedral holes; the tin atoms have distorted tetrahedral environments. Tin(IV) fluoride (which sublimes at 705 °C) forms a very strongly bridged, two-dimensional sheet polymer with octahedrally coordinated tin.

Tin(IV) tetrahalides are Lewis acids and readily form complexes with Lewis bases as well as halide ions (e.g. octahedral M_2SnX_6). The acceptor strength of SnX_4 decreases in the sequence F > Cl > Br > I.

Octahedral tin complexes, $SnX_4{\cdot}2L$, generally have a *cis* geometry; a few *trans* complexes are known for L = N-donors (amines, pyridines, or nitriles), P-donors (triorganophosphines), O-donors (carboxylic acids, carbonyl compounds, alcohols, esters, phosphine oxides, or sulfoxides), and S-donors (thiourea or alkyl sulfides), arsines, stibines, etc. Some five-coordinate tin complexes $SnX_4{\cdot}L$, e.g. $[SnF_4{\cdot}THF]$, $[SnBr_4{\cdot}NMe_3]$ or $[SnCl_4{\cdot}PPh_3]$, are known.

3.2 Chalcogenides[4]

Tin(IV) oxide has a rutile structure, i.e. tin has an almost perfect octahedral geometry.[42] Tin(IV) sulfide and selenide also contain six-coordinate tin, but have the hexagonal CdI_2 layer lattice.[43]

Octahedral coordinated tin is also found in $M_2Sn(OH)_6$ (M = Na or K) and in $MSn(OH)_6$ (M = Mg, Ca, Cu, Zn,

Table 5 Coordination Geometries for inorganic tin(IV) compounds

Coordination type	Coordination number	Examples
Trigonal[43]	3	$[SnE_3]^{2-}$ (E = Se or Te)
Tetrahedral[44]	4	K_4SnO_4 SnH_4
Trigonal bipyramid[45]	5	$[SnCl_5]^-$
Square pyramidal[46]	5	Octahedral[47–50]	6	SnO_2 $CaSnO_3$ $[SnX_6]^{2-}$ $SnCl_4{\cdot}2MeCN$
Dodecahedral[51,52]	8	$Sn(ONO_2)_4$ $Sn(O_2CMe)_4$

Cd, Fe, etc.); for M^{2+} having a radius less than 126 pm the structures are of the NaCl type; for M^{2+} having a radius greater than 126 pm the structures are hexagonal. Metal stannates, $MSnO_3$, produced by heating $MSn(OH)_6$ above 500 °C, have either an ilmenite-type structure (for M^{2+} radius <109 pm) or a perovskite structure (for M^{2+} radius >126 pm).[4]

In contrast to K_4SnO_4, which contains isolated $[SnO_4]$ tetrahedra, M_2SnO_4 (M = alkaline earth metal, Cd, Zn, Mn, or Co) contain $[SnO_6]$ octahedra, which share common edges to give chain or layer structures. The tin atom in $CaSnSiO_5$ has a tetragonally distorted geometry with two short axial and four long equatorial bonds. Compounds $M_2Sn_2O_7$ (M = Bi or lanthanide element) also contain octahedral tin. Potassium and rubidium metastannates (but not the lithium salt) contain square pyramidal five-coordinated tin atoms.[4]

The orthostannate anions $[SnX_4]^{4-}$ (X = S, Se, or Te) contain tetrahedral tin, while $[SnX_3]^{2-}$ contain trigonal planar tin. The salts $Na[Sn_2S_7]$ and $Na_4[Sn_2S_6]\cdot 14H_2O$ contain anions which are formed by vertex- and edge-sharing of $[SnS_4]$ tetrahedra; in $Eu_2Sn_2S_5$ there are two distinct tetrahedral tin sites. In contrast, $[Sn_2Te_6]^{6-}$ contains a Sn–Sn bond (Figure 5).

Complexed Sn–O-bonded compounds can have ladder,[44,45] e.g. $[SnCl_3(OH)\cdot H_2O]_2\cdot 4H_2O$ and $[Sn_3O_2Cl_4(ClO_4)_4]_2$, and cluster, e.g. $[Sn_2(O_2CC_6H_4NO_2\text{-}o)_4O\cdot THF]_2$, structures;[46] such compounds have Sn_2O_2 cores.

Tin tetracarboxylates, e.g. $Sn(O_2CCMe)_4$, are known;[47] $Sn(O_2CCMe)_4$ can be produced from SnI_4 and Ac_2O or from $(CH_2{=}CH)_4Sn$ and AcOH. Tin(IV) nitrate,[48] $Sn(ONO_2)_4$, prepared from N_2O_5 and $SnCl_4$, contains bidentate anions; it forms the adduct $Sn(ONO_2)_4\cdot 2py$, which has monodentate anions. Tin(IV) phosphates, e.g. SnP_2O_7 and $KSn_2(PO_4)_3$, are known, as is tin(IV) hypophosphite. Sulfates, $Sn(SO_4)_4\cdot 2H_2O$, $K_2Sn(SO_4)_3$, and $CaSn(SO_4)_3\cdot 3H_2O$, have also been prepared.

4 MIXED TIN(II)–TIN(IV) COMPOUNDS[3,4]

A number of mixed tin(II)–tin(IV) valency compounds are known. One example is the semiconductor Sn_2S_3,

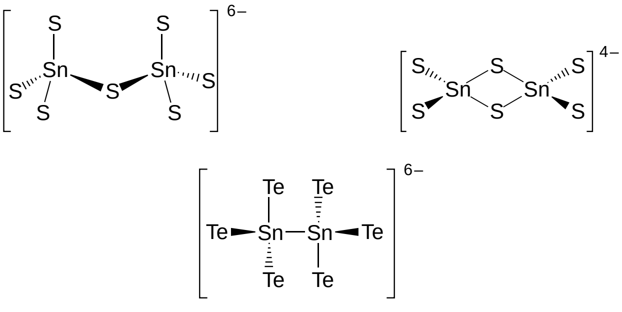

Figure 5 Examples of tin chalcogenides

obtained from appropriate ratios of the elements at 720 °C. This compound has a polymeric lattice with octahedral Sn^{IV} [d(Sn–S) ranging from 2.46 to 2.60 Å] and trigonal bipyramidal Sn^{II} [d(Sn–S) from 2.65 to 2.77 Å].[49] Another mixed Sn^{II}/Sn^{IV} sulfide, $Sn^{II}_4\ Sn^{IV}Sb^{III}S_9$, has $[Sn^{IV}S_6]$ octahedral linked via $[(Sn^{II},Sb^{III})S_8]$ dodecahedra.[50]

The compound $[Sn_3F_8]$, i.e. $[(SnF)_2SnF_6]$, formed by oxidation in HF of SnF_2 by O_2, F_2, or even SO_2, has a structure consisting of *trans* fluorine-bridged $[Sn^{IV}F_6]$ octahedra linked to $[Sn^{II}{-}F]_\infty$ chains; the Sn^{II} sites are pyramidal (three nearest Sn–F contacts of 2.10–2.25 Å, with the next nearest F at 2.55 Å from tin).[51] Fluorides not only link Sn^{II} to Sn^{IV} but also Sn^{II} to Sn^{II} in zig-zag chains of $–(SnF)_n–$.

The structure of the ionic conductor $[NH_4]_3[F_2Sn^{II}(\mu\text{-}F)Sn^{II}F_2][Sn^{IV}F_6]$ contains octahedral $[SnF_6]^{2-}$ units.[52]

The compound $Sn^{II}_2Sn^{IV}_2\ F_4(CO_2CCF_3)_8]\cdot 2CF_3CO_2H$, produced from $Sn^{II}F_2/Sn^{IV}(O_2CCF_3)_4$ solutions, contains a $[Sn^{II}{-}F{-}Sn^{IV}{-}F]_2$ ring with bridging and unidentate CF_3CO_2 units: Sn^{IV} are in fluorine-bridged octahedral sites.[53]

Various mixed valency/mixed metal oxides of the general formula $[Sn^{II}_{2-x}(M^{V}_{2-y}Sn^{IV}_{y})O_{7-(x+y)}]$, (M = Nb or Ta), have been prepared: the Sn^{II} environments in these compounds are similar to those found in tin(II) sulfate.[54] The core of the mixed valence carboxylate $[Sn^{II}Sn^{IV}(O_2CC_6H_4NO_2\text{-}o)_4O\cdot THF]_2$ contains a [SnIV:2O2] ring, with octahedral coordination at tin(IV). Carboxylate anions bridge Sn^{IV} and Sn^{II}; $d(Sn^{IV}{-}O)$ are between 2.047 and 2.067 Å, while pentagonal bipyramidal tin(II) are linked to four bridging carboxylate groups and to THF (apical Sn–O = 2.11 Å equatorial Sn–O = 2.41 and 2.66 Å).[46]

No evidence has been produced for intervalence hopping mechanisms in the mixed valency compounds.

5 SPECTROSCOPIC STUDIES OF TIN COMPOUNDS[3,4]

5.1 Mössbauer Spectroscopy

Mössbauer spectroscopy has proved to be of great value in inorganic tin chemistry (Table 6). Particularly useful have been isomer shift (δ) and quadrupole splitting (Δ) data. The recoil-free fraction and its temperature coefficient are other parameters that have found use in structural elucidations; variable temperature Mössbauer studies can be used, for example, in gaining information regarding the degree of aggregation in solid tin compounds.

5.1.1 *Isomer Shift, δ*

The largest contribution to the isomer shift value arises from the 5s electrons. Calculations have indicated that for tetrahedral and octahedral tin species the isomer shifts

Sn^{IV}	3.48	1.83	–

correlate reasonably linearly with the 5s occupancy number and the 5s electron density at the tin nucleus: higher isomer shift values correspond to higher s electron density. Large differences in the isomer shifts between tin(II) and tin(IV) oxidation states arises from the lone pair orbital present in the tin(II) series. Thus the isomer shift values can be readily used to distinguish between tin(II) and tin(IV) states: the generally accepted ranges of δ for tin(II) compounds is $+2.5$ to $5.0\,mm\,s^{-1}$ and for tin(IV) compounds -0.5 to $+2.1\,mm\,s^{-1}$ (relative to SnO_2). Values for α-Sn and β-Sn are $2.10\,mm\,s^{-1}$ and $2.65\,mm\,s^{-1}$ respectively.

For tin(IV) compounds, δ decreases as the total electronegativity of the groups attached to tin increases: the converse is found for tin(II) species, e.g. $[Sn^{II}(SbF_6)_2(AsF_3)_2]$ has one of the high δ values.

5.1.2 Quadrupole Splitting, Δ

The quadrupole splitting arises from the interaction of the nuclear quadrupole moment with an electric field gradient. Electric field gradients arise from three sources: (i) noncubic coordination geometries, (ii) imbalances in the σ framework of cubic (tetrahedral and octahedral) geometries, and (iii) distortions from regular cubic geometries. In tin(II) species the major contribution to the electric field gradient arises from the p_z electron density in the tin nonbonding orbitals.

Tin(IV) atoms in cubic environments, e.g. $SnCl_4$ and $[SnCl_6]^{2-}$, have no quadrupole splittings: in contrast, the tin(II) species $[SnCl_3]^-$ and SnO, as well as the tin(IV) anion $[SnCl_5]^-$, have splittings.

When the electronegativity difference of ligands on tetrahedral or octahedral tin are small, quadrupole splittings

will be zero or at the most very small; large electronegativity differences lead to large Δ values.

The sign of the quadrupole splitting for many tin(II) compounds, e.g. SnO and SnS, is positive, which is consistent with the main contribution to the field gradient arising from the p-electron excess in the lone pair.

5.1.3 Other Aspects for Tin(II) Compounds

Isomer shift values are larger for SnX_2 than for $SnX_2{\cdot}L$ and $[SnX_3]^-$, e.g. δ for SnF_2 and $NaSnF_3$ are 3.62 and $3.12\,mm\,s^{-1}$, respectively; the value for $[F_2Sn(\mu\text{-}F)SnF_2]^-$ is intermediate ($\delta = 3.32\,mm\,s^{-1}$).[4] Values of the isomer shifts for tin compounds with bonds to lighter elements (N, O, or F) are usually lower than those corresponding to the heavier elements due to the high 5s electron character in the Sn–X bond and hence low 5s character in the lone pair. Consequently, quadrupole splitting values are greater for tin(II) compounds having bonds to the lighter elements. There is no correlation between δ and Δ values for tin(II) compounds.

For $[Sn^{II}X_3]$ species having a basic trigonal pyramidal geometry, δ values correlate with the Sn–X bond distance.

5.1.4 Other Aspects for Tin(IV) Compounds

Isomer shifts increase in tin(IV) compounds as the total electronegativities at tin decrease. An increase in coordination number from four to six also results in a decrease in δ values, e.g. δ values for $SnCl_4$, K_2SnCl_6, and $SnCl_4{\cdot}2MeOH$ are 0.85, 0.45, and $0.54\,mm\,s^{-1}$; δ values for $SnX_4{\cdot}2L$ are 0.22, 0.33, and 0.46 for L = Ph_3PO, Me_2SO, and pyridine, respectively.

Quadrupole splitting values, which generally indicate an imbalance in the p- or d-electron distribution around tin, only are found for tin(IV) compounds with quite different ligands or interactions, e.g. SnF_4 has two short and four long Sn–F bonds and a Δ value of $1.66\,mm\,s^{-1}$ while $SnCl_4{\cdot}2NMe_3$ has a Δ value of 0.

It has been found that *cis*-$SnX_4{\cdot}2L$ can have Δ values twice those for *trans*-$SnX_4{\cdot}2L$, e.g. values for *cis*- and *trans*-$SnBr_4{\cdot}(DMF)_2$ are 0.44 and $0.83\,mm\,s^{-1}$.

5.2 ^{119}Sn NMR Spectroscopy[4,55]

Tin NMR spectroscopy has been shown to be a useful and convenient analytical tool in inorganic tin chemistry. Of the three magnetically active tin isotopes (^{115}Sn, ^{117}Sn, and ^{119}Sn) with spin = 1/2, most use has been made of the ^{119}Sn nucleus. The usual reference standard for δ^{119}Sn values is Me_4Sn, a positive sign denoting lower shielding or a shift to lower frequency (lower field).

Major factors affecting δ^{119}Sn values are (i) the electronegativity of the groups attached to tin and (ii) the coordination number at tin. An illustration of the effect of ligand electronegativities is the change in δ^{119}Sn values for the group of $[SnX_6]^{2-}$ ions. Values of δ^{119}Sn shift to lower frequencies in passing from tetrahedral to trigonal bipyramidal to octahedral symmetries. Some representative solution values for δ^{119}Sn are given in Table 7. Solid-state δ^{119}Sn spectra are being increasingly reported. Comparison of solid-state and solution spectra can point out structural differences in the two phases.

5.3 IR Spectroscopy

Table 8 lists selected tin–element stretching frequencies. The mass effect is the dominant influence on the frequencies.

6 INDUSTRIAL USES OF TIN AND TIN CHEMICALS[56]

6.1 Tin

Tin is used as a coating and in alloys. Tin plate [ca. 0.4 to 25 µm thick] is used as a nontoxic corrosion-resistant cover for sheet steel, e.g. for drink cans. The main alloys of tin are (i) solder (mainly Sn/Pb), (ii) bronze (mainly Cu/Sn), (iii) babbitt (Sn/Pb/Cu or Pb/Sn/Sb/Cu), (iv) pewter (Sn/Sb/Cu) and (v) type metals (Pb/Sn/Sb).

6.2 Tin Compounds

Tin(IV) oxide is used as an opacifer in the ceramics industry in glazes and enamels. Various combinations of SnO_2/metal oxides are used as pigments, e.g. SnO_2/V_2O_5 is a yellow pigment, SnO_2/Sb_2O_5 is a blue-grey pigment, and SnO_2/Cr_2O_3 is a pink pigment.

A deposition of a thin film (<0.1 µm) of SnO_2 (produced from hydrolysis of $SnCl_4$ vapor or hydrolysis/thermolysis of organotin halides) on glass bottles increases the strength of the glass and the resistance to abrasion. At thicknesses from 0.1 to 1.0 µm a thin-film interference effect occurs, with the glass acquiring an attractive irridescense. At greater thicknesses, electrically conducting layers are obtained which, after doping with Sb or Fe ions, are used as electrodes, electroluminescent devices (for low intensity light panels and display signs, etc.), fluorescent lamps, antistatic cover-glasses, transparent tube furnaces, deiceable windscreens, etc. Another property of the thicker SnO_2 layers is their ability to reflect a high proportion of IR radiation whilst remaining transparent to visible radiation.

Tin(IV) oxide is used in various heterogeneous catalyst mixtures, e.g. SnO_2/V_2O_5 for oxidation of arenes to carboxylic acids and anhydrides, and SnO_2/Sb_2O_5 for selective oxidation and ammoxidation of propylene to acrolein, acrylic acid, and acrylonitrile.

Tin(IV) chloride is used as a homogeneous catalyst in Friedel–Craft alkylations and acylations.

1 INTRODUCTION[1–6]

The first organotin compound, Et_2SnI_2, was reported by Frankland in 1849. Interest in organotin chemistry developed steadily over the next decades, but it was not until the discovery of the industrial uses of organotin species (e.g. as PVC stabilizers and as biocidal species), a century or so later, that this area of chemistry expanded rapidly.

The bonding in organotin species is essentially covalent in the solid state, in nonpolar solvents, and in the gas phase. The bonds to tin are, however, readily polarizable, and some ionization can occur in polar solvents. The extent of dissociation is usually low, e.g. the specific conductance of Et_3SnCl is $1.8 \times 10^{-9}\ \Omega^{-1}\ cm^{-1}$ in 1 M solution in benzene and $1 \times 10^{-6}\ \Omega^{-1}\ cm^{-1}$ in nitrobenzene.

Compared to organosilicon and organogermanium compounds, organotin compounds show an increased reactivity and a lower thermal stability; this is linked to the longer C–Sn bonds (ca. 2.15 Å) (cf. C–Si 1.94 Å and C–Ge 1.99 Å) rather than to the electronegativity differences (electronegativities on the Allred–Rochow scale for Si, Ge, and Sn are 1.7, 2.0, and 1.7, respectively). The trend is continued with organolead compounds (C–Pb 2.29 Å).

Tin forms organic derivatives in both the Sn^{II} and Sn^{IV} oxidation states; by far the majority of known organic derivatives are tin(IV) compounds. The four electrons in the valence shell of the tin atom have the $5s^2p^2$ electronic configuration. The valence electrons can undergo sp^3 hybridization and so tetracoordinate tin atoms have tetrahedral geometries. For tin(IV) derivatives, compounds having one to four organic groups can be prepared, with the remaining bonds being to a variety of anionic groups (see Scheme 1 for selected transformations of organotin compounds). For organotin compounds, especially those having electronegative groups (e.g. halides or oxygen groups), coordination numbers greater than four (up to seven) frequently occur. Catenation in organotin chemistry is well developed, with R_3SnSnR_3, $R_3Sn(SnR_2)_nSnR_3$, and *cyclo*-$(R_2Sn)_n$ species known. Over the past few years, evidence has been gained for organotin compounds containing tin–element multiple bonds, e.g. Sn=C, Sn=N, Sn=P, Sn=Sn, etc. (see (**1**)–(**5**)), although ylidic forms may better describe some of these compounds.[7]

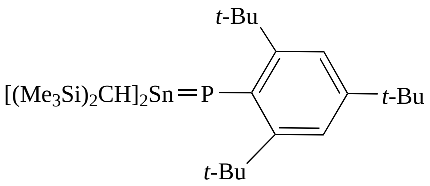
$Me_2Sn{=}NSi(t\text{-}Bu)_2Me$

(**2**)

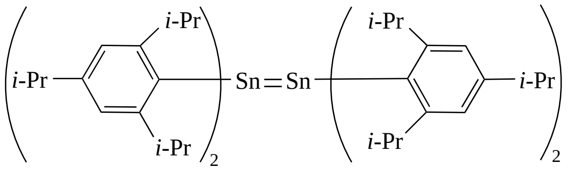


(**3**)

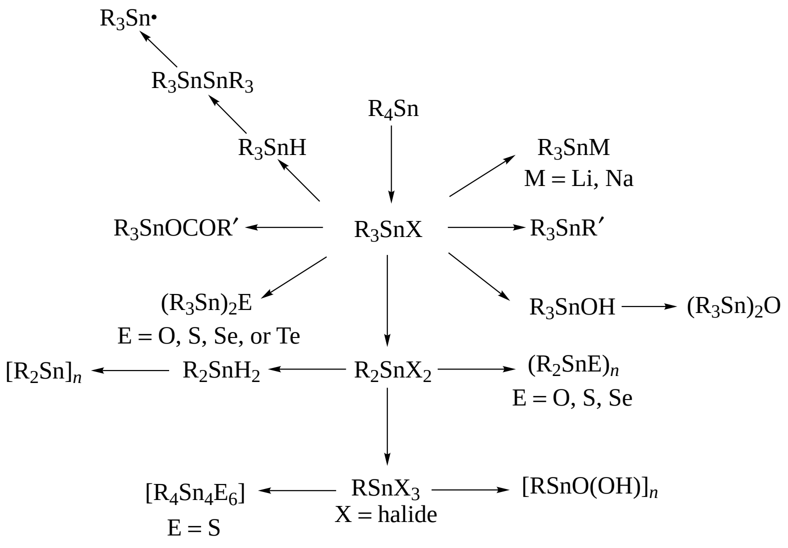
$[(Me_3Si)_2CH]_2Sn{=}Sn[CH(SiMe_3)_2]_2$

Sn–Sn = 2.768(1) Å

(**4**)



For organotin(II) compounds, there are six electrons in the valence shell and one electron pair is nonbonding. The most favorable electronic state is the singlet ($1\sigma^2$) state, i.e. the electron pair resides in one orbital with antiparallel spins. From ^{13}C NMR data it appears that there is considerable s character in the orbitals between the tin atom and the carbon atom. Organotin(II) compounds (R_2Sn and RSnX) are



Scheme 1

known with both π-bonded, e.g. (η^5-$C_5H_5)_2Sn$, and σ-bonded organic groups. As anticipated, organotin(II) compounds are highly reactive and simple dialkyltin or diaryltin (diorganostannylenes) undergo rapid polymerization. Conditions that are found to stabilize divalent organotin compounds (i) have bulky organic groups, (ii) form adducts with Lewis bases, or (iii) coordinate the Sn lone pair to a suitable Lewis acid. Different coordination numbers and geometries are also possible for organotin(II) compounds on utilizing the 5d orbitals, e.g. trigonal planar (sp^2 hybridized), tetrahedral (sp^3), trigonal bipyramidal (sp^3d), and octahedral (sp^3d^2).

Triorganotin radicals, R_3Sn•, having seven valence electrons, have been shown to have a large range of stabilities; radicals with bulky organic groups have appreciable lifetimes, e.g. $[(Me_3Si)_2CH]_3Sn$• has a half-life of 1 year at ambient temperature.

General books, reviews, and monographs cover the field of organotin chemistry.[1–6] Useful review articles on NMR spectroscopy,[8] Mössbauer spectroscopy,[9] and crystal structures[10] of tin compounds have also been published.

2 SYNTHESIS OF CARBON–TIN(IV) BONDS[2,5,6,11]

2.1 General Methods

2.1.1 Direct Synthesis[12]

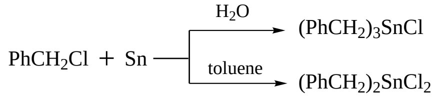
The direct reaction of tin (as foil, powder, or alloy) with organic halides has been used to produce organotin halides. Catalysts and promoters are required for all but the most reactive organic halides; $MePh_3PBr$ and KI were used as catalyst and promoter, respectively, for the formation of Me_2SnCl_2 from MeCl and Sn at 180–190 °C. The dominant products from such direct syntheses are usually the diorganotin dihalides (equation 1).

$$2RX + Sn \longrightarrow R_2SnX_2 \qquad (1)$$

However, the use of stoichiometric amounts of molten quaternary halides R_4MBr (M = N, P, or Sb) at 120–140 °C leads[13] to excellent yields of trialkyltin bromides (R_3SnBr) from alkyl bromides, RBr, and tin powder; the alkylation of tin occurs in a stepwise manner and the process can be stopped at the mono- or diorganotin stages and the process can be modified to give mixed trialkyltin bromides ($R_2R'SnBr$).

Various allyl-, benzyl-, and alkyltin halides have been prepared by direct methods; compounds have included functionally substituted dialkyltin dihalides $X_2Sn[(CH_2)_nY]_2$ ($n = 1$ or 2, Y = R_2NCO, ROCO, RCO; $n = 2$, Y = NC; $n = 3$, Y = RO).

The reactivities of alkyl halides are in the sequence RI > RBr > RCl and MeX > EtX > PrX. Benzyl halide reactions with tin do not require catalysts (equation 2). For less reactive halides, the catalysts and promoters employed include metals (sodium, magnesium, zinc, or copper), Lewis bases (amines, triorganophosphines and -stibines, alcohols, or ethers), iodides, and onium salts (R_4MX). The use of tin–sodium alloys can result in tri- or tetraorganotin products. Electrochemical synthesis has also been reported, e.g. the formation of R_2SnX_2 from the oxidation of anodic tin by RX in benzene solution and the formation of R_4Sn from RI (R = Me or $NCCH_2CH_2$) and cathodic tin.



(2)

The reaction between powdered tin, hydrogen chloride, and an α,β-unsaturated carbonyl or cyano compound produces diorganotin dichloride species (equation 3). Tin(II) halides react similarly to give $X_3SnCH_2CH_2Y$ (equation 4). Direct reactions of tin(II) halides with alkyl halides to give alkyltin trihalides require the same catalysts as used for tin/alkyl halide reactions: trialkylstibines are particularly effective catalysts (equation 5).

$$Sn + 2HCl + 2H_2C{=}CHY \longrightarrow Cl_2Sn(CH_2CH_2Y)_2$$
$$Y = CO_2R,\ COR,\ CONR_2,\ \text{or}\ CN \qquad (3)$$

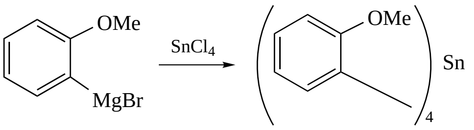
$$SnCl_2 + HCl + H_2C{=}CHY \longrightarrow Cl_3SnCH_2CH_2Y \qquad (4)$$

$$RBr + SnBr_2 \xrightarrow[\Delta]{Et_3Sb} RSnBr_3 \qquad (5)$$

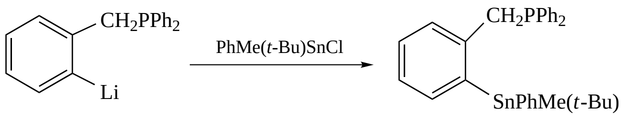
2.1.2 *Synthesis from Tin(IV) Halides*

Reactions of tin(IV) halides or organotin halides with organic derivatives of more electropositive metals provide the most important general synthetic routes to carbon–tin bonds (equation 6). The most frequently used R′–M compounds are those of magnesium and lithium, with sodium, zinc, and aluminum having a more limited use. Some examples of these reactions are given in equations (7–9).

$$R_{4-n}SnX_n + nR'{-}M \longrightarrow R_{4-n}SnR'_n \quad n = 1-4 \qquad (6)$$



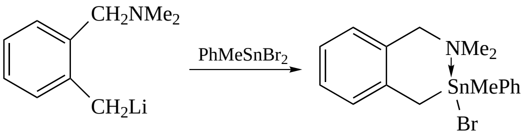
(7)



(8)

$$CH_2I_2 \xrightarrow{Zn/Cu} ICH_2ZnI \xrightarrow{Ph_2SnCl_2} Ph_2Sn(CH_2I)_2 \qquad (9)$$

The normal targeted products of reactions between tin(IV) halides and organomagnesium or organolithium reagents are the tetraorganotins, as it is difficult to control alkylation sufficiently well to a lower extent. However, controlled reactions can be achieved in certain cases, e.g. when bulky groups are present (such as cyclohexyl) or when an organotin halide product can be stabilized by chelation (equation 10).



(10)

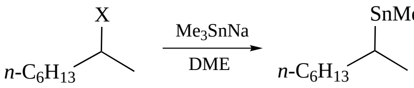
2.1.3 *Synthesis from Triorganylstannyl Anionic Species, R_3SnM*

Reactions of R_3SnM (M = Li, Na, MgX, or Cu) occur with various organic electrophiles, e.g. organic halides and tosylates, aldehydes and ketones, β-enones, and epoxides, to give new carbon–tin bonded compounds.

R_3SnM compounds can be obtained from (i) R_3SnX (X = halide) and M or $ArH^- \ M^+$ (ArH = an arene such as naphthalene; M = Li, Na, or K); (ii) R_3SnSnR_3 and M (M = Li, Na, or K) or R′Li in HMPA; or (iii) R_3SnH and MH (M = Na or K), t-BuMgX, R'_2MLi, or R'_2 NM/LiO-t-Bu (M = K or Cs). Addition of a copper(I) compound will provide the tin–copper or tin–cuprate.

Primary and secondary alkyl halides and tosylates react cleanly with R_3SnM (equation 11); however, with tertiary alkyl halides, some elimination reaction can also result. The mechanisms of the R_3SnM/alkyl halide or tosylate reactions can be (i) S_N2 type (with inversion of configuration); (ii) an electron transfer (or radical pair) mechanism (with possible predominant inversion of configuration); or (iii) an initial halogen–metal exchange, followed by substitution (with overall retention of configuration) (equation 12). Temperature, solvent, halide, and method of preparation of R_3SnM (and consequent presence of additional species, such as RM or M) affect the mechanism.

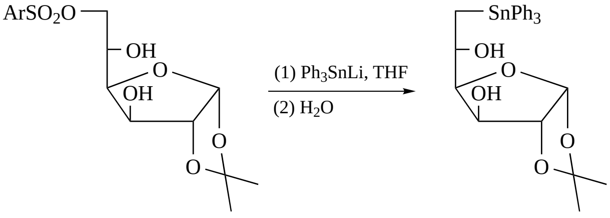
$$R_3SnM + R'X \longrightarrow R_3SnR' \qquad (11)$$



X = $OSO_2C_6H_4Me$-p, 100% inversion
Cl 78% inversion
Br 60% inversion

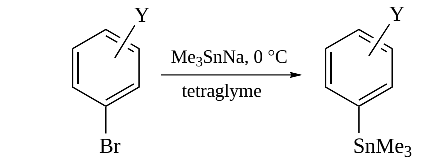
(12)

Mechanisms of triorganotin anionic reactions with haloarenes include $S_{RN}1$ and halogen–metal exchanges.[14] Further examples of the use of R_3SnM compounds are shown in equations (13–15). Various functional group substituents are clearly much less sensitive towards R_3SnM than to RM, e.g. CN, CO_2R, etc.



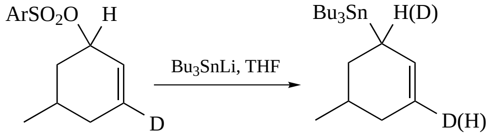
(13)

Ar = p-MeC_6H_4



(14)

Y = *p*-CN, *p*-NH$_2$, *o*-, *m*- or *p*-MeO

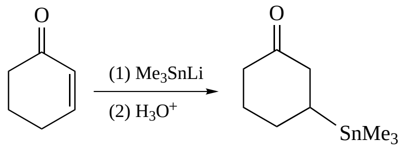


(15)

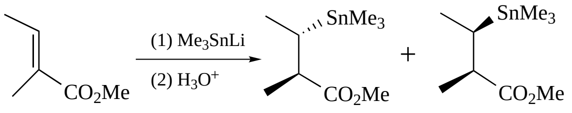
cis:*trans* = 94:6 *cis*:*trans* = 8:92

Aldehydes and ketones react with R_3SnM (M = Li or MgCl) to give α-hydroxyalkyltin compounds after hydrolysis (equation 16). 1,4-Additions occur with RCH=CHCOR′ and $Bu_3SnMgCl$ (in Et_2O), R_3SnLi, or $(R_3Sn)_2CuLi$ (equations 17 and 18). Ring-opened products result from reactions of epoxides, oxetanes, or thiiranes (equations 19–21).

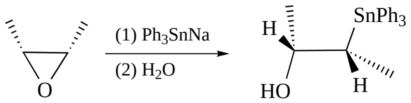
$$Bu_3SnMgCl + RCHO \longrightarrow Bu_3SnCHROH \quad (16)$$



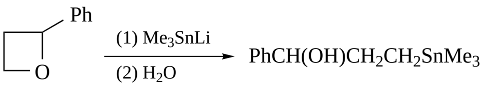
(17)



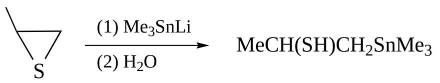
(18)



(19)



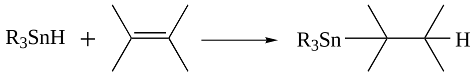
(20)



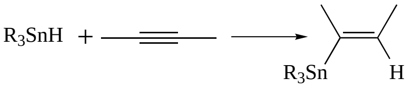
(21)

2.1.4 *Hydrostannation of Alkenes and Alkynes*

Organotin hydrides add to alkenes and alkynes (equations 22 and 23). Unless strongly electron-withdrawing groups are present in the unsaturated species, the additions have radical-chain mechanisms (Scheme 2). For 1-alkenes, tin usually adds predominantly to the terminal carbon (equations 24 and 25).



(22)



(23)

$$H_2C{=}CHC_6H_{13} + Et_3SnH \longrightarrow Et_3SnCH_2CH_2C_6H_{13} \quad (24)$$

$$Bu_2SnH_2 + 2H_2C{=}CHCH_2OH \longrightarrow Bu_2Sn(CH_2CH_2CH_2OH)_2 \quad (25)$$

The regioselectivity of addition to CH_2=CHCN depends on whether a nucleophilic (a) or a radical (b) mechanism operates (Scheme 3).

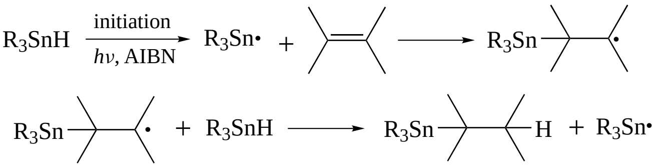
Various functional groups, X, can be tolerated in the alkenes $CH_2{=}CH(CH_2)_nX$, e.g. X = SR, SO_2R, OR, PR_2, $P(OR)_2$; however, amines and other basic groups, e.g. sulfoxides, catalyze decomposition of tin hydrides to tin–tin bonded compounds (equation 26).

$$Ph_3SnH + H_2C{=}CHSO_mC_6H_4Me\text{-}p \xrightarrow{\text{AIBN}} Ph_3SnCH_2CH_2SO_mC_6H_4Me\text{-}p \quad m = 0 \text{ or } 2 \quad (26)$$

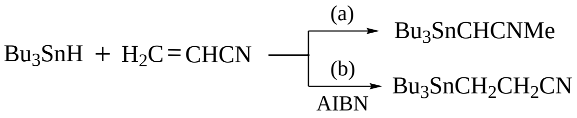
Hydrostannation of terminal alkynes containing a strongly electron-releasing group, e.g. CO_2R or CN, produces mainly the α-adduct via an ionic mechanism. Addition to alkynes bearing an electron-releasing group, such as an alkyl or alkoxyl group, or a weakly electron-withdrawing group, e.g. CH_2OH or Ph, yield mainly the *cis* and *trans* β-adduct (via a radical mechanism), as well as small amounts of the α-adduct. Initial additions occur in a *trans* manner (i.e. to form the *cis* adduct), with subsequent isomerism of the *cis*-R_3SnCH=CHR′ to give the thermodynamically more stable *trans* isomer. Hydrostannation of nonterminal alkynes by R_3SnH provides mainly the *trans* adducts.

2.2 Specific Types of Carbon–Tin Bonded Compounds

The general methods outlined above can be used to synthesize organotins having specific functionalities. Two important groups of organotin compounds are the vinyl- and allyltins; some further details of the synthesis of these compounds are



Scheme 2



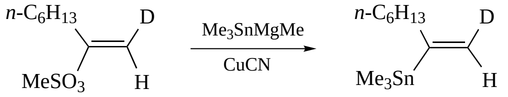
Scheme 3

given below. For functionally substituted alkyltins the general methods have proved to be useful; for example, (i) the use of reactions involving tin halides and YCR^1R^2Li compounds (Y = nitrogen, phosphorus, sulfur, selenium containing group, halo, cyano, or carbonyl) can provide α-substituted derivatives; (ii) hydrostannation of alkenes $CH_2{=}CH(CH_2)_nY$ gives β, γ, and δ derivatives (Y = oxygen, sulfur, phosphorus group, carbonyl); and (iii) reactions of R_3SnM with substituted halides or sulfonates $Y(CRR')_nX$ (X = halide or sulfonate). The conversion of existing functionally substituted alkyltin groups to other groups may also be used, e.g. conversion of $\equiv Sn(CH_2)_nOH$ to $\equiv Sn(CH_2)_nX$ (halide), oxidation of $\equiv Sn(CH_2)_nSR$ to $\equiv Sn(CH_2)_nSO_mR$ ($m = 1$ or 2), and additions of electrophiles, radicals, and carbenes to alkenyl tin species (see also Scheme 4).

2.2.1 Vinyltins

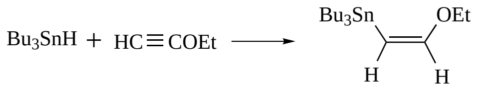
Vinyltin compounds can be generated from the corresponding vinyl-Grignard reagents or vinyllithium compounds with a tin halide, with retention of configuration (equation 27). Reactions between triorganotin anionic species R_3SnM (M = Li, Na, MgX) and vinyl halides or sulfonates provide vinyltin compounds; reactions of the sulfonates (but not iodides) are stereospecific (equation 28). Routes to vinylstannanes from ketones have also been devised (Scheme 5).

$$H_2C{=}CHMgBr + SnCl_4 \xrightarrow{THF} (H_2C{=}CH)_4Sn \quad (27)$$

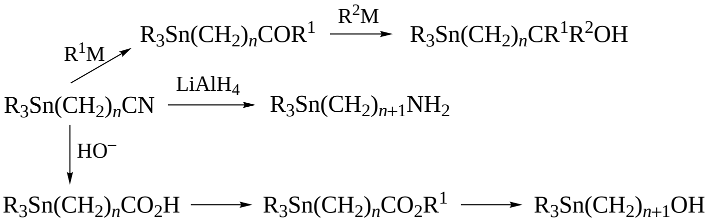


(28)

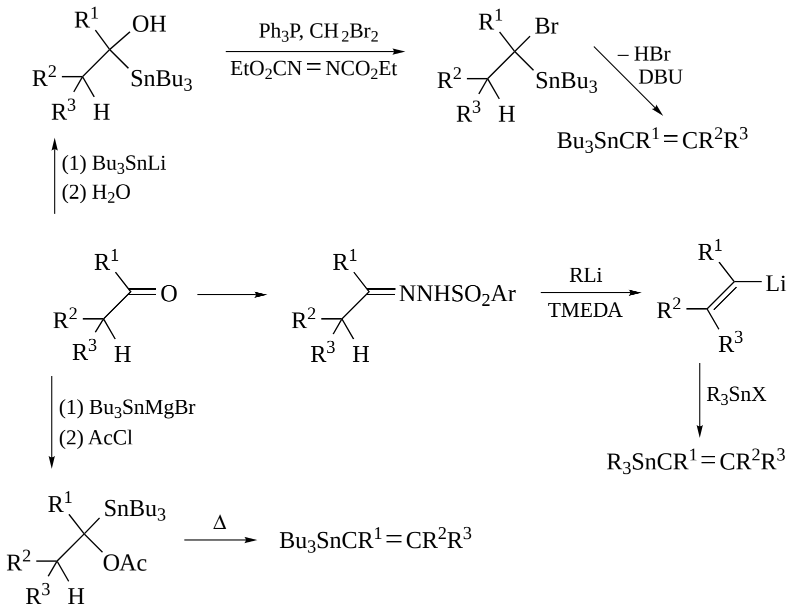
Hydrostannation of 1-alkynes does provide vinyltins (equation 29), but these reactions may not be stereospecific or give the desired regiospecificity. Other methods from alkynes are shown in equations 30 and 31 and Scheme 6. Stannyl cupration of allenes (using $(Bu_3Sn)_2CuLi$ or $(Bu_3Sn)BuCuLi$) also leads to allyl- and vinylstannanes.[15]



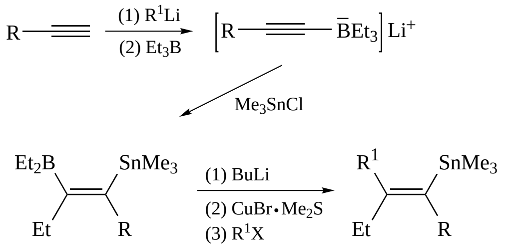
(29)



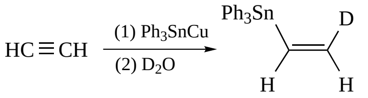
Scheme 4



Scheme 5



(30)

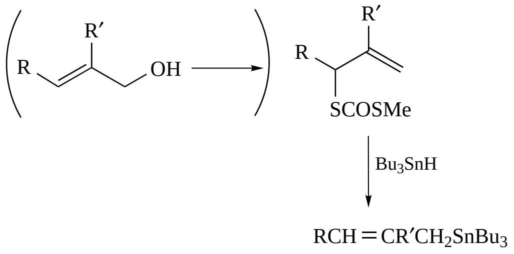


(31)

2.2.2 *Allyltin Compounds*

Allylstannanes are available from reactions of allylmagnesium or allyllithium compounds with tin halides (equation 32). Other syntheses involve reactions of triorganotin anionic species with allylic halides or esters (equation 14), as well as reactions of allylic xanthates, tosylates, etc. with tin hydrides (equation 33).

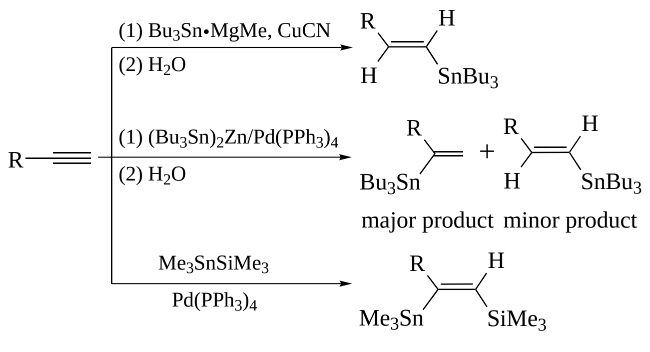
$$H_2C{=}CHCH_2MgCl \xrightarrow{Ph_3SnCl} Ph_3SnCH_2CH{=}CH_2 \quad (32)$$



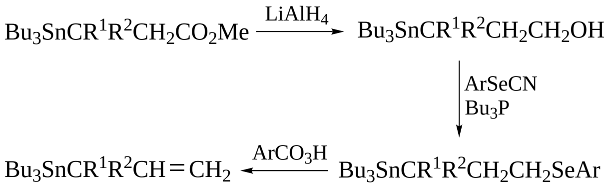
(33)

Hydrostannation of 1,3-dienes produces allyltins. Specific modifications of certain functionally substituted alkyltin compounds have also been used (equation 34 and Scheme 7).

$$Me_3SnCH_2CH{=}PPh_3 \xrightarrow{R^1R^2C{=}O} Me_3SnCH_2CH{=}CR^1R^2 \quad (34)$$



Scheme 6



Scheme 7

3 SPECTROSCOPIC STUDY OF ORGANOTIN COMPOUNDS[16]

Organotin compounds, as well as being open to study by general spectroscopic techniques, e.g. UV, IR, and ^{1}H and ^{13}C NMR spectroscopies as well as mass spectrometry, can also be investigated using such specific techniques as ^{119}Sn (or ^{117}Sn) NMR and ^{119m}Sn Mössbauer spectroscopies. The increasing availability of solid-state NMR spectroscopy provides further means of exploring structures.

Tin has 10 stable isotopes, the largest number of any element, and this can be used to advantage in spectroscopic study. The isotopes and their abundances are as follows: 112 (0.95%), 114 (0.65%), 115 (0.34%), 116 (14.24%), 117 (7.57%), 118 (24.01%), 119 (8.58%), 120 (32.97%), 122 (4.71%), and 124 (5.98%).

3.1 IR Spectroscopy

As a general rule, the positions of Sn–X stretching vibrations are dominated by the mass effect. As the mass of the bonding element increases, so the stretching vibration falls to lower frequencies. The stretching vibrations for Sn–H bonds occur in the region 1820–1920 cm^{-1}; those for bonds to first-row elements (C, N, O, or F) in the region 500–600 cm^{-1}; those for bonds to second-row elements (Si, P, S, or Cl), to third-row elements (Ge, As, Se, or Br), and to fourth-row elements (Sn, Sb, Te, or I) occur in the regions 300–380, 190–260, and 150–210 cm^{-1}, respectively.

These regions should only be used as guidelines for molecular complexes, since the positions of the bands are affected by the nature of the ligand, e.g. the values of ν(Sn–O) for Bu_3SnOR and Me_3SnONO_2 are ca. 500–525 and 220 cm^{-1}, respectively, and by other substituents at tin, as well as by any further coordination, e.g. monomeric R_3SnF have ν(Sn–F) in the region 555–590 cm^{-1}, but for fluoride-bridged $[R_3SnF]$ aggregates ν(Sn–F) occurs at 340–380 cm^{-1}.

3.2 NMR Spectroscopy

Three of the tin isotopes (^{115}Sn, ^{117}Sn, and ^{119}Sn) have spin values of 1/2, but, while in principle all are suitable for NMR study, only ^{117}Sn and, in particular, ^{119}Sn have found practical use.

3.2.1 ^{1}H and ^{13}C NMR Spectra in Solution

As with organic compounds, the ^{1}H and ^{13}C NMR spectra of organotins are used to assign protons and carbon atoms; in addition, values of coupling constants $^{n}J(^{119}\text{Sn–}^{1}\text{H})$ and $^{n}J(^{119}\text{Sn–}^{13}\text{C})$ are useful aids to bonding and to conformations.

Both the one-bond $^{1}J(^{119}\text{Sn–}^{13}\text{C})$ and the two-bond $^{2}J(^{119}\text{Sn–}^{1}\text{H})$ values have been used as guides to the s electron density in carbon–tin bonds. The changes in $^{2}J(^{119}\text{Sn–}^{1}\text{H})$ values for Me_nSnCl_{4-n} (54.7, 58.2, 68.9, 96.9 Hz for $n = 4, 3, 2, 1$), indicate the increasing s electron density in the Me–Sn bond and hence the increasing p character of the Sn–Cl bond as n decreases.

The values of $^{2}J(^{119}\text{Sn–}^{1}\text{H})$ and $^{1}J(^{119}\text{Sn–}^{13}\text{C})$ also increase with the increasing coordination at tin, e.g. $^{1}J(^{119}\text{Sn–}^{13}\text{C})$ values for Me_3SnCl and $Me_3SnCl{\cdot}py$ are 372 and 472 Hz, respectively. The usual ranges quoted for $^{1}J(^{119}\text{Sn–}^{13}\text{C})$ in four-coordinate R_3SnX are 330–400 Hz, in five-coordinate R_3SnX are 450–480 Hz, in four-coordinate R_2SnX_2 are 370–480 Hz, and for octahedral R_2SnX_2 are 900–970 Hz.

Correlations have been established between values of $^{2}J(^{119}\text{Sn–}^{1}\text{H})$ or $^{1}J(^{119}\text{Sn–}^{13}\text{C})$ and the C–Sn–C valency angles in series of diorganotin compounds. A Karplus-type relationship has been indicated between dihedral angle, ϕ, and the $^{3}J(^{119}\text{Sn–}^{13}\text{C})$ values in cyclic systems.

3.2.2 ^{119}Sn NMR Spectra in Solution

The usual reference standard used for ^{119}Sn values is Me_4Sn; negative chemical shifts are upfield from $\delta^{119}\text{Sn}(Me_4Sn) = 0$. Chemical shift values, δ^{119}Sn, are dominated by the paramagnetic contribution and span a range of greater than 4000 ppm.

The important factors which influence δ^{119}Sn are the electronegativities of substituents at tin and the geometry and coordination number at tin. The effect of different coordination numbers of tin on the δ^{119}Sn values can be seen in the following ranges: for four-coordinate organotin(IV), +200 to −150 ppm; for five-coordinate organotin(IV), −90 to −330 ppm; and for six-coordinate organotin(IV), −125 to −515 ppm.

π-Bonded organotin(II), e.g. $(\pi\text{-}C_5H_5)_2Sn$, have δ^{119}Sn values of ca. −1630 to −2250 ppm; the reported value for the σ-bonded Sn^{II} species $[(Me_3Si)_2CH]_2Sn$ is 2315 ppm.

3.2.3 Solid-State NMR Spectra

Solid-state ^{13}C NMR and ^{119}Sn NMR spectra are being more frequently reported as the technique becomes more generally available. The combined use of X-ray crystallography, and solution and solid-state NMR spectra enables comparisons to be made between structures in the two phases. Changes in structures between the two phases are readily indicated by differences in δ^{119}Sn values, e.g. tricyclohexyltin hydroxide in the solid state is a linear polymer (δ^{119}Sn is −217 ppm) but the aggregation is broken down in solution (δ^{119}Sn is +11.66 ppm). Compounds having similar structures in both the solid state and in solution have $\Delta(\delta^{119}\text{Sn})$ values differing by only a few ppm, e.g. for $t\text{-}Bu_2\overline{SnSCH_2CH_2S}$ the δ^{119}Sn values in solution and in the solid state are 171 and 173 ppm, respectively.

The one-bond coupling constant $^{1}J(^{119}\text{Sn–}^{13}\text{C})$ is also of interest; a linear relationship has been reported between these coupling constants in the solid state and the C–Sn–C valency angles in dimethyltin species.

3.3 ^{119}Sn Mössbauer Spectroscopy

Mössbauer spectroscopy is the study of recoilless resonant fluorescence; ^{119}Sn Mössbauer spectroscopy has been found to be a most useful method for studying the bonding and stereochemistry of tin compounds in the solid state. The two most important parameters are the isomer shift (δ, mm s^{-1}) and the quadrupole splitting (ΔE_Q, mm s^{-1}), although the recoil-free fractions and temperature coefficients can also supply useful structural indications.

3.3.1 Isomer Shifts (δ)

The isomer shift values (δ), usually quoted relative to SnO_2, are dependent on the s electron density at the ^{119}Sn nucleus. A larger positive value of δ corresponds to an increase in the nuclear s electron density at tin; the range of δ observed for Sn^{IV} compounds is ca. −0.5 to 2.1 mm s^{-1}, and for Sn^{II} compounds, which contain a lone pair of 5 s electrons, the range is higher, being ca. +2.5 to +5 mm and especially about 3.6–3.9 mm s^{-1} for π-bonded organotin(II) species. For tin(II) species the isomer shift is increased as the total electronegativity of the groups at tin increase; however, for Sn^{IV} compounds the converse is found.

In such series of organotins as R_4Sn and R_3SnOH, δ increases slightly with the electron-releasing ability of R, e.g. from 1.20 to 1.35 mm s^{-1} as R is varied from Me to Bu in R_4Sn. Increases in the coordination number at Sn leads to a decreased δ value. *Cis* octahedral R_2SnX_4 species have lower δ values than *trans* octahedral complexes, e.g. δ values for *cis*-$Ph_2Sn(NCS)_2{\cdot}$bipy and *trans*-$Ph_2SnCl_2{\cdot}$bipy are 0.82 and 1.22 mm s^{-1}, respectively.

3.3.2 Quadrupole Splitting Parameter (ΔE_Q)

If the tin atom has a perfectly spherical symmetry, e.g. as in $SnMe_4$ and $[SnCl_6]^{2-}$, only a single line is observed in

the ^{119}Sn Mössbauer spectrum. However, a deviation from this symmetry (e.g. as in $SnCl_5^-$) will lead to a two-line quadrupole split spectrum, with ΔE_Q equal to the separation of the two lines. The main cause of asymmetry in the ^{119}Sn nuclear charge is an imbalance in the 5p valence electrons. For organotin compounds the spatial arrangement of the organic groups about tin has an effect on the ΔE_Q values; distinct ranges of ΔE_Q are found for different types of stereochemistry. Thus regular tetrahedral R_3SnY and R_2SnY_2 compounds have ΔE_Q values which fall into the range 1.00–2.40 mm s^{-1} (e.g. $(Ph_3Sn)_2S$ and $(Ph_2SnS)_3$ have ΔE_Q values of 1.46 and 1.60 mm s^{-1}, respectively) and ΔE_Q values for *cis* and *trans* trigonal bipyramidal R_3SnX_2 complexes are in the regions 1.20–2.40 and 3.00–4.00 mm s^{-1}, respectively (e.g. *cis*-$Ph_3SnONPhCOPh$ and *trans*-$Ph_3SnCl_2^-$ have ΔE_Q values of 1.94 and 2.89 mm s^{-1}).

For six-coordinate methyltin compounds the value of the C–Sn–C valency angle has been correlated with the value of ΔE_Q.

For *cis*- and *trans*-R_2SnX_4 species, values obtained for ΔE_Q are ca. 2.00 and 4.00 mm s^{-1}, respectively (e.g. *cis*-$Ph_2Sn(SCSNEt_2)_2$ and *trans*-$Ph_2SnCl_2{\cdot}2DMSO$ have ΔE_Q values of 1.72 and 3.86 mm s^{-1}, respectively). Other values obtained for diorganotin(IV) species are for seven-coordinate pentagonal bipyramidal *trans*-$Me_2Sn(NCS)_2{\cdot}terpy$ ($\Delta E_Q = 4.29$ mm s^{-1}) and *cis* five-coordinate trigonal bipyramidal R_2SnX_3 ($\Delta E_Q = 3.00–3.50$ mm s^{-1}) (e.g. $Me_2SnCl_3^-$, $\Delta E_Q = 3.30$ mm s^{-1}).

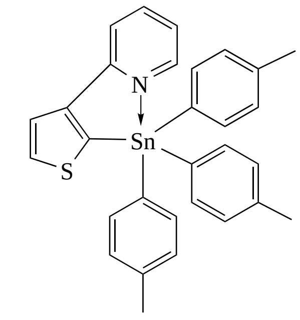
Monoorganotin complexes have similar ΔE_Q values irrespective of their geometry.

For π-bonded organotin(II) compounds, ΔE_Q values are in the region 0 to 1.0 mm s^{-1}; the complexes $(\pi\text{-}C_5H_5)_2SnM(CO)_5$ (M = Cr or Mo) have ΔE_Q values of ca. 2.6–2.7 mm s^{-1}, the ΔE_Q value for the σ-bonded $[(Me_3Si)_2CH]_2Sn$ is 2.31 mm s^{-1}; on complexation with $M(CO)_5$ (M = Cr or W), the ΔE_Q values increase to ca. 4.5 mm s^{-1}.

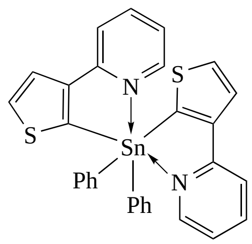
4 TETRAORGANOTIN COMPOUNDS

Tetraorganotin compounds are generally thermally stable, e.g. to 200 °C, and are stable towards air or water. Reactions occur with a variety of reagents, both heterolytic and homolytic (see also Section 5). In most cases tetraorganotin compounds contain tetrahedral, four-coordinate tin atoms; however, a few five- and six-coordinate tetraorganotin compounds have been characterized in the solid state and in solution. In these compounds, an internal nitrogen or oxygen atom is suitably sited to coordinate with the tin center (see (**6–10**)).

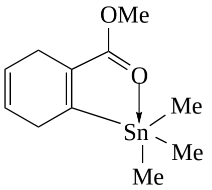
Compound (**10**) has an enhanced reactivity towards electrophilic reagents,[17] which has been ascribed to the ideal siting of the nitrogen atom to take part in nucleophilic assistance at the tin center during the cleavage reactions. Tetraorganotin compounds have in general very low Lewis acidity; only one adduct of a tetraorganotin species has been reported, i.e. $Me_3SnCF_3{\cdot}O{=}P(NMe_2)_3$.



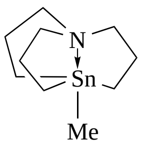
(**6**) Sn–N 2.841(7) Å



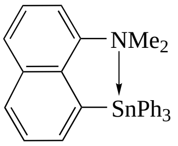
(**7**) Sn–N 2.560(2) Å



(**8**) Sn–O 2.781(3) Å

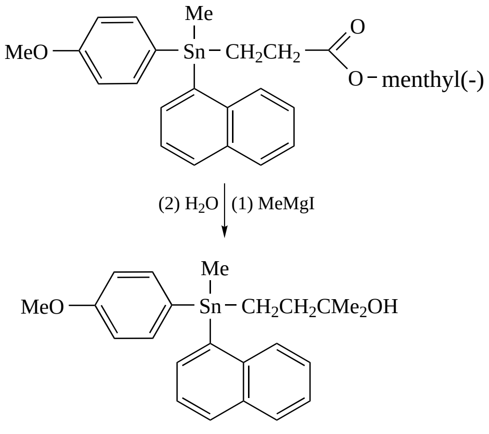


(**9**) Sn–N 2.624(8) Å



(**10**) Sn–N 2.884(3) Å

Resolution of chiral tetraorganotin compounds has been achieved, using chiral auxiliary groups (equation 35), as well as the use of chromatography on chiral stationary phases, e.g. cellulose triacetate for $Me(PhCMe_2CH_2)Ph(Ph_3C)Sn$.



$[\alpha]^{20}_{D}$ +9° (35)

5 CLEAVAGE OF CARBON–TIN BONDS

Tin–carbon bonds may be cleaved in either homolytic or heterolytic reactions.

5.1 Homolytic Cleavage[18]

Homolytic cleavage of a tin–carbon bond in a tetraorganotin compound is less frequently encountered than is heterolytic cleavage. Such radicals as Br•, I•, and the succinimidyl radical can take part in S_N2 displacement with tetraorganotins (Scheme 8). The reactivity of R_4Sn in Me_2CO towards the succinimidyl radical is in the sequence of R = Me > Et > Pr > Bu; this is the reverse of that for radical reactions of iodine and bromine.

Alkoxy radicals attack the α- and β-carbon atoms of tetraalkyltins; however, they react at the tin center in trialkyltin halides (equation 36).

$$t\text{-BuO}\bullet + Bu_2(t\text{-Bu})SnCl \longrightarrow Bu\bullet + (t\text{-BuO})Bu(t\text{-Bu})SnCl \quad (36)$$

5.2 Heterolytic Cleavages of Tin–Carbon Bonds[11]

In heterolytic cleavages of tin–carbon bonds, electrophilic attack (by E) at carbon is usually the more influential, although nucleophilic assistance (by Nu) at tin can also play a role, and in some cases can become dominant (equation 37).

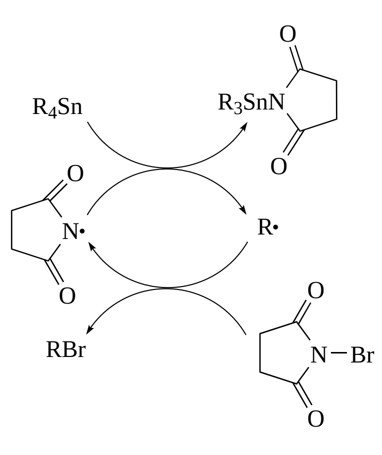
$$\overset{\delta+\ \delta-}{R_3Sn\text{–}R} + \overset{\delta+\ \delta-}{E\text{–}Nu} \longrightarrow R_3Sn\text{–}Nu + R\text{–}E \quad (37)$$

5.2.1 Nucleophilic Cleavages

Nucleophilic cleavages have been reported by hydroxide and alkoxides with C_6F_5Sn, $PhCH_2Sn$, allyl-Sn, RC≡CSn, and, more generally, by organolithiums (equation 38). The transmetalation reaction (equation 38), which proceeds via an 'ate' complex, is an equilibrium. The position at equilibrium depends on the relative stabilities of the carbanion fragments, $(R^2)^-$ and $(R^1)^-$, with the more stable carbanionic fragment providing the greater amount of the organolithium product. Essentially quantitative exchanges occur between R^2Li = alkyl- or phenyl-Li with R^1SnR_3, where R^1 is allyl, vinyl, XCH_2 (X = R^3O, R^3S or R^3Se), etc (equation 39).

$$R_3SnR^1 + R^2Li \rightleftharpoons R_3SnR^2 + R^1Li \quad (38)$$

$$Bu_3SnCH_2OCH_2OMe + BuLi \longrightarrow Bu_4Sn + LiCH_2OCH_2OMe \quad (39)$$



Scheme 8

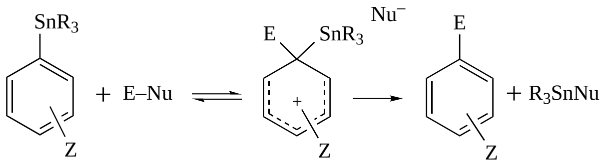
5.2.2 Electrophilic Cleavages

Electrophilic cleavages have been the most reported reactions with regard to both kinetics and synthetic utility (of either the organic or organometallic products). A great array of electrophilic reagents (E–Nu) have been employed, including halogens, proton acids (carboxylic and mineral acids), metal halides (e.g. SnX_4, HgX_2, BX_3, platinum halides), sulfur(II) halides, and sulfur oxides. With the more reactive reagents, more than one carbon–tin bond can be cleaved.

Transfer of organic groups from tin to carbon electrophiles, e.g. alkyl halides and acyl halides, can occur in the presence of a transition metal (e.g. Pd) catalyst (equation 40).[19] Reactivity sequences for electrophilic carbon–tin bond cleavages are generally allyl > phenyl > benzyl > vinyl > methyl > higher alkyl. The precise sequence is somewhat dependent on the solvent and electrophile.

$$R_3SnR^1 + R^2X \xrightarrow{Pd^0 or Pd^{II}} R^1R^2 \quad (40)$$

Aryl–tin bond cleavages by electrophilic reagents are typical electrophilic aromatic substitutions,[2] with greater electron-releasing substituents in the aryl group leading to faster reaction (equations 41 and 42). The mechanism of cleavages of alkyl–tin bonds is usually S_E2; both retention and inversion of configuration have been realized for halogenations (equation 43). For protolysis of carbon–tin bonds, retention of configuration is frequently obtained, e.g. as found in reaction between CF_3CO_2H and cyclohexyl(triisopropyl)stannanes.



(41)

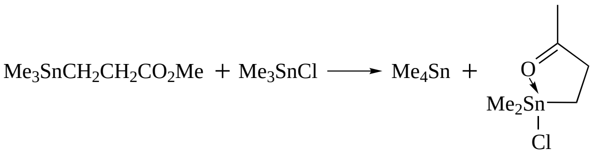
$$Ph_3SnMe + I_2 \longrightarrow IPh_2SnMe + PhI \quad (42)$$

(11) **(12)** (43)

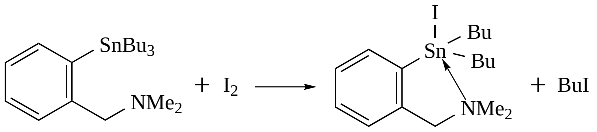
trans-(**11**) ⟶ (**12**) 56%, net inversion
cis-(**11**) ⟶ (**12**) 61%, net inversion

Enhanced reactivities for organotin bonds can be obtained on nucleophilic assistance by donor groups present within the organostannane (equations 44 and 45). In equation (44) the

reactivity of the Me–Sn bond, normally inert to Me_3SnCl, is enhanced by the nucleophilic assistance provided by the ester group. In equation (45) the usual reactivity sequence of benzyltin > alkyltin is overturned by the nucleophilic assistance afforded by the NMe_2 group to cleavage of the Sn–Bu group.



(44)

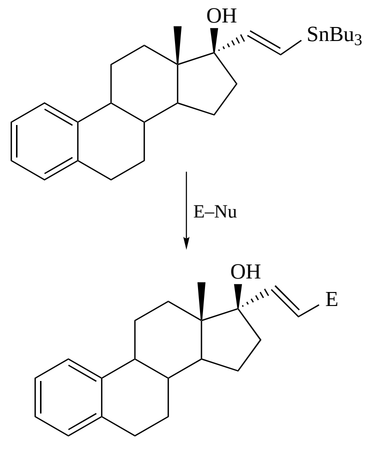


(45)

5.3 Specific Cleavages and Reactions

5.3.1 *Vinyltin*

Generally, cleavage of vinyltin compounds proceeds with retention of configuration during reaction with electrophilic reagents and organolithiums (equation 46). As well as the cleavage shown in equation (46), addition to the double bond has been found in some cases, as in heterolytic reactions, e.g. with ArS–Cl, in epoxidations, and in homolytic reactions, e.g. thiols and Cl_3C-X (X = Cl or Br).



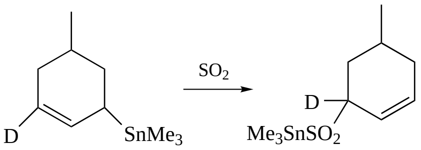
(46)

$E-Nu = H-O_2CCF_3$, I–I, PhSe–Br

5.3.2 *Allyltin*

Allyltin bonds are among the most reactive carbon–tin bonds and they undergo reactions with mild electrophiles, e.g. aldehydes (equation 47).[20] Protonolysis of allyltin bonds proceeds with γ-regioselectivity and *anti* stereoselectivity. Sulfur dioxide cleavages, however, occur with γ-regioselectivity and *syn* stereoselectivity (equation 48). Allyltin bonds are cleaved in homolytic reactions, e.g. by PhSSR, PhSePh, RCO_2Cl, and RX (QX) (equation 49).[21]

$$R_3SnCH_2CH{=}CHR^1 \xrightarrow[\Delta \text{ or Lewis acid catalyst}]{R^2CHO} R_3SnOCHR^2CH_2CH{=}CHR^1 + R_3SnOCHR^2CHR^1CH{=}CH_2 \quad (47)$$



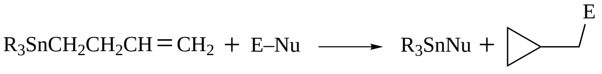
(48)

cis:*trans* = 29:71

$$Bu_3SnCH{=}CHR + Q{-}X \xrightarrow[\text{or AIBN}]{h\nu,\,\Delta} CH(R)(Q){-}CH{=}CH_2 + Bu_3SnX \quad (49)$$

5.3.3 *3-Butenyltin Compounds*

γ-Eliminations have been reported in reactions of 3-butenyltin compounds (equation 50).

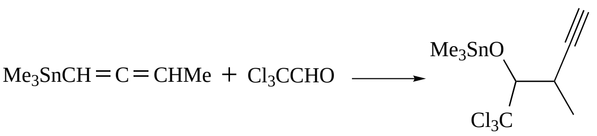


(50)

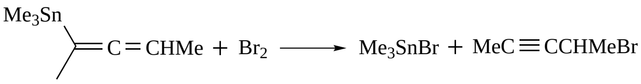
$E-Nu = Cl-Cl, I-I, Br-Br, ArS-Cl$

5.3.4 *Propargyltin and Allenyltin Compounds*

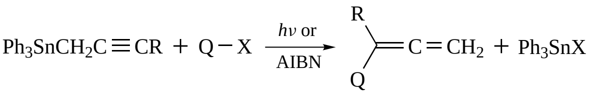
These compounds contain reactive carbon–tin bonds which are cleaved with complete rearrangement by electrophilic species (equations 51 and 52). Propargyltins also undergo S_H2' reactions with RSO_2Cl, Cl_3CCl, RBr, or RI (≡QX) (equation 53).



(51)



(52)



(53)

5.3.5 *Functionally Substituted Alkyltin Compounds*

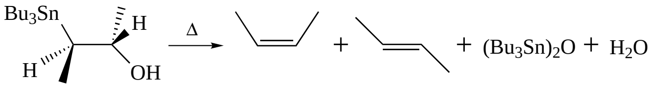
The presence of a functional group, Y, in an alkyl group in an organotin compound, e.g. $R_3Sn(CH_2)_nY$, can (i) affect

the reactivity of the Sn–$(CH_2)_n$Y bond (by its electronic influence), (ii) affect the reactivity of the R–Sn bond (by nucleophilic assistance from Y at the tin center), or (iii) alter the type of reaction undergone (e.g. β- or γ-elimination). Depending on Y, other reactions, such as oxidation, reduction, salt formation, and substitution, can occur at Y without C–Sn bond cleavage.

Organotin compounds bearing such β-substituents as OH, OR, SR, NR_2, or PR_2 can undergo β-elimination, as shown in equations (54–56).[22] Alkene eliminations have been reported for alkyltins which have β-hydrogens when reacting with Ph_3C^+ BF_4^-; the reaction proceeds via *trans* elimination (equation 57). An example of γ-elimination is shown in equation 58.

$$Ph_3SnCH_2CH_2OH \xrightarrow{H_3O^+} Ph_3SnOH + H_2C{=}CH_2 \quad (54)$$

$$Ph_3SnCH_2CH_2NMe_2 \xrightarrow{ArSCl} Ph_3SnCl + H_2C{=}CH_2 + Me_2NSAr \quad (55)$$



100 °C	9	:	89

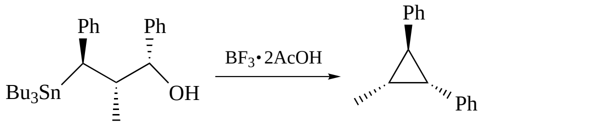
(56)

$$Me_3SnCHRCH_2R' \xrightarrow{Ph_3C^+BF_4^-} [Me_3SnBF_4] + RCH{=}CHR' + Ph_3CH \quad (57)$$



(58)

6 ORGANOTIN(IV) HALIDES AND PSEUDOHALIDES[5]

6.1 Synthesis

6.1.1 Synthesis of Halides

Organotin(IV) halides have been obtained directly from organic halides, RX and tin, or tin chlorides, as outlined in Section 2.1.1.

The Kocheshkov redistribution reaction between tetraorganotins and tin(IV) halides, in appropriate mole ratios, is a general method of synthesis of organotin halides (equations 59 and 60). It is a particularly useful reaction, since it is difficult to control the alkylation of SnX_4 by organolithium or Grignard reagents to the desired extent.

$$nR_4Sn + (4 - n)SnX_n \longrightarrow 4R_nSnX_{4-n} \quad (59)$$

$$Ph_3SnMe + 3SnCl_4 \longrightarrow 3PhSnCl_3 + MeSnCl_3 \quad (60)$$

Carbon–tin bonds are also readily cleaved by halogens (reactivity sequence $Cl_2 > Br_2 > I_2$), hydrogen halides, and metallic halides (including $TiCl_4$, $AlCl_3$, BCl_3, platinum chlorides, and $HgCl_2$) to give organotin halides. Scheme 9 shows products of monosubstitution; depending on the R groups and the halogenating agent, further substitution is possible. The reactivity of R–Sn bonds towards electrophiles such as halogen is usually in the sequence allyl > Ph > $PhCH_2$ > CH_2=CH > Me > Et > Pr > Bu (see equation 42). For bromine reactions, tightly controlled conditions (i.e. temperature, solvent, and rate of addition) are necessary to minimize the formation of some diorganotin dibromides, even at a $R_4Sn:Br_2$ mole ratio of 1:1. Reactions of the less reactive iodine can be more easily limited to monosubstitutions, but disubstitution can arise with the more reactive organotins.

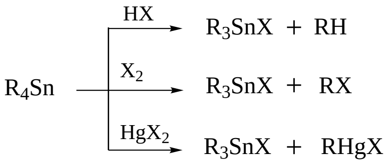
Organotin halides can also be obtained from oxides or hydroxides on reaction with hydrogen halides (or ammonium halides) (equation 61) and from tin–tin bonded species on reaction with halogens (equation 62).

$$[R_2SnO]_n + 2nHX \xrightarrow{-H_2O} nR_2SnX_2 \quad (61)$$

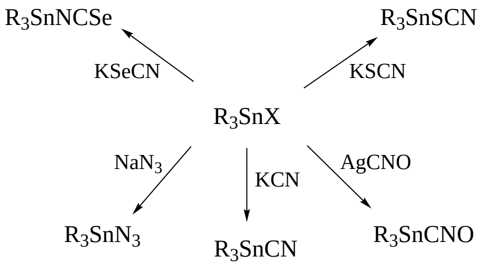
$$R_3Sn{-}SnR_3 \xrightarrow{X_2} 2R_3SnX \quad (62)$$

6.1.2 Synthesis of Pseudohalides

Organotin halides can be converted to the corresponding pseudohalides on treatment with suitable metal salts (Scheme 10). Tin oxides or hydroxides have been used with NH_4Y, HY, or Me_3SiY and tin amides have been used with HY (Y = SCN (or NCS), NCO, N_3, CN, etc.)



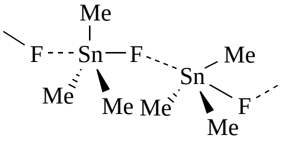
Scheme 9



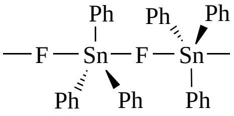
Scheme 10

6.2 Physical and Structural Properties

Triorganotin fluorides, except those with bulky organic groups, are highly associated, are very sparingly soluble in common organic solvents, and have high melting points. Me_3SnF, mp ca. 320 °C, has the asymmetrically fluoride-bridged structure (**13**). Ph_3SnF, $(PhCH_2)_3SnF$, and $(Me_3SiCH_2)_3SnF$ have symmetrically bridged structures[23] with linear Sn–F–Sn linkages (**14**).



(**13**)



(**14**)

In contrast, bulky $(2,4,6\text{-}Me_3C_6H_2)_3SnF$, $[(Me_3Si)_3C]R_2SnF$ (R = Me or Ph) and $(PhMe_2Si)_3CMe_2F$ are monomeric in the solid state and have appreciable solubility, e.g. in chloroform. The simple triorganotin chlorides, bromides, and iodides (along with the di- and monoorganotin derivatives) generally have lower melting points and are usually very much more soluble in chlorocarbon and alcohol solvents than their fluoride analogs; methyltin chlorides, bromides, and iodides have appreciable solubility in water.

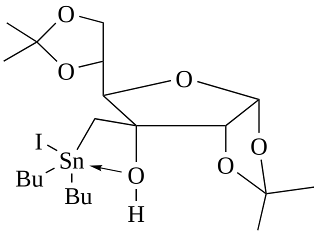
The iodides are the least thermally stable in the series of related halides. Configurational stability of organotin halides is limited, e.g. chiral $MePh(PhCMe_2CH_2)SnCl$ can be obtained but, once formed in solution, it rapidly racemizes.

The organotin halides R_nSnX_{4-n} (X = Cl, Br, or I) are tetrahedral molecules in the vapor phase and as liquids. As a solid, Me_3SnCl has been shown to have a weakly chloride-bridged structure, but one which is broken up on dissolution. The geometry about tin in crystalline R_3SnCl becomes progressively more ideally tetrahedral in the sequence R = cyclohexyl > Ph > $(Me_3Si)_2CH$. Triorganotin bromides and iodides, due both to the reduced electronegativity and the larger size of the halides, more strongly favor monomeric tetrahedral structures, e.g. as shown by Ph_3SnBr.

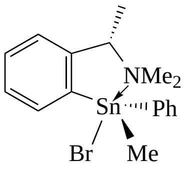
Various triorganotin halides that have in-built donor groups have been found to be chelated in the solid state, with pentacoordinate trigonal bipyramidal tin atoms; the chelation can persist in solution too. Four-, five-, and six-membered chelate rings can be formed, e.g. (**15**)–(**17**).[24–26]

For pseudohalides, intermolecular bridging is usually a strong feature, e.g. in $Me_3SnC{\equiv}N$ (bridging N), $R_3SnN{=}C{=}S$ (R = Me or Ph) (bridging S), Ph_3Sn–N–C=O (bridging O), and $Me_3SnN{=}N{=}N$ (bridging α-N).

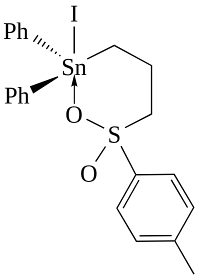
Ionization of tin–halogen bonds can occur in triorganotin halides containing two intramolecular donor groups, e.g. (**18**).[26] Diorganotin dihalides and bis-pseudohalides also exhibit strong tendencies to form aggregated species with



(**15**)

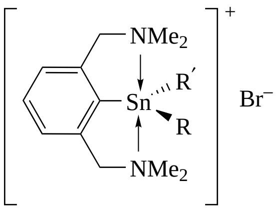


(**16**)

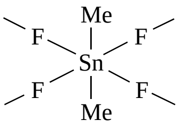


(**17**)

hexacoordinate tin atoms, as in dimethyltin difluoride (**19**) and dimethyltin dicyanide.

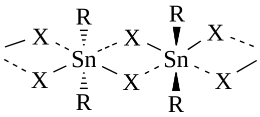


(**18**) R = R′ = Me or Ph; R = Me, R′ = Ph

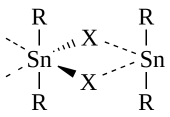


(**19**)

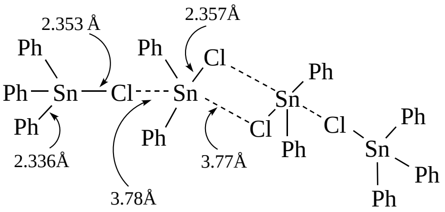
The halide bridging still persists in dialkyltin dichlorides[27] and dibromides, but is somewhat weaker and is of an asymmetric nature, either as in (**20**) or (**21**). Diphenyltin dichloride and methylphenyltin dichloride have weak tetrameric associated structures; the two terminal tin atoms are tetracoordinate, with the middle two tin atoms being hexacoordinate. Dicyclohexyltin dichloride has essentially a one-dimensional polymeric structure with a five-coordinate tin atom, but with an additional weak tin chlorine interaction (**22**). Both bis(2-biphenylyl)tin dichloride and 5,5-dichloro-10,11-dihydrodibenzo[*b*,*f*]stannepin (**23**) are monomeric in the solid state.[28]



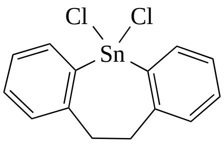
(**20**)
R = Me, Et or Bu; X = Cl;
R = Et, X = Br



(**21**)
R = Et, X = I; R = Me, X = NCS

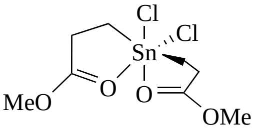


(**22**)

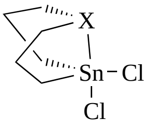


(**23**)

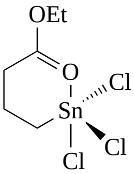
Diorganotin dihalides with in-built donor groups can form monomeric octahedral complexes (with two in-built donor centers) or trigonal bipyramidal complexes (with one in-built donor center), e.g. (**24**) and (**25**). Methyltin trihalides are assumed, from spectroscopic evidence, to have polymeric structures. For monoorganotin halides with in-built donor centers, chelate structures with trigonal bipyramidal tin atoms are possible, e.g. (**26**) and (**27**).



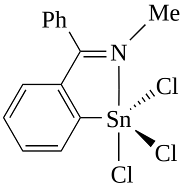
(**24**)



(**25**) X = NMe, O or S



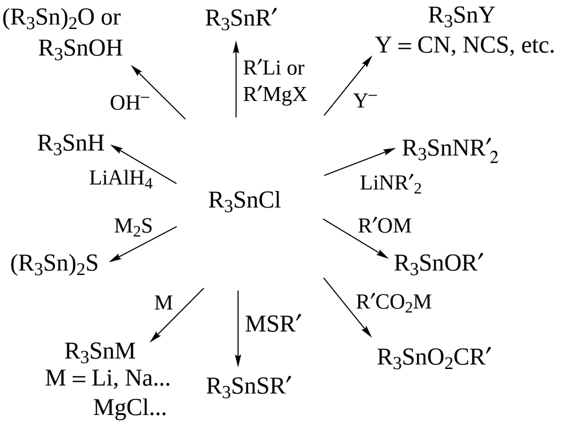
(**26**)



(**27**)

6.3 Reactions

Scheme 11 illustrates for R_3SnCl many of the transformations undertaken by organotin halides and pseudohalides. As already pointed out, trimethyltin halides dissolve to an appreciable extent in aqueous systems to give $[Me_3Sn(OH_2)_2]^+$; its $[BPh_4]^-$ salt has been isolated. A tetraaquadication $[Me_2Sn(OH_2)_4]^{2+}$ is similarly obtained from Me_2SnX_2. The general hydrolysis sequence for organotin halides is shown in Section 12.



Scheme 11

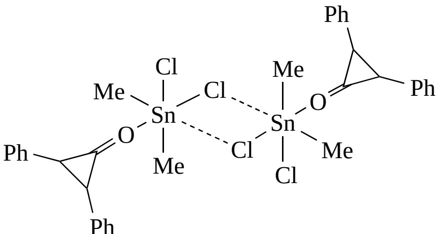
6.4 Lewis Acidity

Organotin halides and pseudohalides are Lewis acids. As has already been indicated, they exhibit a strong tendency to expand their coordination number beyond four. This can be achieved by intermolecular associations or by forming complexes either with external ligands or via intramolecular complexation.

Sequences of acceptor strengths of organotin halides and pseudohalides for R_3SnX are X = NCS > Cl > Br > I and for R_nSnX_{4-n} are $RSnX_3 > R_2SnX_2 > R_3SnX$. Stronger complexes are found for O and N ligands than for S and P ligands.

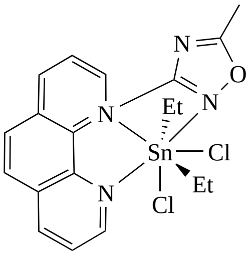
For $R_3SnX{\cdot}L$ complexes, trigonal bipyramidal geometry is obtained, e.g. for $Me_3SnCl{\cdot}py$ and $Ph_3SnCl{\cdot}OPPh_2CH{=}CHP(O)Ph_2$. Complexes of diorganotin dihalides and bis-pseudohalides can contain five-, six-, or seven-coordinate tin, e.g. $[Ph_2SnCl_2(2\text{-}H_2N\text{-benzothiazole})]$ (trigonal bipyramidal tin), $[Me_2SnBr_2(py)_2]$ (*trans* octahedral geometry), $[Ph_2Sn(NCS)_2(bipy)]$ (*cis* octahedral geometry), and $[Me_2Sn(NCS)_2(terpyridyl)]$ (pentagonal bipyramidal geometry with *trans* methyl groups).

A chloride-bridged dimeric complex $[Me_2SnCl_2{\cdot}(2,3\text{-diphenylcyclopropanone})]$ (**28**) has been characterized. A seven-coordinate tin complex (**29**) has also been prepared.



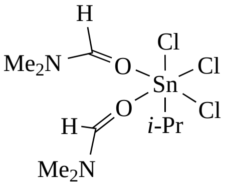
(**28**)

Both trigonal bipyramidal, e.g. as in $MeSnBr_3{\cdot}DMF$, and octahedral complexes of organotin trihalides are known, e.g. *fac*- and *mer*-$[i\text{-}PrSnCl_3{\cdot}(DMF)_2]$ (**30**) have been



(**29**)

characterized.[29] Anionic complexes, $[R_3SnX_2]^-$, $[R_2SnX_3]^-$, $[RSnX_4]^-$, and $[RSnCl_5]^{2-}$, etc., can also be isolated, e.g. (**31**) and (**32**).[30]



fac-(**30**)

(**32**)

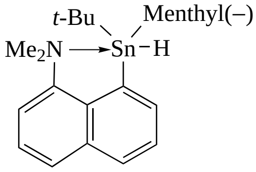
7 ORGANOTIN(IV) HYDRIDES

Reduction of organotin halides R_nSnX_{4-n} by $LiAlH_4$ or $NaBH_4$ in Et_2O at room temperature is the most frequently used route to R_nSnH_{4-n} (equation 63). Alternative routes include hydrolysis of tin–alkali metal or tin–alkaline earth metal bonded compounds. (equation 64). Deuterides may be similarly obtained using, for example, $LiAlD_4$ with organotin halides or D_2O with anionic Sn species.

$$Ph_3SnCl \xrightarrow{LiAlH_4} Ph_3SnH \tag{63}$$

$$Bu_3SnNa \xrightarrow{H_2O} Bu_3SnH \tag{64}$$

The thermal stability of R_nSnH_{4-n} falls in the sequence $n = 3 > 2 > 1$ and R = aryl > alkyl. They can normally be distilled under reduced pressure, but are sensitive towards oxygen. In their spectrum the Sn–H bond has a sharp absorption at 1800–1880 cm^{-1}. The hydrides are monomeric in both gas and solution phases. The crystal structure of the chiral tin hydride (−)-(*t*-Bu)(8-Me_2N-naphthyl)(menthyl)tin hydride (**33**) has been determined.[31]

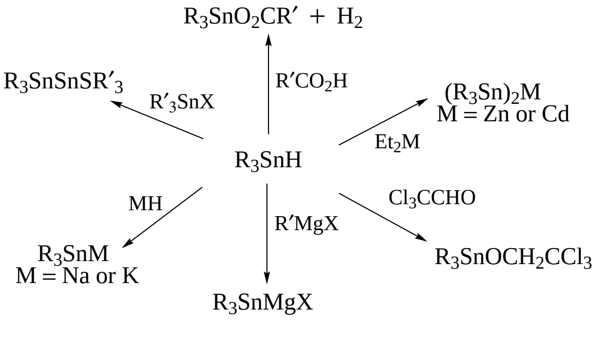


(**33**) Sn–N = 2.931 and 2.885 Å
Sn–H = 1.52(5) and 1.63(5) Å

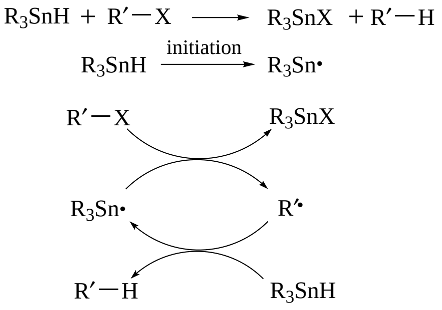
Organotin hydrides can undergo either heterolytic or homolytic reactions. Reactions with carboxylic acids and with R'_3SnX (X = OR, NR_2, or other nucleophilic groups) are considered to be heterolytic reactions. Other heterolytic reactions of triorganotin hydrides are shown in Scheme 12.

Addition of tin hydrides to C=O and C=NR groups can proceed via a polar mechanism, or via a radical mechanism if azobis(isobutyronitrile) (AIBN) is added or UV irradiation is used. Alkenes with strongly electron-withdrawing groups, e.g. $CH_2{=}CHC{\equiv}N$, undergo nucleophilic addition reactions with R_3SnH to give the α-adduct; however, in the presence of a radical initiator, homolytic addition occurs to give the β-adduct (Scheme 3). Most additions of tin hydrides to alkenes (hydrostannations) proceed via homolytic chain mechanisms and usually a radical initiator (AIBN or UV light) is employed (Scheme 2).

Another important homolytic reaction of tin hydrides is the reduction of carbon–halogen bonds; the reaction is promoted by initiators and retarded by radical traps (Scheme 13). Reactivity decreases in the sequence X = I > Br > Cl and $Bu_3SnH > Bu_2SnH_2 \approx Ph_3SnH > BuSnH_3$. Other groups X in RX that can be reduced by tin hydrides include –OC(S)R, SR, SePh, TePh, NC, and NO_2. The intermediate radical, R′• in Scheme 13, can be trapped by additional substances, e.g. alkenes, or may undergo



Scheme 12



Scheme 13

cyclization or some other rearrangement before reaction with R_3SnH. Tin hydrides have found great use in organic synthesis.

8 TIN–TIN BONDED COMPOUNDS[2,32–34]

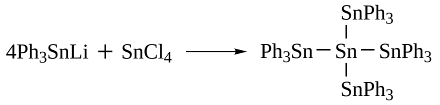
Various tin–tin bonded compounds are known. The simplest tin–tin bonded compounds, hexaorganoditins, R_3SnSnR_3, are available by several routes, including: (i) from triorganotin halides and alkali metals in ether or liquid ammonia (equation 65); (ii) from triorganotin halides and triorganotin lithium compounds (equation 66); and (iii) from triorganotin hydrides in the presence of a base (such as pyridine) or on reaction with Sn–O, Sn–N, or Sn–S species (Scheme 14).

$$2R_3SnCl + M \longrightarrow R_3SnSnR_3 \quad M = Na, Li, etc. \qquad (65)$$

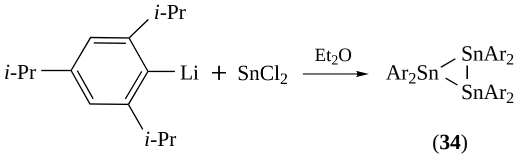
$$R_3SnCl + R'_3SnLi \longrightarrow R_3SnSnR'_3 \qquad (66)$$

Extensions of these reactions lead to polytin species (equations 67 and 68). Oligomerization of diorganostannylenes provides cyclic species (Scheme 15). The resulting ring size is clearly dependent on conditions; various interesting cyclic species are available from hindered organostannylenes (equation 69 and Scheme 16).[35,36] The cyclic polystannanes have been reported to undergo disproportionations in solution, e.g. *cyclo*-$(Me_2Sn)_6$ in solution reorganizes to $(Me_2Sn)_n$ (n = 7, 8, and 9).

$$Ph_3SnH + (Me_2NCH_2CH_2CH_2)_2Sn(NEt_2)_2 \longrightarrow (Ph_3Sn)_2Sn(CH_2CH_2CH_2NMe_2)_2 \qquad (67)$$



(68)



(69)

(**34**)

An electron diffraction study of $Me_3SnSnMe_3$ has been carried out, as have crystal structure determinations of various R_3SnSnR_3 (e.g. R = Ph, *p*-MeC_6H_4, $PhCH_2$, and *t*-Bu), linear tri- and polytins (e.g. *t*-Bu_3SnSn-*t*-Bu_2Sn-*t*-Bu_3), $Ph_3SnSn(CH_2CH_2CH_2NMe_2)_2SnPh_3$, $Ph_3Sn(Sn\text{-}t\text{-}Bu_2)_nSn Ph_3$ (n = 3 or 4), and cyclic polytin species, e.g. (**34**; Ar = 2,6-$Et_2C_6H_3$ or 2,4,6-*i*-$Pr_3C_6H_2$)[37] and (**35**)–(**41**).[38–40] The three-membered ring (Sn_2N) compound (**37**) was obtained from a stannylene and an acyl azide (equation 70).[41] The tin–tin bond lengths vary in the region 2.68–2.90 Å.[38–41] Compound (**40**), a dark-violet blue, air-sensitive compound, was produced on thermolysis of *cyclo*-$[(2,6\text{-}Et_2C_6H_3)_2Sn]_3$.[38]

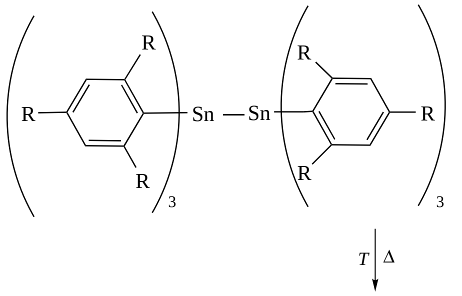
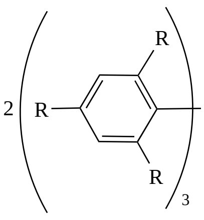
The lower hexaalkylditins can be distilled in vacuo without decomposition. More elaborate ditins can suffer tin–tin homolytic cleavages on heating (equation 71). The dissociation energies for Me_6Sn_2, (**41a**), and (**41b**) are 225, 190, and 125 kJ mol^{-1}, respectively.



(71)

(**42a**) R = Me; *T* = 180 °C
(**42b**) R = Et; *T* = 100 °C



Tin–tin bonds also undergo photochemical cleavage (equations 72 and 73). The chemical reactions undergone by tin–tin compounds are illustrated in Scheme 17 and equation (74). Mixed Group 14 metal–metal compounds have also been studied, e.g. $(p\text{-}MeC_6H_4)_3SnPb(C_6H_4Me\text{-}p)_3$.[42]

$$R_3SnSnR_3 \xrightarrow{h\nu} 2R_3Sn\bullet \quad (72)$$

$$(R_2Sn)_n \xrightarrow{h\nu} R_2\dot{S}n(SnR_2)_{n-2}\dot{S}nR_2 \longrightarrow nR_2Sn\colon \quad (73)$$

$$cyclo\text{-}[t\text{-}Bu_2Sn]_4 \xrightarrow{I_2} I(t\text{-}Bu)_2Sn(Sn\text{-}t\text{-}Bu_2)_2Sn(t\text{-}Bu)_2I \quad (74)$$

9 ORGANOSTANNYL RADICALS[2]

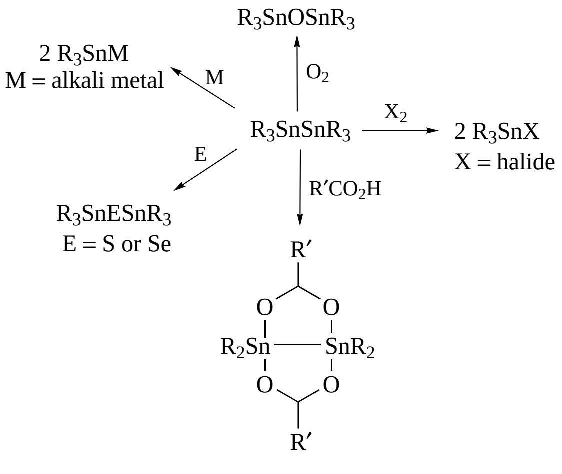
Organostannyl radicals, $R_3Sn\bullet$, are generated as short-lived species in several reactions, e.g. of R_3SnH. Photolysis of hexaorganoditins, especially in the presence of *t*-BuOO-*t*-Bu, is a most convenient method of obtaining stannyl radicals for physical and ESR spectroscopic studies. Other routes to organostannyl radicals include (i) abstraction of hydrogen from R_3SnH using *t*-BuO• (generated from *t*-BuOO-*t*-Bu); (ii) photolysis of cyclopentadienyl-SnR_nX_{3-n} (X = chloro, alkyl, or C_5H_5) (which provides $R_nX_{3-n}Sn\bullet$); (iii) β-scission of a radical carrying a β-organotin substituent (equations 75 and 76); (iv) photolysis of solutions containing monomeric stannylenes, e.g. $[(Me_3Si)_2CH]_2Sn$ (equation 77); and (v) γ-irradiation of R_4Sn in hydrocarbon matrices at low temperatures (equation 78). Thermolysis of hindered $Ar_3SnSnAr_3$, e.g. Ar = 2,4,6-$R_3C_6H_2$ (R = Me, Et, or *i*-Pr), can also reversibly lead to triarylstannyl radicals (equation 71).

$$\begin{matrix} R_3SnO-CPh_2 \\ | \\ R_3SnO-CPh_2 \end{matrix} \xrightarrow{rt} 2R_3SnO\dot{C}Ph_2 \xrightarrow{60\,^\circ C} 2R_3Sn\bullet + O{=}CPh_2 \quad (75)$$

$$Me_3SnCH_2CHMe_2 \xrightarrow[-t\text{-}BuOH]{t\text{-}BuO\bullet} Me_3SnCH_2\dot{C}Me_2 \longrightarrow Me_3Sn\bullet + H_2C{=}CMe_2 \quad (76)$$

$$[(Me_3Si)_2CH]_2Sn\colon \xrightarrow{h\nu} [(Me_3Si)_2CH]_3Sn\bullet \quad (77)$$

$$Me_4Sn \xrightarrow[\text{adamantane } 77\,K]{\gamma\text{-irradiation}} Me_3Sn\bullet \quad (78)$$



Scheme 17

The bulky stannyl radical $[(Me_3Si)_2CH]_3Sn\bullet$ has a half-life of ca. 1 year. The organostannyl radicals have pyramidal structures, with the unpaired electron in an orbital with a large degree of s character.

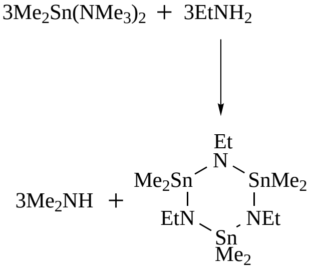
10 TIN–NITROGEN BONDED COMPOUNDS[2,43]

Tin–nitrogen bonded compounds are generally formed by reaction of an alkali or alkaline earth metal amide with an organotin halide; compounds of the types $R_nSn(NR'_2)_{4-n}$, (n = 1–3), $(R_3Sn)_nNR'_{3-n}$ (n = 1–3), and *cyclo*-$(R_2SnNR')_n$ (n = 2 or 3) can be prepared (equation 79). Other routes include transaminations (equations 80 and 81). Tin carboxamides and sulfonamides have been obtained by reaction of tin oxides or hydroxides with amides (equation 82).

(79)

(**43**)

$$2Me_3SnNMe_2 + EtNH_2 \longrightarrow (Me_3Sn)_2NEt + 2Me_2NH \quad (80)$$



(81)

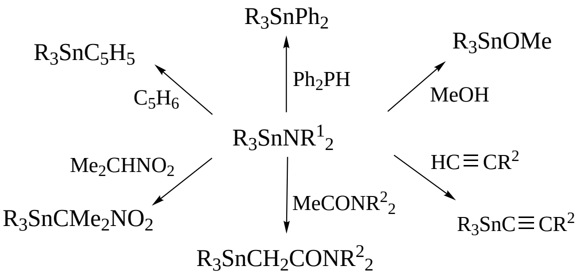
$$(Bu_3Sn)_2O + 2H_2NCOMe \longrightarrow 2Bu_3SnNHCOMe \quad (82)$$

10.1 Structures

Tetrahedral, four-coordinate tin is generally found in organotin amides. An electron diffraction structure revealed $(Me_3Sn)_3N$ to have a planar $[Sn_3N]$ core. The bulky amino-halides $[(Me_3Si)_2CH]_2Sn(X)NHC_6H_2$-*t*-$Bu_3$-2,4,6 (X = Cl or F) are monomeric compounds.[44] The $(SnN)_n$ rings in $[t\text{-}Bu_2SnNR]_2$ (R = *t*-Bu or SO_2Me) and $[t\text{-}Bu_2SnNH]_3$ were shown by X-ray crystallography to be planar.[45] An associated structure was indicated from Mössbauer data for the stannylaziridine compound (**43**). 1-Tricyclohexyltin-1,2,4-triazole is also associated in the solid state (via Sn–N(4) bridging); in contrast, the more bulky 1-$(PhCMe_2CH_2)_3Sn$-2,4-triazole is monomeric.

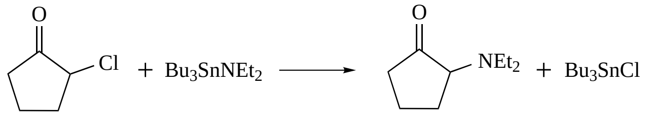
10.2 Reactions

Aminotin species are readily hydrolyzed and react with protic reagents (Scheme 18). Substitution reactions occur with reactive halides (equations 83 and 84), as do addition reactions with heterocumulenes, e.g. O=C=C=C=O

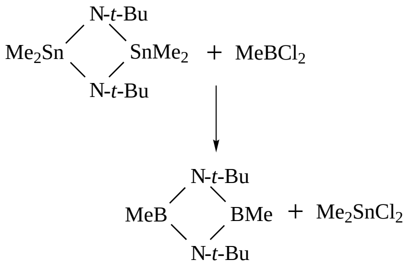


Scheme 18

(equation 85),[46] and with some simple carbonyl compounds (equation 86).



(83)



(84)

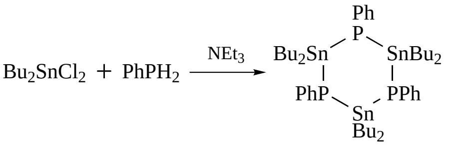
$$2Me_3SnNMe_2 + O{=}C{=}C{=}C{=}O \longrightarrow (Me_3Sn)_2C(CONMe_2)_2 \quad (85)$$

$$Me_2Sn(Cl)NEt_2 \xrightarrow{CS_2} ClMe_2SnSCSNEt_2 \quad (86)$$

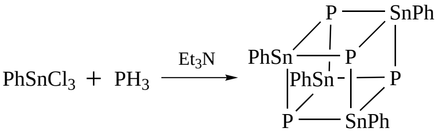
11 TIN–PHOSPHORUS, –ARSENIC, AND –ANTIMONY BONDED COMPOUNDS

Synthesis of these compounds can be achieved by routes similar to those used for Sn–N bonded species (equation 87). Reactions of di- and trihalotins with R'_2PH_{3-n} (n = 0, 1) can lead to cages and rings (equations 88 and 89). The more bulky *t*-Bu_2SnCl_2 provides cyclic Sn_2P_2 compounds (**44**) on reaction with $NaPH_2$, $(Me_3Si)_2PMe$, or LiPH-*t*-Bu. Crystal structures have been determined for $[(Me_2Sn)_6P_2]$ and for $[(Me_2Sn)_5P_2]$ (**45**), which is obtained from $HMe_2SnSnMe_2H$ and phosphorus. Compounds with tin–phosphorus double bonds have also been reported,[47] e.g. $[(Me_3Si)_2CH]_2Sn{=}PC_6H_2$-*t*-$Bu_3$-2,4,6.

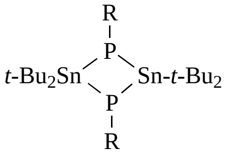
$$3Me_3SnCl + EH_3 \xrightarrow{NEt_3} 3(Me_3Sn)_3E \quad E = P \text{ or } As \quad (87)$$



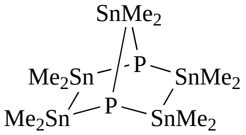
(88)



(89)

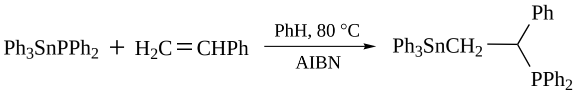


(**44**) R = H, Me or *t*-Bu



(**45**)

Examples of compounds with a Sn–Sb bond[48] are $(Me_3Sn)_2Sb–Sb(SnMe_3)_2$ (**46**) and $(Me_3Sn)_3Sb$ (**47**); photolysis of (**46**) provides (**47**). IR spectra of $(Me_3Sn)_3E$ (E = P, As, or Sb) indicate planar $[Sn_3E]$ cores. The Sn–P, Sn–As, and Sn–Sb bonds are thermally relatively stable, but are oxygen and water sensitive. Tin−phosphorus bonded compounds add[49] to heterocumulenes (as do Sn–N bonded compounds), and to alkenes, allenes, and alkynes such as $CH_2{=}CHCH_2Cl$, $CH_2{=}CHPh$ and $PhC{\equiv}CH$ (unlike Sn–N bonded species) (equation 90).



(90)

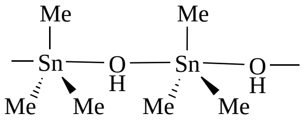
12 TIN–OXYGEN BONDED COMPOUNDS[1,2]

A vast array of tin−oxygen bonded compounds is known. The majority of organotin−oxygen bonded compounds contain tin with a coordination number greater than four due to the high donor affinity of oxygen for tin and the relatively large nuclear charge at tin. Association results from oxygen bridging, which, however, can be prevented if bulky groups are present.

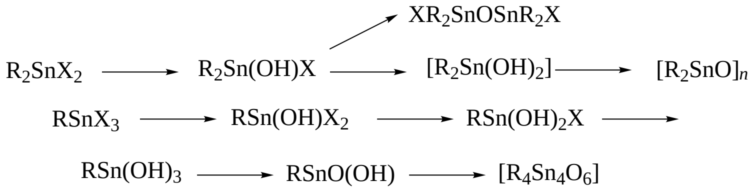
12.1 Organotin Oxides and Hydroxides

These compounds are most readily obtained by hydrolysis of organotin halides, especially under basic conditions, although hydrolysis of alkoxides and amides, etc., can also be used. Hydrolysis of di- and trihalides occurs in a stepwise fashion and various of the partial hydrolysis products have been characterized (Scheme 19).

Triorganotin hydroxides, R_3SnOH (R = Me, aryl, or bulky alkyl groups, e.g. $PhCMe_2CH_2$), are resistant to dehydration to the oxide, $(R_3Sn)_2O$; for other R_3SnOH, dehydration results relatively easily, e.g. on melting or on dissolution in nonaqueous media. Tris(2,4,6-trimethylphenyl)tin hydroxide is monomeric in the solid state (Sn–O = 1.999 Å).[50] Solid Me_3SnOH, which can be sublimed above 80 °C, has the associated structure (**48**) with OH groups bridging near planar Me_3Sn groups. Dehydration of Me_3SnOH, using sodium in benzene or CaH_2, provides the readily hydrated liquid $(Me_3Sn)_2O$, which in the gas phase has a Sn–O–Sn valency angle of 141° and a Sn–O bond length of 1.94 Å. The crystal structure of triphenyltin hydroxide consists of a zigzag chain of planar Ph_3Sn groups asymmetrically bridged by OH groups. Dehydration of Ph_3SnOH occurs at ca. 100 °C to give $(Ph_3Sn)_2O$, which has a four-coordinate tin atom and a Sn–O–Sn valency angle of 137°. Of interest, valency angles of 180° are found in solid $(PhCH_2)_3SnOSn(CH_2Ph)_3$ and t-Bu_3SnOSn-t-Bu_3.



(**48**)



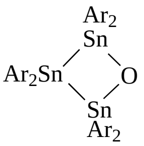
Scheme 19

The hydroxides are characterized in the IR spectra by ν(O–H) bands at 3610–3630 cm^{-1} and δ(OH) at 890–920 cm^{-1}; oxides have a broad ν(Sn–O–Sn) band at 740–770 cm^{-1}.

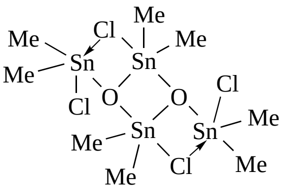
12.2 Diorganotin Hydroxides and Oxides

Diorganotin oxides (R_2SnO) generally are polymeric species, which are insoluble in inert solvents; bulky compounds, e.g. (t-$Bu_2SnO)_3$ and $(EtCMe_2SnO)_3$, are trimeric in the solid state with planar Sn_3O_3 cores.

An interesting heterocycle (**49**) with a planar Sn_3O core was prepared by aerial oxidation[51] of the *cyclo*-tetratin, Ar_2Sn–$SnAr_2$–$SnAr_2$–SnArBr (Ar = 2,6-$Et_2C_6H_3$). The crystal structure determination of the partial hydrolysis product of Me_2SnCl_2, viz. $ClMe_2SnOSnMe_2Cl$ (**50**), reveals a dimeric ladder-type structure with a central planar Sn_2O_2 core. This Sn_2O_2 feature is found in many structures.



(**49**) Ar = 2,6-$Et_2C_6H_3$



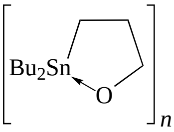
(**50**)

12.3 Monoalkyltin Hydroxides and Oxides

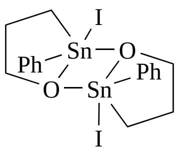
The fully hydrolyzed organotin trihalides are the aggregated alkane- or arenestannoic acids $[RSn(O)(OH)]_n$.

12.4 Alkoxides

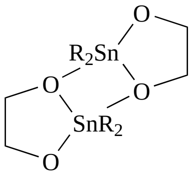
Simple organotin alkoxides or phenoxides are available from the halides on reaction with MOR or MOAr, as well as from the oxides and the alcohol or phenol on azeotropic dehydration. These compounds are generally sensitive to H_2O and to CO_2. Cyclic alkoxides, e.g. (**51**) and (**52**),[52] and cyclic dialkoxides from diols, e.g. (**53**), can also be prepared. These complexes are usually oligomeric.



(**51**)

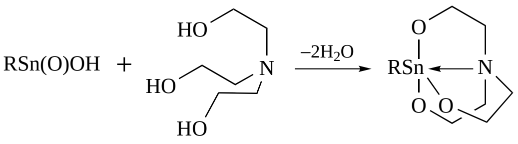


(**52**)



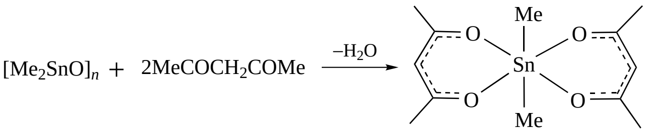
(**53**)

Stannoic acids react with triols, e.g. triethanolamine (equation 91). Triorganotin alkoxides R_3SnOR' (as well as oximes, etc.), similar to R_3SnOH, show a strong tendency to form one-dimensional polymers with oxygen bridging near planar R_3Sn units. Steric crowding at tin (but not at oxygen) reduces the tendency to associate; for example, as R in $R_3SnONC_6H_{11}$ changes in the sequence Me, Et, Pr, Ph, association becomes progressively weaker and the R_3Sn becomes more pyramidal in shape, and for R = Ph the geometry at tin is tetrahedral.



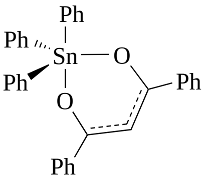
(91)

Derivatives of 1,3-diones can be prepared from the oxides with the dione (equation 92); as shown by (**54**) and (**55**), chelate complexes are formed.



(**54**)

(92)



(**55**)

12.5 Reactions of the Sn–O Bond

The reactions of tin oxides and alkoxides fall into two categories: cleavage reactions and addition reactions. Cleavage or substitution reactions include reactions with acidic protic reagents, including amides (equation 93), thiols (equation 94), and acyl chlorides or anhydrides (equation 95). Addition reactions occur with heterocumulenes (equations 96 and 97).

$$(Bu_3Sn)_2O + HNPhCOMe \longrightarrow Bu_3SnNPhCOMe \quad (93)$$

$$(Bu_3Sn)_2O + HSR \longrightarrow Bu_3SnR + H_2O \quad (94)$$

$$Bu_3SnOR + MeCOCl \longrightarrow Bu_3SnCl + MeCO_2R \quad (95)$$

$$Me_3SnOMe + H_2C{=}C{=}O \longrightarrow Me_3SnCH_2CO_2Me \quad (96)$$

$$Bu_3SnOMe + PhNCO \longrightarrow Bu_3SnNPhCO_2Me \quad (97)$$

12.6 Organotin Carboxylates

Organotin carboxylates are generally available from the oxides (or hydroxides) on reaction with the carboxylic acid (equation 98), or from the organotin halides with sodium carboxylates (equation 99). Electrophilic cleavage of the

more reactive carbon–tin bonds by RCO_2H also provides carboxylates (equation 100).

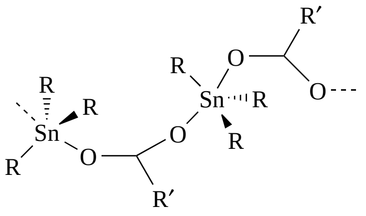
$$(R_3Sn)_3O + 2R'CO_2H \xrightarrow[-H_2O]{PhMe,\Delta} R_3SnO_2CR' \quad (98)$$

$$R_nSnCl_{4-n} + (4-n)R'CO_2Na \longrightarrow R_nSn(O_2CR')_{4-n} \quad (99)$$

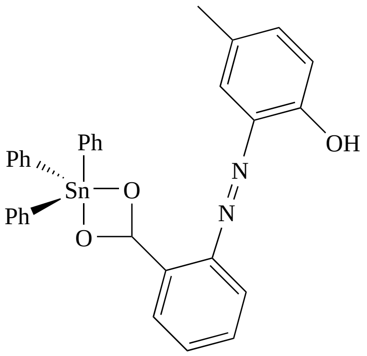
$$R–Sn\equiv + R'CO_2H \longrightarrow RH + R'CO_2Sn\equiv \quad (100)$$

12.6.1 *Structures of Carboxylates*[53]

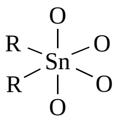
The crystal structures of triorganotin carboxylates, R_3SnO_2CR', fall into two groups: (i) the majority, including those with R = Me, $CH_2{=}CH$, Ph, and $PhCH_2$, which have a one-dimensional polymeric structure (**56**); and (ii) those with a monomeric five-coordinate trigonal bipyramidal tin atom, e.g. (**57**), with bulky R groups. For diorganotin dicarboxylates, structures such as *cis*-(**58**) and *trans*-(**59**) octahedral forms as well as skew-trapezoidal forms (**60**) are found.



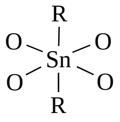
(**56**)



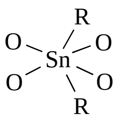
(**57**)



(**58**)



(**59**)



(**60**)

12.6.2 *Reactions of Carboxylates*

Most triorganotin carboxylates are stable to hydrolysis; however, $R_2Sn(O_2CR')_2$ and $RSn(O_2CR')_3$ show a progressive ease towards hydrolysis to form oxycarboxylates, e.g. $[R_2Sn(OCOR')OSnR_2OCOR']_2$ and $[RSn(O)O_2CR']_6$. The structure of the latter type of complex (e.g. R = Bu or Ph; R' = cyclohexyl) is drum-like.

Certain carboxylates R_3SnO_2CR' (e.g. R' = H, $C\equiv CR^2$, $CH_2{=}CH$, or C_6F_5) can be decarboxylated to R_3SnR' (equation 101). Other reactions include halide/carboxylate exchanges (equation 102).

$$Bu_3SnO_2C{\equiv}Ph \xrightarrow{60\,^\circ C} Bu_3Sn{\equiv}Ph \quad (101)$$

$$R_2Sn(O_2CR')_2 + R_2SnX_2 \longrightarrow 2R_2Sn(X)O_2CR' \quad (102)$$

12.7 Nitrates

Di- and triorganotin nitrates can be prepared from the corresponding oxides (or hydroxides) and nitric acid, or from treatment of the halides with $AgNO_3$ in acetone at 0 °C. Anhydrous $Me_2Sn(NO_3)_2$, which is explosive on heating, is available from Me_4Sn and N_2O_4 in dry EtOAc. Methyltin trinitrate has been produced from $MeSnCl_3$ and N_2O_5 in CCl_4.

The NO_3 groups are bidentate O,O ligands in $MeSn(NO_3)_3$ and in $Me_2Sn(NO_3)_2$, whereas in $[Me_3SnNO_3{\cdot}H_2O]$ the NO_3 group is monodentate: the three compounds have pentagonal bipyramidal, octahedral, and trigonal bipyramidal geometries, respectively.

The anionic species $[Ph_3Sn(NO_3)_2]^-$ also contain monodentate nitrate groups.[54] A different binding mode is found for NO_3 in anhydrous Me_3SnNO_3; it bridges Me_3Sn units to form a one-dimensional polymer.

12.8 Sulfates, Sulfinates, and Sulfonates

Preparative routes to these derivatives are shown in equations (103–108). The compounds $Me_3SnOSOR'$ (R' = Me and $CH_2CH{\equiv}CH$) and $Me_3SnOSeOMe$ have polymeric chain structures with bridging O_2ER' (E = S or Se) groups, whereas $Me_2Sn(OSO_2F)_2$ has a polymeric sheet-type structure. A trigonal pyramidal tin atom is present in $(Me_3SnO)SO_2{\cdot}2H_2O$, with each H_2O acting as an axial ligand to each tin.[55]

$$2R_3SnX + Ag_2SO_4 \longrightarrow (R_3SnO)_2SO_2 \quad (103)$$

$$(R_3Sn)_2O + H_2SO_4 \longrightarrow (R_3SnO)_2SO_2 \quad (104)$$

$$R_4Sn + SO_2 \xrightarrow{<0\,^\circ C} R_3SnOSOR \quad (105)$$

$$R_3SnCl + NaOSOR' \longrightarrow R_3SnOSOR' \quad (106)$$

$$(R_3Sn)_2O + R'SO_3H \longrightarrow R_3SnO–S(O)OR' \quad (107)$$

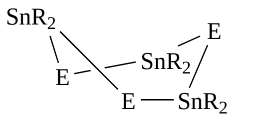
$$R_4Sn + SO_3 \xrightarrow{<0\,^\circ C} R_3Sn–O–S(O)OR \quad (108)$$

13 TIN–SULFUR, –SELENIUM, AND –TELLURIUM BONDED COMPOUNDS

The best studied of these compounds are the tin–sulfur bonded species, with $(R_3Sn)_2S$, $(R_2SnS)_n$, $(R_4Sn_4S_6)$, and $R_nSn(SR')_{4-n}$ ($n = 1-3$) being particularly well investigated. The most frequently met Sn–Se and Sn–Te (Sn–E) bonded compounds are $(R_3Sn)_2E$, $(R_2SnE)_n$, and R_3SnER'. Their preparation usually involves reaction of the corresponding halide (or oxide) with H_2E or HER′ in the presence of a base or the use of sodium salts of the acids. Alternative methods include insertion of sulfur, selenium, or tellurium into tin–tin or tin–alkali metal bonds. The compounds R_3SnEH (E = S, Se, or Te) are generally unstable and decompose to $(R_3Sn)_2E$ and H_2E.

13.1 Structures

The tin atoms in these compounds have near tetrahedral geometry. Bis(triphenyltin) sulfide (Sn–S = 2.37 Å) and selenide (Sn–S = 2.525 Å) are monomeric molecules with nonlinear Sn–E–Sn valency angles; in the more bulky $(t\text{-}Bu_3Sn)_2E$, the valency angles decrease[56] in the sequence E = S, Se, Te, angle = 134.2, 127.2, 122.3°. In contrast to the polymeric diorganotin oxides, the diorganotin chalcogenides (R_2SnE) form ring structures, normally trimeric[57] with a twist-boat conformation (**61**) for the smaller R groups (e.g. R = Me or Ph); while dimers (**62**) with planar Sn_2E_2 cores are found for more bulky R groups (e.g. R = *t*-Bu).[58] In addition, a polymeric form of $[i\text{-}Pr_2SnS]_n$ has been reported. The sesquisulfides $R_4Sn_4S_6$ have an adamantane-type structure (**63**).



(**61**)

		d(Sn–E)Å
R = Me;	E = S	2.41
	E = Se	2.53
	E = Te	2.74

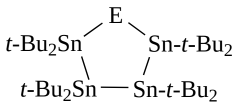
(**69**) Ar = 2,4,6-i-$Pr_3C_6H_2$



(**70**) E = S, Se or Te

13.2 Reactions

The Sn–S, Sn–Se, and Sn–Te bonded compounds are less reactive than Sn–O bonded species, e.g. towards water. Reactions proceed with a variety of electrophilic reagents (e.g. alkyl halides, halogens, and sulfur(II) halides).

13.3 Other Tin-Sulfur Bonded Compounds

Triorganotin dithiocarbamates, $R_3SnSCSNR'_2$, and dithiophosphates, $R_3SnSP(S)(OR')_2$, usually contain monodentate ligands. However for the di- and monoorganotin derivatives, these ligands normally act as chelating groups, for example as in $Ph_2Sn[S_2P(OEt)_2]_2$ and $Me_2Sn(S_2CSNMe_2)_2$ (skew trapezoidal tin), in $Ph_2Sn[S_2P(O\text{-}i\text{-}Pr)_2]_2$ (*trans* octahedral geometry), and in $MeSn(S_2CNEt_2)_3$ (distorted pentagonal bipyramidal tin).

13.4 Organotin(II) Compounds: Stannylenes[1,61,62]

Simple, unhindered, R_2Sn^{II} compounds (e.g. R = Me or Ph) have only a fleeting existence under normal conditions, and, in the absence of a trapping agent, rapidly oligomerize to $[R_2Sn]_n$ after formation. However, sufficient stability is realized[63] for study on isolation in argon matrices at low temperatures, e.g. 5 K for Me_2Sn. Conditions have been found to stabilize alkyl and aryl stannylenes at ambient temperatures. These conditions, each of which may be adequate on their

own,[1,25] are (i) the use of bulky organic groups, e.g. (**71**); (ii) the formation of adducts with Lewis bases, especially intramolecular bases, e.g. (**72**), (**73**), and (**74**); and (iii) the coordination of the lone pair at Sn with suitable transition metal acceptors, e.g. (**75**). In addition, π-bonded organostannylenes, e.g. Cp_2Sn, have good thermal stabilities.

Scheme 21

13.5 σ-Bonded Organotin(II) Compounds

Simple σ-bonded R_2Sn^{II} species have been generated (i) by thermolysis or photolysis of diorganotin oligomers $(R_2Sn)_n$; (ii) by controlled reaction of R_2SnCl_2 with $ArH^{-\bullet}$, M^+ (e.g. naphthalene$^{-\bullet}$, Na^+) or ArH^{2-}, $2M^+$ (e.g. anthracene^{2-}, $2Li^+$; Anth^{2-}, $2Li^+$); and (iii) by thermal elimination from 7-stannanorbornenes (Scheme 20).

Dimethylstannylene (either $(CH_3)_2Sn$ or $(CD_3)_2Sn$), when isolated in an argon matrix, was shown by IR spectroscopy to have a C_{2v} symmetry.[63] Conflicting predictions of bond lengths and dipole moments for Me_2Sn have been made from different theoretical treatments; however, a singlet ground state was suggested from such studies. From experimental studies, different spin states for R_2Sn have been indicated by the different reactivities of photochemically and thermally generated R_2Sn, e.g. towards MeCOCOMe.

The more hindered and stable $[(Me_3Si)_2CH]_2Sn$ has been obtained[64] by the routes shown in Scheme 21.

In the solid state, red $[(Me_3Si)_2CH]_2Sn$ (**71**) was shown by X-ray crystallography to exist as a nonplanar, centrosymmetric, weakly datively bonded dimer (**76**) (Sn–Sn = 2.768(1) Å); in hydrocarbon solutions, NMR spectra indicated a monomer–dimer equilibrium with the energy of dissociation = 12.8 kcal mol^{-1} (equation 109). From an electron diffraction study, $[(Me_3Si)_2CH]_2Sn$ in the gas phase has a V-shaped monomeric structure, with C–Sn–C = 97(2)°. The related stannylene (**77**) is monomeric in the solid state, with the shortest Sn···Sn distance of 7.4 Å. The dark-red air- and moisture-sensitive compound (**77**) exists in a dimer–monomer equilibrium in solution.[65] Two crystal modifications of $[2,4,6\text{-}(F_3C)_3C_6H_2]_2Sn$ have been reported;[66] one is monomeric and the other is a weakly associated dimer with a Sn–Sn distance of 3.639(1) Å. There are Sn–F interactions (equation 110).

The distannene (**80**) is in equilibrium with a cyclic trimer (**81**) (equation 111).[67] Other chelated stannylenes include (**82**)–(**85**) (equations 112 and 113).[25,68] Compound (**82**) is a yellow, very oxygen-sensitive compound, stable to 180 °C and is soluble in organic solvents. In the solid the N–Sn–N and C–Sn–C valency angles are 165.2 and 93.8°, respectively, and it has a pseudotrigonal bipyramidal structure. It forms a white $W(CO)_5$ adduct (**83**).

(113)

A novel dialkyl-Sn compound (**86**), stabilized by coordination to Zn, has been isolated and characterized. (equation 114).[25,69] The compound $[(Ph_2P)_2CH]_2Sn$ (**87**), obtained from $SnCl_2$ and $(Ph_2P)_2CHLi$, is a three-coordinate tin species with a pyramidal $[SnCP_2]$ core;[70] however, at a higher temperature (50 °C) ^{31}P NMR suggests a two-coordinate C–Sn–C bonded species. In contrast, $[(Me_2P)_2CH]_2Sn$ (**88**) contains a four-coordinate tin atom with four Sn–P contacts.

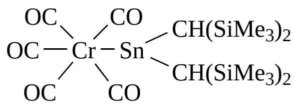
(**88**)

13.6 Reactions

σ-Bonded R_2Sn^{II} compounds, apart from oligomerizations, readily undergo oxidative addition and insertion reactions to give Sn^{IV} species, as shown in Scheme 22.

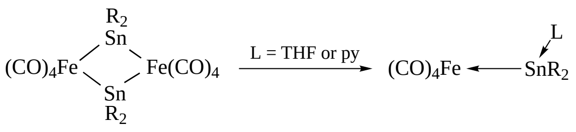
Cleavage of carbon–tin bonds has also been reported by protic species, e.g. in reactions of $[2,6\text{-}(F_3C)_2C_6H_3]_2Sn$ with MeOH and p-MeC_6H_4SH to give $2,6\text{-}(F_3C)_2C_6H_3SnOMe$ and $(p\text{-}MeC_6H_4S)_2Sn$, respectively.

Organotin(II) compounds also act as ligands in transition metal complexes. The stable stannylene $[(Me_3Si)_2CH]_2Sn$ has been widely studied and has been shown to replace a CO group in $M(CO)_6$ (M = Cr or Mo) on irradiation; the resulting Cr complex $[(Me_3Si)_2CH]_2SnCr(CO)_5$ (**89**)



(**89**)

contains a planar $[C_2SnCr]$ arrangement. The bonding involves both σ-donation from tin to the transition metal and back donation from the transition metal to the p or d orbitals of tin. Bridging stannylene complexes are also known, e.g. (**90**); the latter has been obtained from $Na_2Fe(CO)_4$ and R_2SnCl_2, and from $Fe(CO)_5$ and $R_2Sn(CH{=}CH_2)_2$. As shown in equation (115), the bridging by the stannylene can be broken on treatment with donors such as THF or py. The bonding of the donor group, L, in (**91**) involves use of the empty p orbital on Sn.

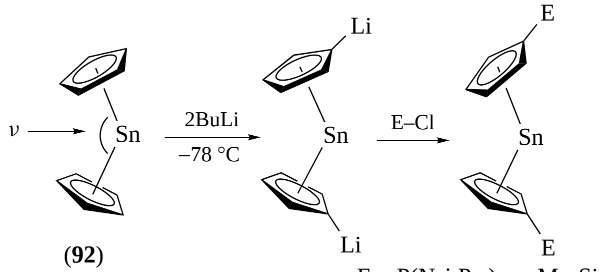


(**90**) R = Me, *t*-Bu or Ph (**91**)

(115)

13.7 π-Bonded Stannylenes[71]

π-Bonded stannylenes have also been studied extensively. Stannocene, $(\eta^5\text{-}C_5H_5)_2Sn$ (**92**), was first prepared in 1956 from $SnCl_2$ and C_5H_5Na. Subsequently, other



(**92**)

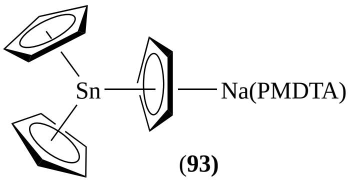
E = P(N-*i*-Pr2)2 or Me3Si

Scheme 23

bis(cyclopentadienyl)-stannanes have been prepared by similar means, e.g. $(\eta^5\text{-}RC_5H_4)_2Sn$ (R = *t*-Bu, $CH_2{=}CMe$–, or Me) and $(\eta^5\text{-}R_5C_5)_2Sn$ (R = $PhCH_2$, Ph, or Me). Ring lithiation of $(\eta^5\text{-}C_5H_5)_2Sn$ by BuLi is another method utilized in the preparation of substituted derivatives (Scheme 23).

Stannocene $(\eta^5\text{-}C_5H_5)_2Sn$ (**92**), is monomeric in the gas phase, and in the solid state X-ray crystallography revealed $(\eta^5\text{-}C_5H_5)_2Sn$ to have a bent sandwich structure, with a ring centroid–Sn–ring centroid angle (ν) of 148.0 and 143.7° in two independent molecules. Crystal structures of various substituted bis(cyclopentadienyl)stannanes have also been determined; generally it has been found that the larger the substituents on the rings, the nearer to parallel the rings become, e.g. the value of (ν) for $(\eta^5\text{-}Ph_5C_5)_2Sn$ is 180°.

The structure of most stannocenes is attributed to an sp^2 hybridized tin atom, with two of the three hybrid orbitals interacting with the π-systems of the rings and the third hybrid orbital containing the unshared electron pair. A tris(cyclopentadienyl)stannate complex (**93**) has been characterized; it has a trigonal planar paddle-wheel geometry.[72]



(**93**)

NMR spectra of $(\eta^5\text{-}MeC_5H_4)_2Sn$ in solution indicate rapid intermolecular exchanges at ambient temperature; ring substitution generally slows down these exchanges.

Crystal structures of monocyclopentadienyl–Sn^{II} derivatives have also been determined. The tin atom in $(\eta^5\text{-}Me_5C_5)Sn^+BF_4^-$ sits above the center of the ring; the tin–ring centroid distance is shorter than that found in $(\eta^5\text{-}Me_5C_5)_2Sn$. In both $(\eta^5\text{-}t\text{-}BuC_5H_4)Sn^+$ BF_4^- and $(\eta^5\text{-}C_5H_5)SnCl$ the atoms are not above the ring center: the ring centroid–Sn–Cl angle is 117.4° in the latter. The X-ray structures of $(Me_5C_5Sn{\cdot}L)^+OSO_2CF_3^-$ (L = py or bipy) have also been determined; the donor–ligand coordinations change the

bonding mode of Sn to the cyclopentadienyl from η^5 toward η^2 or η^3.

Stannylenes have also been prepared with π-ligands related to the cyclopentadienyl group; these include 1,3-diborolenyl, 1,2-azaborolenyl, and diazastannocene species, e.g. (**94**)–(**96**).[73] Other π-complexes of Sn^{II} which have been obtained include carboranyl derivatives, e.g. (**97**), and the very air-sensitive arene derivatives $[(\eta^6\text{-}R_2C_6H_4)SnCl\cdot AlCl_4]$ (R = H or Me) and $[(\eta^6\text{-}C_6H_6)Sn(AlCl_4)_2]\cdot PhH$ (**98**).[74]

13.8 Reactions of π-Bonded Stannylenes

Solid $(\eta^5\text{-}C_5H_5)_2Sn$ undergoes only a slow polymerization at room temperature; polymerization occurs much more readily in DMF. Rapid oxidation of $(\eta^5\text{-}C_5H_5)_2Sn$ occurs in air to $(C_5H_5)_2SnO$; oxidation proceeds more slowly for more substituted bis(cyclopentadienyl)stannylenes with, for example, $[\eta^5\text{-}(PhCH_2)_5C_5]_2Sn$ being reported to be air stable.

Oxidative additions to give Sn^{IV} species occur on reaction with a variety of reagents, including organic halides, disulfides, halogens, $Sn^{IV}Cl_4$, and $HgCl_2$.

Disproportionation reactions have been reported (equation 116), as have cleavage reactions which remove one group (equation 117) or both groups, e.g. by proton acids HA (HA = alcohols, phenols, thiols, $HONR_2$, $HON{=}CR_2$, HO_2CR, RSO_3H) to give inorganic SnA_2 species.

$$(\eta^5\text{-}C_5H_5)_2Sn + SnX_2 \longrightarrow 2\eta^5\text{-}C_5H_5SnX \qquad (116)$$

$$X = Cl,\ Br\ or\ N(SiMe_3)_2$$

$$(\eta^5\text{-}C_5Me_5)_2Sn + F_3CCO_2H \longrightarrow \eta^5\text{-}C_5Me_5SnO_2CCF_3 \qquad (117)$$

Ionic salts have been formed, e.g. $(\eta^5\text{-}Me_5C_5)Sn^+X^-$ ($X^- = CF_3SO_3^-$, $AlCl_4^-$, or BF_4^-) on reaction of $(\eta^5\text{-}Me_5C_5)_2Sn$ with CF_3SO_3H, $AlCl_3$, and HBF_4, respectively.

Bis(cyclopentadienyl)stannylenes can act as ligands in transition metal complexes, e.g. as in $(\eta^5\text{-}C_5H_5)_2Sn\text{–}M(CO)_5$ (M = Cr, Mo, or W).

14 INDUSTRIAL[75] AND BIOLOGICAL[76] APPLICATIONS

The use of organotins in industry rose especially markedly in the period from the mid 1960s to the mid 1980s. The largest use is as stabilizers for poly(vinyl chloride); the industrial applications of nontoxic organotin compounds, especially R_2SnX_2, account for a great proportion of the total consumption. The triorganotin compounds, R_3SnX, have found application as biocides and pesticides; however, a greater restriction has been placed on their use in the last few years.

14.1 Stabilizers for Poly(vinyl chloride), $[CH_2CHCl]_n$

Di- and triorganotin thiolates and carboxylates have been the most widely used organotin compounds in this area: typical compounds are $R_2Sn(SCH_2CO_2C_8H_{17})_2$ and $RSn(SCH_2CO_2C_8H_{17})_3$ (R = Me, Bu, C_8H_{17}, or $BuO_2CCH_2CH_2$), $R_2Sn(SC_{11}H_{25})_2$ (R = Me or Bu), $R_2Sn(OCOR')_2$ (R = Bu; R′ = $C_{11}H_{23}$, $CH{=}CHCO_2R''$; R = Me, Bu, or C_8H_{17}) and $[R_2Sn(OCOCH{=}CHCO_2)]$ (R = Me, Bu, or Oct). The Sn–S compounds are especially good as heat stabilizers, particularly during the processing of PVC at 180–200 °C, whereas the carboxylates provide good long-term UV/light stability. Frequently, monalkyltin and dialkyltin compounds are used together, as marked synergistic effects are produced.

Decomposition of PVC proceeds via loss of HCl and by autoxidation; these lead to embrittlement and to coloration, due at least in part to the formation of conjugated polyenes.

The modes of action of the organotin stabilizers added to the extent of ca. 1–5% are considered to be complex, but include (i) anionic exchanges at reactive chloride (i.e. allylic centers) within the polymer, which provides more stable species; and (ii) reaction with any free HCl.

14.2 Catalytic Applications

Dialkyltin dicarboxylates, e.g. $Bu_2Sn(O_2CC_{11}H_{23})_2$, are useful catalysts for polyurethane foam formation and as cross-linking agents for room-temperature vulcanization. Monobutyltins have been used as catalysts in transesterification and esterification reactions, e.g. in the reaction between phthalic anhydride and 2-ethylhexanol.

14.3 Biocidal Applications[76]

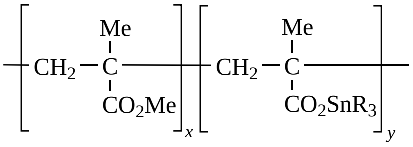
The biocidal activity of triorganotin compounds has been utilized in a number of applications, including as antifungal agents for crops, as acaricides, as antifouling agents in marine coatings of paints, and as wood preservatives. A more limited use has been made of the lower toxic effects of diorganotin species.

The biological activity of R_nSnX_{4-n} varies with R and n, the activity being maximum for $n = 3$. The sequence of activity is $R_3SnX > R_2SnX_2 > RSnX_3$; any activity of R_4Sn probably results from in vivo dealkylations to R_3SnX compounds. The nature of the X group in general has little affect on the biological activity, unless it possesses its own activity; in contrast, the nature of the organic group R is most important. In the trialkyltin species, trimethyltin compounds possess maximum toxicity to mammals and insects, triethyltins are most toxic to mammals, tripropyltins to Gram-negative bacteria, and tributyltins to Gram-negative bacteria and fungi. Further increases in the alkyl chain length results in a decrease in the biological toxicity, and, for example, triooctyltin compounds are essentially nontoxic to all living organisms. Triphenyltin compounds are highly active to fish, fungi, and mollusks, and tricyclohexyltins and trineophyltins are effective acaricides that possess low mammalian toxicity.

Both dialkyltins and trialkyltins inhibit oxidative metabolism, but in different ways. Triorganotin species act on the coupling ATPase, but the diorganotins act on substrate oxidation.

Examples of organotin compounds to have found applications as agrochemicals are Ph_3SnX (OH or OCOMe) (antifungicide for crops) and tricyclohexyltin hydroxide, $[(PhCMe_2CH_2)_3Sn]_2O$, and tricyclohexylstannyl-1,2,4-triazole (acaricides).

Tributyltin species, especially $(Bu_3Sn)_2O$ and tributyltin phosphate and naphthenate, have been used in wood preservation as fungicides and as biocides for destructive insects. Tributyltins (and to a lesser extent, triphenyltins) have been used in marine antifoulant paints due to their broad range activity. The use of organotin polymers in which the triorganotin groups are chemically bound to the polymer backbone, e.g. as in poly[tributyltin methacrylate–methyl methacylate], has been particularly useful (**99**). In contact with seawater, the organotin ester link is continuously hydrolyzed and the triorganotin moiety is released at a controlled rate. In addition, the depleted outer polymer layer is then eroded by the motion of the seawater past it, which not only exposes fresh surfaces but continually provides smooth surfaces. These 'self-polishing' paints can provide protection for up to five years.



(99)

14.4 Diorganotin Biocidal Activity

Diorganotin species, e.g. $Bu_2Sn(O_2CC_{11}H_{23})_2$, have found use as anthelminthic agents in poultry, as insecticides for sheep and cattle, and as aparasitic agents for turkeys.

14.5 Anticancer Activity[77,78]

There have been various reports of the anticancer activities of organotin species, e.g. towards P388 lymphocytic leukemia in mice. Research work continues strongly in this area, but it appears that chemical use of organotin anticancer drugs is at the very best several years away.

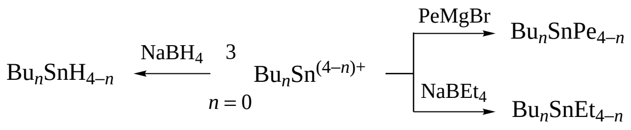
15 ENVIRONMENTAL ASPECTS[79,80]

Because of the wide-ranging toxicity of the lower triorganotin species in particular, there is great interest in the distribution and extent of organotins in the environment, especially in estuarine and other aquatic systems. All industrial applications, in principle, will introduce organotins into the environment; however, it is the use of organotin marine antifoulants which has raised most concern. The liberal use of triorganotin antifouling paints has led to serious environmental pollution, particularly in areas where a large number of boats operate. The general toxicity of triorganotins, e.g. tributyltin compounds, means that nontargeted organisms, e.g. Pacific oysters, mussels, dog-whelks, and other shell-fish can (and have) become affected, and it is clear that greater care and restrictions have to be exercised in the use of these useful, but very toxic, materials.

While organotin species are stable in sterile environments (both aqueous as well as solid phases) and in the dark at usual environmental temperatures, the breakdown of triorganotin species occurs rapidly in sunlight and by biological action.

$$R_3Sn^+ \longrightarrow R_2Sn^{2+} \longrightarrow RSn^{3+} \longrightarrow Sn^{4+}$$

Scheme 24



Scheme 25

These lead to the less toxic di- and monoorganotins, as well as inorganic tin species on successive dealkylation reactions (Scheme 24).

Triorganotin compounds, except Me_3SnX, have low solubility in water, but they have high affinities for soils and sediments and hence can concentrate there. Biomethylation of organotins is now well documented and so methylalkyltins, e.g. $MeBu_2Sn^+$, can be found in environmental samples. Environmental methylation of tin species can result from the interaction of such methylating agents as methylcorrinoids or betaines (from dead organisms) and methyl iodide or dimethyl sulfide (from living organisms).

Such is the difference in the toxicities of the tin species found in the environment, it is of utmost importance to carry out speciation studies rather than to simply determine the total tin content in any sample. Quantitative methods of determination are available for very low concentrations (at ppb and below).

One well-used speciation method involves the production of volatile tetraorganotins by treatment of environmental samples (suitably concentrated) using Grignard reagents (e.g. pentylmagnesium bromide) or sodium tetraethylborate, followed by separation and determination of the resulting products (e.g. by GC or GC/AAS techniques). An alternative method involves the generation of volatile organotin hydrides from treatment with $NaBH_4$ (Scheme 25).

1 INTRODUCTION

Titanium is a relatively common element comprising 0.63% of the earth's crust, making it the ninth most abundant element and the second most abundant transition element (after iron). Despite this abundance, it is only during the latter part of the twentieth century that the element has developed any industrial potential, which is due largely to the difficulties associated with its refinement.

1.1 Discovery

Titanium was discovered in 1791 by an English clergyman and amateur chemist, William Gregor. He identified it in a black sand (now known to be ilmenite, $FeTiO_3$, named after Russia's Ilmen lake and mountains) from the Menacchan Valley in Cornwall. Four years later, the German chemist M. H. Klaproth independently discovered the element in the TiO_2 form, as rutile. He gave it the name titanium after the Titans, who in Greek mythology were the sons of Earth.

1.2 Preparation of the Metal

Titanium is widely distributed in the earth's crust, the principal ores being ilmenite and rutile. It is not possible to obtain titanium metal by the usual method of reduction of the dioxide with carbon, because of the formation of a very stable carbide. Moreover, the metal is reactive toward both dioxygen and dinitrogen at elevated temperatures. Hydrogen reduction at 900 °C only reduces TiO_2 as far as Ti_2O_3, while reduction of TiO_2 with the common reducing metals, for example, Na, Al, Ca, or Mg, seldom yields pure products. Reduction of the tetrachloride is, therefore, the basis of the preferred methods.

Reduction to elemental titanium was first commercialized in the 1950s. A successful laboratory method is reduction of the dioxide with excess calcium hydride in a molybdenum boat. The reaction is carried out at 900 °C in a vacuum or an atmosphere of hydrogen (equation 1).[1] Extremely pure titanium can be prepared on a laboratory scale by the van Arkel–de Boer method;[2] in this method, pure TiI_4 is vaporized and decomposed on a hot wire in a vacuum.

$$TiO_2 + CaH_2 \longrightarrow Ti + 2CaO + 2H_2 \quad (1)$$

Industrially, titanium is prepared using the Kroll process;[3,4] in this process, ilmenite or rutile is treated at red heat with chlorine and carbon, producing $TiCl_4$ (equation 2). The $TiCl_4$ is fractionally distilled from $FeCl_3$ and other impurities and then reduced with molten magnesium at ca. 1000 °C in an atmosphere of argon (equation 3). The $MgCl_2$ and excess Mg are removed either by volatilization at 1000 °C or by leaching with dilute HCl. This leaves titanium as a spongy mass, which may be cast into ingots using an electric arc under an atmosphere of argon.

$$2FeTiO_3 + 7Cl_2 + 6C \xrightarrow{900\,^\circ C} 2TiCl_4 + 2FeCl_3 + 6CO \quad (2)$$

$$TiCl_4 + 2Mg \xrightarrow{1000\,^\circ C} Ti + 2MgCl_2 \quad (3)$$

2 PROPERTIES OF THE METAL

Table 1 summarizes some of the more important properties of titanium.

Titanium is a silvery ductile metal with important industrial uses because it is less dense than iron, much stronger than aluminum, and almost as corrosion resistant as platinum. This rare combination of properties makes it ideal for a variety of uses, particularly in engines, aircraft frames, marine equipment, and industrial plants. Titanium metal and alloys also replace bone and serve in dental implants. At normal

temperatures, the metal is hexagonal ($D_{6h} - 6/mmc$, $Z = 2$);[5] however, the metal undergoes a phase change at 882 °C to give the β-form, which is cubic ($O_{h-}Im3m$, $Z = 2$).[5] At elevated temperatures, the metal has an enormous affinity for dioxygen, dinitrogen, and dihydrogen, however, it is only for H_2 that the absorption is reversible. Titanium dust is explosive in air, and even the fresh surface of the metal will spontaneously ignite in dioxygen at 25 atm. Traces of dioxygen and dinitrogen render the metal very brittle and hence of little utility.

Titanium is not attacked by mineral acids in the cold or by hot aqueous alkali, but it dissolves in HF, hot HCl, hot HNO_3, and hot concentrated H_3PO_4. It reacts with many metals and nonmetals, for example, Al, Sb, Be, Cr, Fe, and B, forming intermetallic or interstitial compounds.

2.1 General Properties of the Group 4 Elements

Titanium is the first member of the 3d transition series and has four valence electrons, $3d^24s^2$. The most stable and most common oxidation state is IV; however, compounds in a range of lower oxidation states, −I, 0, II, III, are also known, although they are readily oxidized to Ti^{IV} by air, water, or other reagents. The standard reduction potentials in volts versus NHE in acid solution are given in Scheme 1. The actual potentials of the titanium complexes are, of course, strongly dependent on the ligand environment and conditions.

Table 1 Some physical properties of titanium

Atomic number	22
Atomic weight	47.88 (±0.03)
Number of naturally occurring isotopes (all stable)	5
^{46}Ti (8.25% abundance, I = 0)	
^{47}Ti (7.44% abundance, I = 5/2)	
^{48}Ti (73.72% abundance, I = 0)	
^{49}Ti (5.41% abundance, I = 7/2)	
^{50}Ti (5.18% abundance, I = 0)	
Additional radioactive isotopes	>15
Electronic configuration	$[Ar]3d^24s^2$
Electronegativity (Ti^{IV}, Sanderson scale)	1.5
Mp (°C)	1667
Bp (°C)	3285
ΔH_{fus} (kJ mol^{-1})	18.8
ΔH_{vap} (kJ mol^{-1})	425
ΔH_f (monatomic gas) (kJ mol^{-1})	469
Density (25 °C) (g cm^{-3})	4.5
Electrical resistivity (20 °C) (μΩ cm)	42.0

The most common coordination number of titanium is six, although four-, five-, seven-, and eight-coordinate compounds are known (Table 2). Table 3 summarizes the common oxidation states of titanium with the associated coordination numbers and stereochemistries. Zirconium shows a similar range of oxidation states (*see* ***Zirconium & Hafnium: Inorganic & Coordination Chemistry***); however, Zr^{II} and Hf^{II} are much less stable, relative to Zr^{IV} and Hf^{IV}, than is the case for titanium.

The metal conducts heat and electricity, similar to iron or nickel. In the Ti^{IV} oxidation state, there are some similarities with the group 14 elements (Si, Ge, Sn, and Pb), particularly Sn. For example, the ionic radius of Ti^{4+} is 0.68 Å and of Sn^{4+}, 0.71 Å. Similarly, SnO_2 and TiO_2 are isomorphous, while the tetrachlorides of both elements are readily hydrolyzed liquids. However, the d electrons of the group 4 elements contribute more effectively to metal–metal bonding in the bulk materials than do the p electrons of the group 14 elements. A consequence of this is the increase in the difference between the melting points, boiling points, and enthalpies of atomization on passing from C and Si to Ti, Zr, and Hf, than from C and Si to Ge, Sn, and Pb.

3 TITANIUM COMPOUNDS

3.1 Oxides and Sulfides

The most important oxide of titanium is the dioxide, TiO_2, also known as titania. This importance arises predominantly from the use of TiO_2 as a white pigment in the manufacture of paint and paper and as a filler in rubber and plastics. Titanium

$$TiO^{2+} \xrightarrow{+0.10} Ti^{3+} \xrightarrow{-0.37} Ti^{2+} \xrightarrow{-1.63} Ti$$

Scheme 1

Table 2 Atomic radii of titanium[6]

Type of radius	Coordination	Radius (pm)	Crystal radius (pm)	Effective ionic radius (pm)
Metal radius		147		
Covalent		136		
Ionic: Ti^{II}	6-coordinate		100	86
Ti^{III}	6-coordinate		81	67
Ti^{IV}	4-coordinate		56	42
	5-coordinate		65	51
	6-coordinate		74.5	60.5
	8-coordinate		88	74

Table 3 Oxidation states and stereochemistry of titanium

Oxidation state	Configuration	Coordination	Stereochemistry	Example
Ti^{-I}	d^5	6	Octahedral	$[Ti(bpy)_3]^-$
Ti^0	d^4	6	Octahedral	$[Ti(bpy)_3]$
Ti^{II}	d^2	4	Distorted tetrahedral	$[Ti(Cp)_2(CO)_2]$
		6	Octahedral	$TiCl_2$
Ti^{III}	d^1	3	Planar	$[Ti\{N(SiMe_3)_2\}_3]$
		5	Trigonal bipyramidal	$[TiBr_3(NMe_3)_2]$
		6	Octahedral	$[Ti(urea)_6]^{3+}$
Ti^{IV}	d^0	4	Tetrahedral	$TiCl_4$
		5	Trigonal bipyramidal	$[TiOCl_2(NMe_3)_2]$
			Square pyramidal	$[TiOCl_4]^{2-}$
		6	Octahedral	$[TiF_6]^{2-}$
		7	Pentagonal bipyramidal	$[TiCl(S_2CNMe_2)_3]$
			Capped trigonal prismatic	$[TiF_5(O_2)]^{3-}$
		8	Dodecahedral	$[TiCl_4(diars)_2]$
		11	–	$[TiCp(S_2CNMe_2)_3]$

dioxide is also used in skin care and cosmetics products and in sunscreens. The use of TiO_2 as a pigment stems from its exceptionally high refractive index in the visible region of the electromagnetic spectrum, which is higher than the refractive index of diamond, as shown in Table 4. Thus, while large crystals of TiO_2 are transparent and do not refract, fine particles scatter light very strongly. Moreover, TiO_2 is chemically inert, so that it has displaced the pigment 'white lead' $(PbCO_3)_2{\cdot}Pb(OH)_2$. The photochemistry of TiO_2 has enabled important applications.[7]

Natural TiO_2 has three crystalline forms: rutile, the most common form, and anatase and brookite, both of which convert to rutile at elevated temperatures. All contain six-coordinate titanium atoms[8] though in anatase and brookite, the octahedra of oxygen atoms is distorted. Natural forms of TiO_2 are often colored due to the presence of impurities. Synthetic TiO_2 is manufactured either by oxidizing $TiCl_4$ with oxygen or by the hydrolysis of Ti^{IV} sulfate. Rutile can be reduced to give a wide range of nonstoichiometric oxide phases such as the Magneli-type phases Ti_nO_{2n-1} ($4 \leq n \leq 9$), the broad nonstoichiometric phases TiO_x ($0.7 \leq x \leq 1.3$), and the lower oxides Ti_3O_5 and Ti_2O_3.

A large number of complex oxides or 'titanates' are known. These are produced by fusing TiO_2 at high temperatures with stoichiometric amounts of the appropriate metal oxide. Orthotitanates, $M^{II}TiO_3$, in which the M^{II} is approximately the same size as Ti^{IV} (M = Mg, Mn, Fe, Co, Ni), all have the ilmenite structure, $FeTiO_3$. Recently, a single hanging crystal of ilmenite was discovered in each nest comb of the hornet *Vespa orientalis*.[9] The purpose and the origin of these crystals are still unclear, although they may indicate the downward direction and also help the hornets assess symmetry as they are building their nests. Metatitanates, $M^{II}TiO_3$, contain M^{II} ions that are larger than Ti^{IV} (M = Ca, Sr, Ba); in these compounds the preferred structure is that of perovskite, $CaTiO_3$. A third important structural type of titanate is the spinel structure, $MgAl_2O_4$, which is possessed by the compounds $M^{II}{}_2TiO_4$ (M = Mg, Zn, Mn, Fe, Co).

Table 4 Refractive index of various materials

Substance	Refractive index
NaCl	1.54
SiO_2	1.54–1.56
TiO_2 (rutile)	2.61–2.90
TiO_2 (anatase)	2.49–2.55
Diamond	2.42

An extensive series of phases of general formula $Ba_xTi_yO_{x+2y}$ are formed from the reaction of TiO_2 with barium oxide. The simplest, $BaTiO_3$, is known as barium titanate. These materials are of interest because of their ferroelectric properties, which result from the differences in the relative sizes of the Ba^{II} and Ti^{IV} ions. The Ti^{IV} ions are located between six Ba^{II} ions, which occupy octahedral positions. However, the Ti^{IV} ions are small compared to the Ba^{II} and so are free to move within their octahedral Ba^{II} 'holes'.

The sulfides have been studied much less than the oxides, but it is clear that many similarities exist. Like the oxides, a number of stable phases exist and nonstoichiometry is prevalent. The most important sulfide is TiS_2, which has the CdI_2 layer structure,[6] in which the Ti atoms occupy octahedral sites between alternate layers of close-packed sulfur atoms. The adjacent sulfur layers are able to intercalate Lewis bases such as aliphatic amines. Similar intercalation compounds can be made with MS_2 and MSe_2 compounds (M = Ti, Zr, Hf, V, Nb, Ta). Many of these compounds exhibit useful electrical properties including superconductivity (*see* ***Superconductivity***).

3.2 Halides

The most important halides are the tetrahalides.[10,11] TiF_4 is obtained either by the action of HF on $TiCl_4$ or by direct

combination of the elements at 200 °C. It is a hygroscopic white solid. The structure was relatively recently solved,[12] to reveal columns of corner-linked TiF_6 octahedra. $TiCl_4$ is a pungent colorless liquid (mp −2.3 °C, bp 136 °C), which is the starting material for the formation of most Ti compounds. $TiCl_4$ itself is formed by heating Cl_2 and TiO_2 in the presence of a reducing agent. $TiCl_4$ fumes in moist air and is vigorously hydrolyzed by water (equation 4). Partial hydrolysis results in the formation of oxychlorides.

$$TiCl_4 + 2H_2O \longrightarrow TiO_2 + 4HCl \quad (4)$$

$TiBr_4$ is formed in an analogous manner to $TiCl_4$, whereas TiI_4 is formed by reacting TiO_2 and AlI_3 at a temperature of 130–400 °C. They are orange and brown colored crystalline solids, respectively, which consist of molecular lattices isomorphous with EI_4 (E = Si, Ge, Sn). The interesting gradation in color shown by the titanium tetrahalides is due to a charge-transfer band, which moves toward lower energies as the anion becomes more easily oxidized by the small, highly polarizing titanium cation. All the tetrahalides behave as Lewis acids, dissolving in polar solvents to give a series of addition compounds and adducts.

One very important use of $TiCl_4$ is in Ziegler–Natta catalysis. (*see* ***Titanium: Organometallic Chemistry*** and ***Oligomerization & Polymerization by Homogeneous Catalysis***). The catalyst, a mixture of $TiCl_4$ and $AlEt_3$, induces the polymerization of ethylene under ambient conditions. Prior to this technology, ethylene could only be polymerized at high pressure and temperature. The mechanism is still not entirely understood; however, the most likely explanation is given in Scheme 2. This mechanism involves: (1) replacement of a coordinated chloride by an ethyl group derived from $AlEt_3$; (2) an ethylene molecule becoming bound to a vacant coordination site on the surface; (3) cis-insertion as the ethylene migrates to the ethyl group; and (4) another ethylene becoming bound at the vacant coordination site. The insertion is then repeated.

The trihalides of titanium can be prepared by reducing the tetrahalides with the metal. With the exception of the trifluoride, which has a magnetic moment of 1.75 BM, as expected for a d^1 ion, all the trihalides have low magnetic moments, indicative of metal–metal interaction. The structures consist of halogen-bridged polymers containing six-coordinate titanium.

The dihalides TiX_2 (X = Cl, Br, I) are black solids and have the CdI_2 structure. Magnetic susceptibility data provide evidence for extensive metal–metal bonding within the compounds. These compounds are sufficiently strongly reducing to reduce water.

Halides with the stoichiometry Ti_7X_{16} (X = Cl, Br) have also been prepared.[13] They are black crystalline solids sensitive to both oxidation and hydrolysis. They consist of octahedrally coordinated Ti^{IV} and Ti^{II} atoms in the ratio 1:6 (i.e. $TiCl_4 \cdot 6TiCl_2$).

3.3 Complex Halides

A large number of complex halides are known and have been reviewed.[14] The most common complex fluorides involve the TiF_5^- moiety. Complexes are conveniently prepared by adding $[N(n\text{-}Pr)_2H_2]F$ and a stoichiometric amount of the donor to a solution of TiF_4. Alternatively, an equimolar quantity of $[N(n\text{-}Pr)_2H_2]_2[TiF_6]$ is added to a solution of TiF_4L_2.[15] Solutions formed by the former method that do not form $[TiF_5L]^-$ were shown by ^{19}F NMR to contain the $[Ti_2F_{11}]^{3-}$ moiety.[15]

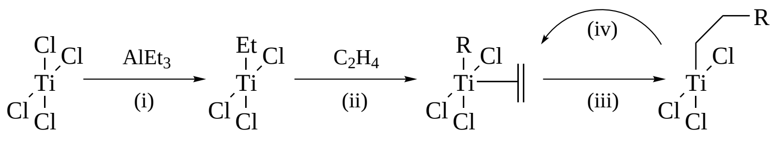
The $TiCl_6^{3-}$ anion is believed to form when Ti^{II} fused with chloride melts, but it can be isolated from the direct reaction of $TiCl_3$ with excess anhydrous pyHCl, or by the reaction of $TiCl_3(MeCN)_3$ with pyHCl. However, when Et_4NCl and Et_4NBr are reacted with $TiCl_3(MeCN)_3$, the expected hexahalo salts are not formed but $[TiCl_4(MeCN)_2]$ and (Et_4N) $[TiCl_3Br(MeCN)_2]$ are produced.[16] Reaction of $TiCl_4$ with *t*-butylamine in dichloroethane at −78 °C yields $[TiCl_2(NHBu\text{-}t)_2(NH_2Bu\text{-}t)_2]_n$, which loses the coordinated *t*-butylamine upon standing at room temperature.[17]

The $[Ti_2Cl_{10}]^{2-}$ species is also known.[18] For example, adducts of the type $(PCl_5)_n \cdot mTiCl_4$ (n, m = integer) have been known since 1867. Reaction of PCl_5 with $TiCl_4$ in $POCl_3$ and $SOCl_2$ gives $[PCl_4]_2[Ti_2Cl_{10}]$ and $[PCl_4][Ti_2Cl_9]$ respectively, which are unusual examples of face-shared bioctahedra containing transition metal ions in the +4 oxidation state.[19]

Reaction of $TiCl_4$ and $B_2[NMe_2]_4$ gives the unusual $\{[Me_2N]_2BCl\}_2[TiCl_4]_3$ species, as well as small quantities of Me_2NTiCl_3 and $Me_2NBu \cdot Ti_2Cl_6$.[20] The latter complex contains coordinated dimethylamino moieties, and a pentacoordinate structure has been proposed.[21] The $Ti_5Cl_{11}^-$ ion has been isolated in the salt $[(Ph_3P)_3PtCl]^+$ $[Ti_5Cl_{11}]^-$.[22]

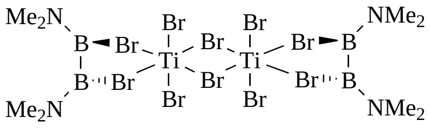
Concomitant with the work on the chloride system, $\{[Me_2N]_2BBr\}_2\{TiBr_4\}_3$ has been prepared, and the following coordination has been proposed:[23]

$$Br_4Ti \leftarrow NMe_2B(Br)Me_2N \rightarrow TiBr_4 \leftarrow NMe_2B(Br)Me_2N \rightarrow TiBr_4$$



Scheme 2

Reaction of $TiBr_4$ with $B_2[NMe_2]_4$ gives dinuclear $B_2Br_2[NMe_2]_2{\cdot}TiBr_3$ (**1**).[24] Complexes $M_2[TiBr_5(H_2O)]$ (M = Cs, Rb, pyH) are also known.[25]



(**1**)

The species TiI_6^{2-} is unknown. The only evidence for its formation comes from the treatment of $[Et_4N]_2TiCl_6$ with liquid HI, which yields a very unstable black solid. It has been predicted, by comparison with the electronic spectra of the TiX_6^{2+} (X = Cl, Br) species, that TiI_6^{2-} would be black.[26]

4 COORDINATION CHEMISTRY

A large number of titanium complexes are known and it is not possible to review the literature comprehensively in the space available. More comprehensive treatises have been published by Stephan,[27] McAuliffe,[26] and Clark.[14] Titanium in its common oxidation states is quite labile. Water exchange is used as a convenient benchmark. The rate constant for water exchange in the Ti^{III} species $[Ti(H_2O)_6]^{3+}$ is $1.8 \times 10^5\,s^{-1}$ at room temperature,[28] and a lower limit of $3.4 \times 10^3\,s^{-1}$ has been placed on the exchange of terminal water ligands in oligomeric hydrolyzed Ti^{IV} solutions.[29] These values can be compared to rate constants for exchange of $1.6 \times 10^2\,s^{-1}$ for $[Fe(H_2O)_6]^{3+}$ and 2.4×10^{-6} for the famously inert $[Cr(H_2O)_6]^{3+}$.[30]

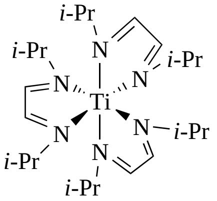
4.1 Low-valent Titanium Complexes

Although the coordination chemistry of Ti^{IV} and, to a lesser extent, Ti^{III} has been relatively well investigated, few complexes are known in the lower oxidation states and are almost all unstable to oxidation.[10,14,26,27] Reduction of $TiCl_4$ with excess of dilithium 2,2′-bipyridyl in THF with excess bipyridyl gives $Li[Ti(bpy)_3]{\cdot}3THF$, as shown in equations (5) and (6). Further reduction to $Li_2[Ti(bpy)_3]{\cdot}3.7THF$ is possible.[26]

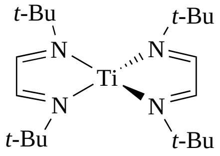
$$TiCl_4 + 2Li_2bpy + bpy \xrightarrow{THF} [Ti(bpy)_3] + LiCl \qquad (5)$$

$$TiCl_4 + 2.5Li_2bpy + 0.5bpy \xrightarrow{THF} Li[Ti(bpy)_3]{\cdot}3.7THF + 4LiCl \qquad (6)$$

Diazadiene or diimine ligands of the general type R–N=CH–CH=N–R (Rdab) are known to stabilize complexes in low oxidation states.[31] Cloke and coworkers have prepared titanium(0) complexes of Rdab (R = *i*-Pr, *i*-Bu) by cocondensation of titanium vapor with an excess of ligand in heptane.[32] [Ti(σ,σ-*N*,*N′*-*i*-Prdab)$_3$] (**2**) is an air-sensitive, blue colored crystalline solid. ^{1}H NMR data show the methyl groups of *i*-Pr substituents to be diastereotopic, confirming that the titanium center has octahedral coordination. [Ti(σ,σ-*N*,*N′*-*t*-Budab)$_2$] (**3**) forms as air-sensitive, red colored crystals. The latter complex is four-coordinate, and is presumed to be tetrahedral. Photoelectron spectroscopic data for both complexes confirm that coordination occurs through the N atoms of the ligands.



(**2**)



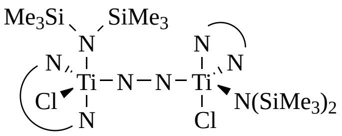
(**3**)

Titanium(II) complexes are better understood. Reaction of the deeply colored $TiX_2(MeCN)_2$ (X = Cl, Br) complexes with other ligands gives $TiCl_2L_2$ (L = C_4H_8O, $C_5H_{10}O$, py, 0.5bpy, 0.5phen) and $TiBr_2$(bpy). The latter species react with water to liberate dihydrogen.[33] One example of an aquo-coordinated Ti^{II} complex was recently described, however. The UV/visible spectrum and structure from X-ray powder data of the aqueous Ti^{II} compound, $TiF_2(H_2O)_4$, were recorded after its formation from the dissolution of titanium metal in strong acid.[34]

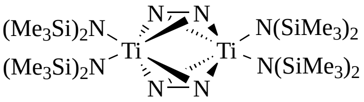
Reaction of Na_2TiCl_4 with NMe_3 results in oxidation of the halide, leading to the formation of $TiCl_3(NMe_3)_2$.[35] Dialkylamides of Ti^{II} can be prepared by the volatility-controlled disproportionation of Ti^{III}.[36]

Gambarotta and coworkers have shown that reduction of $TiCl_3(THF)_3$ with lithium, in the presence of a large excess of TMEDA, allows the large-scale preparation of *trans*-$(TMEDA)_2TiCl_2$.[37] The TMEDA ligands are easily replaced by other amines, allowing the quantitative preparation of $TiCl_2L_4$ (L = 0.5*N*,*N′*,*N′*-trimethylethylenediamine, py, 0.5bpy).[37] Furthermore, reaction of *trans*-$(TMEDA)_2TiCl_2$ with $(Me_3Si)_2NLi$ leads to the formation of $\{[(Me_3Si)_2N]TiCl(TMEDA)\}_2[\mu\text{-}N_2]$ (**4**).[38] The complex consists of two identical $\{[(Me_3Si)_2N]TiCl(TMEDA)\}$ fragments, each bonded to one of the two nitrogen atoms of a bridging dinitrogen moiety. The Ti–(μ-N_2)–Ti moiety is almost linear. The Ti–N bonds are short, 1.762 Å, while the N–N distance is long, 1.289 Å, indicating considerable electronic delocalization over the $Ti_2(\mu\text{-}N_2)$ moiety. The titanium atom has a square pyramidal coordination geometry, but is elevated 0.466(3) Å above the plane. However, reaction with 2 equiv of $(Me_3Si)_2NLi$ in the presence of TMEDA yields the black crystalline solid

$\{[(Me_3Si)_2N]_2Ti\}_2(\mu\text{-}\eta^2\eta^2\text{:-}N_2)_2[(TMEDA)_2Li]$ (**5**), which is a mixed-valence Ti^I/Ti^{II} species.[38] The X-ray crystal structure of (**5**) shows it to consist of two separate $[Li(TMEDA)_2]$ and $[\{[(Me_3Si)_2N]_2Ti\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)_2]$ ionic fragments. The titanium-containing unit is dinuclear and is formed by two $[(Me_3Si)_2N]_2Ti$ groups that are symmetrically and perpendicularly arranged on the two sides of the two parallel dinitrogen molecules. Both titanium atoms are six coordinate, four of the coordination sites being occupied by the four nitrogen atoms of the two coplanar dinitrogen molecules. The N–N distance (1.379 Å) is significantly longer than that displayed in complex (**4**). The Ti–N distances are similarly elongated (Ti(1)–N(3) = 2.236 Å, Ti(1)–N(4) = 2.290 Å). These differences in the bond lengths are attributed to the different modes of bonding in the two complexes. The different bonding mode of the dinitrogen moiety in the two complexes (i.e. end-on versus side-on) could only be attributed to the different steric bulk of the two complexes.



(**4**)



(**5**)

The cyclopentadienyl derivative of titanium(II), Cp_2Ti (*see* ***Titanium: Organometallic Chemistry***), has eluded isolation as a discrete compound.[26] However, $Cp_2Ti(PMe_3)_2$ (equation 7) provides a convenient route to the Cp_2Ti unit since the two phosphine ligands are easily displaced by a large number of substrates (e.g. CO, C_4H_4, C_4H_8, dmpe, MeCN) under very mild conditions.[39]

$$Cp_2TiCl_2 + Mg + 2PMe_3 \xrightarrow{THF} Cp_2Ti(PMe_3)_2 + MgCl_2 \qquad (7)$$

Phosphine complexes of the second and third row transition elements are common; in contrast, those of the early first-row transition elements are not.[40] Wilkinson and coworkers prepared a series of *trans*-$MCl_2(dmpe)_2$ complexes (M = Ti, V, Cr, Mn, Fe).[41] The red–black colored titanium complex *trans*-$TiCl_2(dmpe)_2$ was prepared in high yield by reacting $TiCl_4$, dmpe, and magnesium in THF. The complex was characterized using X-ray crystallography, which confirmed the trans geometry of the ligands. Attempts to prepare $TiMe_2(dmpe)_2$ by alkylating $TiCl_2(dmpe)_2$ with MeLi or Me_2Mg were unsuccessful, leading only to the isolation of a red–black material of stoichiometry *trans*-$TiMe_{1.3}Cl_{0.7}(dmpe)_2$, which was considered to be a mixture of $TiMeCl(dmpe)_2$ and $TiMe_2(dmpe)_2$. The reaction of $TiCl_3{\cdot}THF$ or $TiCl_4{\cdot}2THF$ with $LiPCy_2$ yields the dark brown adduct $Ti(PCy_2)_2$.[42] This complex is pyrophoric and reacts readily with iodine in benzene to give $TiI_2(PCy_2)_2$ and $TiI_3(PCy_2)_2$.[42]

4.2 Titanium(III) Complexes

The magnetic and electronic properties of Ti^{III} complexes have been well studied. Nearly all Ti^{III} complexes exhibit room temperature–magnetic moments close to the spin-only value of 1.73 BM.[10,14,26] However, rather than showing a great deal of temperature dependence, as would be expected for a d^1 ion in an electrostatic field of perfect O_h symmetry, the magnetic moments level off and in general vary from ~1.5 BM at 80 K to ~1.8 BM at about 300 K. These effects arise because of distortion and covalence, which cause a delocalization of the electron[10,14,26] (*see* ***Magnetism of Transition Metal Ions***).

The electronic spectra of Ti^{III} complexes can give a hint to quite subtle structural information. In a perfect octahedral field, the ^2D ground term of Ti^{III} is split into a $^2T_{2g}$ lower term and a ^2E_g upper term. The broad asymmetric band at ca. 20 100 cm^{-1} in the visible spectrum of $Ti(H_2O)_6{}^{3+}$ arises from a $^2T_{2g} \rightarrow {}^2E_g$ transition. The energy of this transition for a complex is a direct measure of the ligand field strength. The asymmetry comes from splitting of the ^2E_g term as a consequence of the Jahn–Teller effect.[26]

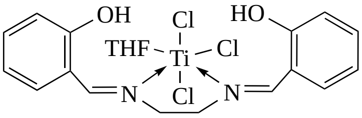
Most Ti^{III} complexes are octahedral and are produced by reacting $TiCl_3$ with an excess of ligands, giving rise to a range of stoichiometries, for example, $[TiL_6]^{3+}$, $[TiL_4X_3]$, $[TiL_3X_3]$, and $[TiL_2X_4]^-$. Fowles and coworkers isolated a range of Ti^{III} iodide complexes, TiI_3L_2, TiI_3L_3 (L = NMe_2, py, α-picoline), and $TiI_3(MeCN)_4$, the last being assigned the formula $[TiI_2(MeCN)_4]I$.[43] The X-ray crystal structure of $TiBr_3(NMe_3)_2$ shows it to be monomeric with a trigonal bipyramidal structure.[44] In contrast, reaction of $TiCl_3[N(SiMe_3)_2]_3$ with $LiN(SiMe_3)_2$ yields $Ti[N(SiMe_3)_3]_3$, which is a rare example of a three-coordinate Ti^{III} complex.[45]

Bi- and polydentate ligands also form Ti^{III} complexes with a variety of stoichiometries. For example, $[Ti(L)_3]^{3+}$ complexes are produced by the ligands en and pn,[14] whereas bpy and phen give $[TiCl_2(L)_2][TiCl_4(L)]$,[14] $[TiI_2(phen)_2]I$,[43] and $[TiI_2(bpy)_2][TiI_4(bpy)]$.[43]

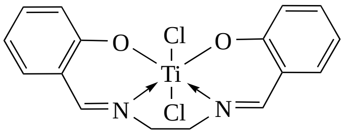
A number of neutral and anionic complexes containing oxalato ligands have been prepared, for example, $Ti_2(ox)_3{\cdot}10H_2O$,[46] $Cs[Ti(ox)_2(H_2O)_3]{\cdot}2H_2O$,[47] and $K_3[Ti(ox)_3(H_2O)]{\cdot}6H_2O$.[48] All contain seven-coordinate pentagonal bipyramidal Ti atoms, though an eight-coordination sphere has been proposed for the $K[Ti(ox)_2]{\cdot}2H_2O$ complex.[26]

Bowden and Ferguson obtained an interesting range of Ti^{III} Schiff-base complexes starting from $TiCl_3(THF)_3$ and potentially quadridentate Schiff bases.[49] Species (**6**), initially green, slowly turns red (**7**) on stirring in THF. Reduction of $[TiCl_2(salen)]$ with zinc dust in THF gives $[\{Ti(salen)(THF)_2\}][ZnCl_4]$. Magnetic moments ($\mu_{eff}$ =

0.96 BM) suggest a strong Ti–Ti interaction. Treatment of the blue solution with pyridine leads to the isolation of monomeric [TiCl(salen)(py)]·THF.[49] Reaction of $TiCl_3$ with the macrocyclic ligand 1,4,7-trimethyl-1,4,7-triazacyclononane (tacn) at 20 °C affords blue [(tacn)$TiCl_3$], while at higher temperatures, this reaction leads to the formation of green colored crystals containing [(tacn)$Ti^{III}Cl_3$], with [(tacn)Ti^{IV}(O)Cl_2] as an impurity.[50]



(**6**)



(**7**)

Titanium(III) phosphine complexes have received more attention than their titanium(II) analogs.[40] The first titanium(III) phosphine complex, $TiCl_3(PEt_3)\cdot C_2H_4$, was prepared by Chatt *et al.*[51] More recently, the monomeric complexes $TiCl_3(PR_3)_2$ ($R_3 = MeH_2$, Me_2H, Me_3, Et_3) have been prepared by the direct reaction of the components in toluene at 85 °C.[52] Weaker donors such as PPh_3 and PCl_3 do not complex with titanium(III). Recent work has also shown that $TiCl_3(THF)_3$ reacts with the diphosphine *i*-$Pr_2PCH_2CH_2P$-*i*-Pr_2 (dppe) to form the purple colored dimer $[TiCl_3(dppe)]_2$, which converts reversibly into the green monomeric complex $TiCl_3$(dppe) (THF). Most Ti^{III} complexes are susceptible to oxidation in air.

4.3 Titanium(IV) Complexes

As a result of the high ionic charge to radius ratio of titanium(IV), normal salts of titanium(IV) are difficult to prepare from aqueous solutions; these often yield basic, hydrolyzed species. A tris-catechol species, $[Ti(cat)_3]^{2-}$, prepared by Raymond *et al.* is one exception: it is stable in aqueous solution up to pH 12.[53] The catechol ligand is so stabilizing to Ti^{IV} that the Ti^{IV}/Ti^{III} reduction potential is shifted from the value of +0.1 V cited as the standard potential in acid in Scheme 1 to a value for $[Ti(cat)_3]^{2-}$ of −1.14 V vs. NHE, affording a powerful example of ligand tuning of metal redox potential.

Several oxotitanium(IV) compounds have been isolated, and were originally thought to contain TiO^{2+} ions. This notion, however, seems to be incorrect, the compounds actually being polymeric in the solid state. For example, $TiOSO_4\cdot H_2O$ consists of –Ti–O–Ti–O– chains, with each titanium being further coordinated to one water molecule and an oxygen from each of the three sulfates, giving a distorted octahedral geometry about the titanium. Similarly, $TiO(acac)_2$ is dimeric with a Ti(μ-O)$_2$Ti ring,[54] while the anion of $(NH_4)_2TiO(C_2O_4)_2\cdot H_2O$ is tetrameric with a central eight-membered $(–Ti–O–)_4$ ring.[55]

In contrast, studies on aqueous solutions of titanium(IV) in 2 M $HClO_4$ are consistent with the presence of doubly charged cationic species. However, it is not clear whether the predominant species is $[TiO]^{2+}$ or $[Ti(OH)_2]^{2+}$.[29]

Complexes containing Ti=O bonds are rare, although a few, mainly with porphyrins, have been characterized, for example, (*meso*-DME)Ti=O.[56] The Ti=O bonds appear to be short (∼1.62 Å), while IR bands are in the region 890–972 cm^{-1}, which is consistent with a Ti=O double bond.[57]

The Ti^{IV} halides readily give adducts of stoichiometry TiX_4L_2 and TiX_4(L–L) with donor molecules, where L and L–L are mono- and bidentate ligands, respectively. The potentially bidentate ligand *o*-allylaniline reacts with TiX_4 (X = Cl, Br) but only complexes via the nitrogen atom, forming the pentacoordinate monomeric complexes TiX_4L.[58] Titanium(IV) is predicted to be a 'hard' acid, whereas titanium(III) might be expected to show intermediate 'hard/soft' behavior. However, contrary to expectation, titanium(IV) has sometimes been shown to prefer sulfur to oxygen as a donor atom, as evidenced by the Ti–S bonds in the 1,4-thiozen complexes $TiX_4(C_4H_8OS)_2$.[35] Adducts of $TiOCl_2$ with MeCN and NMe_3 form $TiOCl_2L_2$; when L = NMe_3, the complexes are monomeric, the IR spectra indicating the presence of a terminal Ti=O moiety (978 cm^{-1}), whereas the MeCN adduct is probably polymeric, presumably having a Ti–O–Ti bridge (ν(Ti=O) ca. 890 cm^{-1}). Other complexes containing titanium in a trigonal bipyramidal geometry include the adduct formed from the reaction of $TiCl_4$ and $N(SiMe_3)_3$, which has planar four-membered $(Ti–N)_2$ rings with planar geometry at N, apparently with considerable π-bonding in the rings. These are linked by chlorine bridges to give the five-coordinate titanium atoms.[59] In contrast, the reaction of $TiCl_4$ with $Li[N(SiMe_3)_2]$ yields $[TiCl\{N(SiMe_3)_2\}_3]$.[60] Steric crowding prevents complete substitution of the chlorine atoms, and the complex has a distorted tetrahedral structure.

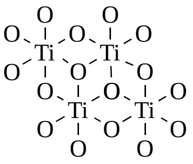
Some of the most useful and thus widely studied complexes of titanium(IV) are the alkoxides.[26,61] The materials range from solids to volatile liquids that can be distilled or sublimed and that are readily soluble in organic solvents. The complexes are easily hydrolyzed, even by traces of moisture. The ease of hydrolysis decreases with the increasing chain length of the alkyl group. Such reactions yield polymeric species, which contain either –OH or –O– bridges.

The complexes are prepared by reacting sodium alkoxide with titanium tetrachloride in the appropriate alcohol (equation 8). An alternative method is shown in equation (9). If a proton-accepting reagent, such as ammonia, is not employed,

the reaction only proceeds as far as the $TiCl_2(OR)_2$ derivative. Compounds such as $Ti(OMe)_4$ are usually insoluble polymers, although a soluble tetramer, $[Ti(OMe)_4]_4$ (**8**), that has the same M_4O_{16} framework as $[Ti(OEt)_4]_4$ has been isolated. Both frameworks are centrosymmetric, containing six-coordinate titanium in a group of four edge-sharing octahedra.

$$TiCl_4 + 4NaOR \longrightarrow Ti(OR)_4 + 4NaCl \quad (8)$$

$$TiCl_4 + 4ROH + 4NH_3 \longrightarrow Ti(OR)_4 + 4NH_4Cl \quad (9)$$



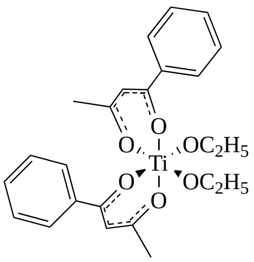
(**8**)

In solution, the degree and type of polymerization is dependent on both the –OR group and the solvent. For example, in benzene, primary –OR groups give trimers, whereas secondary and tertiary –OR groups form only monomers. Few adduct complexes of $Ti(OR)_4$ are known.[14] An example is $Ti_2(OR)_8 \cdot en$ (R = Et, *i*-Pr), but the complexes almost completely dissociate in solution.[14] However, $Ti(OPh)_4$ readily forms 1:1 adducts with PhOH, NH_3, NH_2Me, $NHMe_2$, NMe_3, py, dioxin, $PhNH_2$, and Me_2CO.[62]

The ready hydrolysis, particularly of the lower titanium alkoxides, has led to a number of interesting applications. They can be used to apply a thin, transparent, adherent surface coating of TiO_2 to a variety of materials, including fabrics that require waterproofing, glass, and enamels, each of which become scratch resistant, and also in heat-resistant paints. The manufacture of paint provides the most important application of titanium alkoxides. When chelated with ligands such as β-diketonates, the resulting complexes $[Ti(OR)_2(L–L)_2]$ are resistant to hydrolysis. Furthermore, the complexes are water-soluble and when used in concentrations of less than 1% form gels with the cellulose ether colloids used to thicken latex paints. These gels impart the required characteristics for thixotropic, or nondrip paints. The area of titanium alkoxides has been extensively reviewed by Bradley.[61]

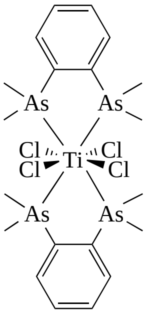
A large number of bidentate and chelated titanium(IV) complexes have been prepared. By far, the greatest number of reports concern the β-diketonate complexes, which provide an extensive series of types TiX_3L, $TiX_4(LH)$, TiX_2L_2, $[TiL_3]^+$, TiOXL, and $[TiOL]_2$ (L = β-diketonate, LH = β-diketone).[22]

One bis(β-diketonato)Ti^{IV} compound (budotitane) (**9**) has demonstrated anticancer activity and has been tested in the treatment of colon cancer.[63] It and the more extensively studied organometallic compound Cp_2TiCl_2 are thus potential anticancer therapeutics (*see also* ***Metal-based Drugs***).[63]



(**9**)

A number of titanium(IV) complexes have been characterized in which titanium shows coordination numbers greater than six. Investigations of the diars complexes of the Ti^{IV} halides resulted in the first example of eight coordination in the first-row transition series.[40] In $[TiCl_4(diars)_2]$ (**10**), the dodecahedron contains two diars forming an elongated tetrahedron, and four chlorine atoms in a flattened tetrahedron with respect to the fourfold inversion axis.[64] Despite numerous attempts to prepare similar complexes with a range of other bidentate ligands, only those with the *o*-phenylene or a similar backbone have proved successful. Other diars complexes include $[TiX_4(diars)]$ (X = Cl, Br), $[(TiF_4)_2(diars)]$, and $[TiI_4(diars)_2]$.[40]

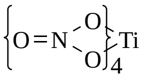


(**10**)

A large number of titanium(IV) phosphine complexes are known,[40] most being adducts of the tetrachloride $TiCl_4(PR_3)_2$, although $TiBr_4(PPh_3)$ and $TiBr_4(PPh_3)_2$ have also been reported.[65] The former has C_{3v} symmetry, whereas the latter has a cis octahedral structure. There is some evidence for the existence of the dinuclear species $Ti_2Cl_2(PR_3)$.[40] There is a paucity of well-characterized arsine and stilbine complexes. Thus, it seems quite surprising that a large number of patents have dealt with catalyst systems employing these compounds in the polymerization and oligomerization of alkenes.[26]

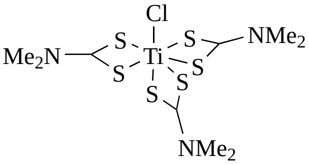
A further example of an eight-coordinate dodecahedral complex of titanium(IV) is the volatile, anhydrous $Ti(NO_3)_4$ in which the nitrate groups are bidentate, coordinating through two oxygen atoms (**11**). The nitrate groups are arranged symmetrically about the metal atom with D_{2d} symmetry in a flattened tetrahedral manner.[66]

There has been a great deal of interest in the complexes of 1,2-dithiolenes and 1,1-dithiolato complexes, which arises



(**11**)

not only from their industrial applications but also from the bonding in the complexes.[26] The X-ray crystal structure of $Ti(S_2CNEt_2)_4$ shows it to contain discrete eight-coordinate molecules.[67] Furthermore, $TiCl(S_2CNMe_2)_3$ has been shown by X-ray crystallography to be seven coordinate (**12**).[68] The molecule has a pentagonal bipyramidal structure with the chlorine atom in the axial position. Prior to this structure elucidation, the existence of seven-coordinate titanium(IV) was uncertain.[68]



(**12**)

Fay and coworkers[68] have prepared a series of $Ti(S_2CNR_2)_nCl_{4-n}$ compounds ($n = 2$, 3, 4; R = Me, *i*-Pr, *i*-Bu; or $n = 3$, R = Et) by reacting $TiCl_4$ with anhydrous sodium *N*,*N*-dialkyldithiocarbamates in CH_2Cl_2 or benzene. The complexes are monomeric and nonelectrolytes. Thus when $n = 2$, 3, or 4, the titanium atom exhibits coordination numbers of six, seven, and eight respectively. These workers have also studied the monothiocarbamate complexes $Ti(R_2mtc)_4$.[69] The complexes are shown by ^1H NMR and X-ray diffraction to be eight-coordinate dodecahedra, which have an all-cis structure with four sulfur atoms on one side and four oxygen atoms on the other.

Reaction of aqueous solutions of titanium(IV) complexes with H_2O_2 results in an intense orange color. This color can be used analytically to determine titanium. It is due to the formation of the stable peroxo species $[Ti(O_2)(OH)]^+$.[70] There is a great deal of interest in peroxo complexes of titanium(IV) macrocycles and porphyrins.[26] Such complexes are readily oxidized to the corresponding peroxo complex by oxidizing the (por)TiO (por = porphyrin) complex to $(por)Ti(O_2)$ with H_2O_2 or benzoyl peroxide.[71] The crystal structure of the octaethylporphyrin-derived $(OEP)Ti(O_2)$ (**13**) is typical: Ti–O(1) = 1.822 Å, Ti–O(2) = 1.827 Å, and O–O = 1.445 Å.

1 INTRODUCTION

The majority of titanium organometallic chemistry involves complexes in which the titanium is in its highest oxidation state (+4) and cyclopentadienyl (*see Cyclopentadienyl*) derivatives serve as ancillary ligands. However, considerable chemistry has also been developed in which the titanium is in the +3 and +2 oxidation state, with lesser amounts of chemistry known for titanium in lower oxidation states (+1, 0). Since the early 1980s, chemists have placed considerable emphasis on the fine-tuning of the structure and reactivity of titanium organometallic complexes. Particular emphasis has been devoted to tailoring the structure and reactivity of bis(cyclopentadienyl)titanium derivatives by incorporating electron-donating, electron-withdrawing, sterically demanding, bridging (constrained geometry), or chiral substituents on the cyclopentadienyl ring. Additional efforts at modifying the structure and reactivity have focused on varying the oxidation state or coordination geometry at the titanium center. Titanium organometallic chemistry through 1980 has been extensively reviewed by Bottrill, Gavens, Kelland, and McMeeking.[1] Several other articles in this encyclopedia are based on the application of titanium organometallic chemistry to catalysis and organic synthesis (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***; ***Metathesis Polymerization Processes by Homogeneous Catalysis***; and ***Oligomerization & Polymerization by Homogeneous Catalysis***).

2 CARBONYL AND PHOSPHINE COMPLEXES WITHOUT π-LIGANDS

The hypothetical titanium heptacarbonyl $Ti(CO)_7$ is as yet unknown. However, $Ti(CO)_6$ has been prepared and characterized by matrix isolation techniques. $Ti(CO)_6$, thus prepared, is found to be unstable above −200 °C.[2] Titanium carbonyls Ti(CO)x (x = 1–6) are formed during deposition of laser-ablated titanium atoms with CO during condensation in excess Ne, or on annealing and photolysis of the matrix.[3] Titanium carbonyl complexes (*see* ***Carbonyl Complexes of the Transition Metals***) have also been observed spectroscopically (by IR) as intermediates in the low-temperature reaction of $Ti(CH_2Ph)_4$ and its dicyclohexylamine adduct with CO.[4]

Reduction of $TiCl_4(THF)_2$ with sodium naphthalenide in the presence of 2.1–2.3 equivalent of dmpe in THF at −70 to −80 °C followed by treatment with CO at 1 atm gives $Ti(CO)_3(dmpe)_2$ as shown in (equation 1). Treatment of $Ti(CO)_3(dmpe)_2$ with CO at room temperature gives $Ti(CO)_5(dmpe)$.[5] $Ti(CO)_3(dmpe)_2$ is monomeric in the solid state, possessing a monocapped octahedral structure. One of the carbonyls in $Ti(CO)_3(dmpe)_2$ can be replaced by treatment with PF_3 to give $Ti(CO)_2(PF_3)(dmpe)_2$.[6]

$$TiCl_4(dmpe)_2 + 2.1\text{–}2.3NaC_{10}H_8 + CO(1\,atm) \longrightarrow Ti(CO)_3(dmpe)_2 \quad (1)$$

Ellis and coworkers have found $Ti(CO)_5(dmpe)$ to be much more reactive than $Ti(CO)_3(dmpe)_2$, and have found that it can serve as a synthetic equivalent for $Ti(CO)_7$. Reaction of $Ti(CO)_5(dmpe)$ with NaCp, NaInd, or $K[(HB(pz)_3)]$ leads to loss of one carbonyl and dmpe to give the corresponding anionic complexes $[CpTi(CO)_4]^-$ (equation 2), $[IndTi(CO)_4]^-$, and $[HB(pz)_3Ti(CO)_4]^-$, respectively, in 70–80% yield. Treatment of $Ti(CO)_5(dmpe)$ with $NaEPh_3$

(E = Ge, Sn) results in loss of one CO to give the corresponding anionic complexes $[Ti(CO)_4(dmpe)(EPh_3)]^-$. Treatment of $Ti(CO)_5(dmpe)$ with the tridentate ligand trmpe gives $Ti(CO)_4(trmpe)$.[5] $Ti(CO)_4(trmpe)$ has also been prepared directly by the treatment of $TiCl_4(THF)_2$ with potassium naphthalenide in the presence of CO and trmpe.[7]

$$Ti(CO)_5(dmpe) + NaCp \longrightarrow Na[C_5H_5Ti(CO)_4] \quad (2)$$

Ellis and coworkers have extensively studied the chemistry of hexacarbonyltitanate(2−), $[Ti(CO)_6]^{2-}$. Reductive carbonylation (*see Reductive Carbonylation*) of $Ti(CO)_4(trmpe)$ with (cryptand 2,2,2)potassium naphthalenide at −70 °C followed by warming to room temperature gives the thermally robust $[K(cryptand\ 2.2.2)]_2[Ti(CO)_6]$ in quantitative yield.[8] Treatment of $Ti(CO)_6{}^{2-}$ with azobenzene gives $[Ti(PhN{=}NPh)(CO)_4]^{2-}$ (equation 3) in 40–65% yield. Hydrolysis of $[Ti(PhN{=}NPh)(CO)_4]^{2-}$ gives 1,2-diphenylhydrazine and the hydroxo-carbonyl titanium complex, $[Ti_2(\mu\text{-}OH)_2(CO)_8]^{2-}$ (equation 3), which was structurally characterized as the $[K(18\text{-crown-}6)]^+$ salt.[9]

$$Ti(CO)_6{}^{2-} + Ph\text{-}N{=}N\text{-}Ph \longrightarrow [Ti(PhN{=}NPh)(CO)_4]^{2-} \quad (3)$$

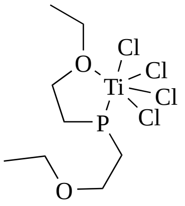
Reaction of $[Ti(CO)_6]^{2-}$ with MeOH and PhOH gives the metal-carbonyl dimers $[Ti(CO)_4(\mu\text{-}OR)]_2{}^{2-}$ (R = Me, Ph). The structure and reactivity of these complexes suggest that the bridging alkoxy ligands function as π-donors satisfying the electronic requirements of each titanium.[10] Reaction of $BH_3\cdot THF$ with $[K(15\text{-crown-}5)_2]_2[Ti(CO)_6]$ or $[K(18\text{-crown-}6)_2]_2[Ti(CO)_6]$ gives $[K(15\text{-crown-}5)_2]_2[Ti(CO)_4(\eta^3\text{-}BH_4)]$ and $[K(18\text{-crown-}6)][Ti(CO)_4(\eta^3\text{-}BH_4)]^-$ respectively. Treatment of $[K(15\text{-crown-}5)_2]_2[Ti(CO)_4(\eta^3\text{-}BH_4)]$ with KC_4H_4N gives $[K(15\text{-crown-}5)_2]_2[(\eta^5\text{-}C_4H_4N)Ti(CO)_4]$.[11]

Treatment of $Ti(CO)_6{}^{2-}$ with R_3SnCl (R = Me, Ph, cyclohexyl) in THF gives the thermally stable $R_3SnTi(CO)_6{}^-$ salts in 70–80% isolated yields.[12] In an analogous manner, reaction of $Ti(CO)_6{}^{2-}$ with $ClC(p\text{-}C_6H_4R)_3$ (R = H, OCH_3) in THF gives $Ti(CO)_4[\eta^5\text{-}C(p\text{-}C_6H_4R)_3]$ in 28–30% yields.[13]

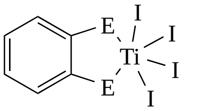
The reduction of TiI_4 with 1 equivalent of Na/Hg amalgam in the presence of PMe_3 gives the bioctahedral complex $Ti_2I_6(PMe_3)_4$. The Ti–Ti distance of 4.30 Å in $Ti_2I_6(PMe_3)_4$ clearly indicates the absence of a Ti–Ti bond.[14]

Treatment of *trans*-$TiX_2(dmpe)_2$ (X = Cl, Br) with CO at low temperature gives the thermally unstable $TiX_2(CO)_2(dmpe)_2$. In an analogous manner, treatment of the mixed halide complex $TiClBr(dmpe)_2$ with CO gives the corresponding dicarbonyl complex $TiClBr(CO)_2(dmpe)_2$. NMR experiments suggest that these complexes adopt a bicapped octahedral structures, with the halide ligands in the capping sites and the carbonyl ligands mutually cis.[15]

Reaction of benzylbis(2-ethoxyethyl) phosphine ($PhCH_2P(CH_2CH_2OEt)_2$) with $TiCl_4$ gives $TiCl_4[PhCH_2P(CH_2CH_2OEt)_2]$ (**1**). The crystal structure of $TiCl_4[PhCH_2P(CH_2CH_2OEt)_2]$ shows the metal to have a distorted octahedral geometry, where the ligand acts as a P,O-bonding chelate ligand (*see Chelating Ligands*).[16] Treatment of TiI_4 with one equivalent of the bidentate ligands $o\text{-}(PMe_2)_2C_6H_4$ and $o\text{-}(AsMe_2)_2C_6H_4$ in anhydrous CH_2Cl_2 gives $TiI_4(o\text{-}(PMe_2)_2C_6H_4)$ and $TiI_4(o\text{-}(AsMe_2)_2C_6H_4)$ (**2**), respectively.[17]

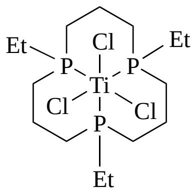


(**1**)



(**2**) E = PMe_2, $AsMe_2$

The reactions of 1,5,9-triethyl-1,5,9-triphosphacyclododecane, $[12]aneP_3Et_3$, with $TiCl_3$ THF gives $TiCl_3([12]ane\ P_3Et_3)$ (**3**).[18]



(**3**)

3 CARBONYL, PHOSPHINE, ALKENE, AND ALKYNE COMPLEXES WITH π-LIGANDS

The cyclopentadienyl titanium carbonyl anions $[CpTi(CO)_4]^-$ and $[Cp^*Ti(CO)_4]^-$ have been prepared and extensively studied by Ellis and coworkers.[19] Reduction of $CpTiCl_3$ or Cp^*TiCl_3 with alkali-metal naphthalenide at low temperature under a CO atmosphere followed by cation exchange gives $[Et_4N][CpTi(CO)_4]$ (equation 4) and $[Et_4N][Cp^*Ti(CO)_4]$, respectively, in moderate yield. X-ray crystallographic analysis of $[Ph_4As][CpTi(CO)_4]$ indicates that $[CpTi(CO)_4]^-$ is isostructural with the neutral isoelectronic vanadium complex $CpV(CO)_4$ (*see* ***Vanadium: Organometallic Chemistry***). The unsolvated $Na[(C_5H_5)Ti(CO)_4]$ was found to be explosive at room temperature. Treatment of $[CpTi(CO)_4]^-$ with Ph_3SnCl or Ph_3PAuCl gives the corresponding heterobimetallic titanium(II) complexes $CpTi(CO)_4E$ (E = Ph_3Sn, Ph_3PAu).[20–22]

$$CpTiCl_3 + 4NaC_{10}H_8 + CO \longrightarrow Na[CpTi(CO)_4] \quad (4)$$

The zerovalent cyclopentadienyl (*see Cymantrene*) titanium carbonyl phosphine complexes $[CpTi(CO)_3(PR_3)]^-$ and

$[Cp^{*}Ti(CO)_3(PR_3)]^-$ (R = Me, Ph) are prepared by the photo substitution reactions of $[CpTi(CO)_4]^-$ and $[Cp^{*}Ti(CO)_4]^-$, respectively, with phosphine ligands. The analogous dmpe complexes $[CpTi(CO)_2(dmpe)]^-$ and $[Cp^{*}Ti(CO)_2(dmpe)]^-$ are prepared by the reductive cleavage of $Cp_2Ti(CO)_2$ and $Cp^{*}_2Ti(CO)_2$ in the presence of dmpe. Protonation of the $[CpTi(CO)_3(PR_3)]^-$ and $[Cp^{*}Ti(CO)_3(PR_3)]^-$, gives the thermally unstable carbonyl hydrides $CpTi(CO)_3(PR_3)H$ and $Cp^{*}Ti(CO)_3(PR_3)H$, respectively. However, protonation of the analogous $[Cp^{*}Ti(CO)_2(dmpe)]^-$ gives $Cp^{*}Ti(CO)_2(dmpe)H$ which could be isolated at room temperature.[23]

Treatment of $(CpTiCl_2)_x$ with 1 equivalent or BuLi in the presence of dmpe in ether gives the diamagnetic $CpTiCl(dmpe)_2$, which upon treatment with MeLi or BuLi gives $CpTiMe(dmpe)_2$ and $CpTiH(dmpe)_2$. respectively.[24]

Addition of $BH_3{\cdot}THF$ to $[K(15\text{-crown-}5)_2]_2[Ti(CO)_6]$ and $[K(18\text{-crown-}6)]_2[Ti(CO)_6]$ gives $[K(15\text{-crown-}5)_2]_2[Ti(CO)_4(\eta^3\text{-}BH_4)]$ and $[K(18\text{-crown-}6)][Ti(CO)_4(\eta^3\text{-}BH_4)]^-$. Treatment of $[K(15\text{-crown-}5)_2]_2[Ti(CO)_4(\eta^3\text{-}BH_4)]$ with potassium-pyrrole gives $[K(15\text{-crown-}5)_2]_2[(\eta^5\text{-}C_4H_4N)Ti(CO)_4]$.[25]

Reduction of $(\eta^5\text{-}C_5Me_5)TiCl_3$ with sodium naphthalenide at $-60\,°C$ in DME in the presence of dmpe, followed by carbonylation at one atm, gives the unstable olive-green complex $(\eta^5\text{-}C_5Me_5)Ti(CO)(dmpe)Cl$ which has been characterized in solution by NMR and IR.[26]

4 ALKYL AND ARYL COMPLEXES WITHOUT π-LIGANDS

The synthesis and reactivity of σ-bonded alkyl (*see Alkyl Complexes*) and aryl titanium(IV) complexes has been extensively reviewed by Bottrill *et al.*[27]

Dialkyltitanium complexes have long been proposed as intermediates in the thermal and photochemical decomposition of tetraalkyltitanium complexes. Treatment of $TiCl_2(dempe)_2$ with alkyllithium reagents gives mixed alkyl/halide products caused by incomplete exchange of the strongly held Cl.[28] However, treatment of $TiCl_2(dmpe)_2$ with an excess of $LiBH_4$ forms paramagnetic $Ti(\eta^2\text{-}BH_4)_2(dmpe)_2$, which upon treatment with MeLi gives $TiMe_2(dmpe)_2$ (equations 5 and 6). Surprisingly, $TiMe_2(dmpe)_2$ is found to be diamagnetic, and could be characterized by ^1H and ^{13}C NMR. Single-crystal X-ray and neutron diffraction studies have been carried out on $TiMe_2(dmpe)_2$ at 173 and 30 K, respectively. The titanium center in $TiMe_2(dmpe)_2$ adopts a regular octahedral structure with the methyl groups trans to each other. The Ti–C–H bond angles are all found to be 109 °C or greater, indicating no agostic bonding (*see Agostic Bonding*) in the solid state.[29]

$$TiCl_2(dmpe)_2 + 2LiBH_4 \longrightarrow Ti(\eta^2\text{-}BH_4)_2(dmpe)_2 + 2LiCl \quad (5)$$

$$Ti(\eta^2\text{-}BH_4)_2(dmpe)_2 + 2LiMe \longrightarrow TiMe_2(dmpe)_2 \quad (6)$$

Treatment of $TiCl_4$ with one equivalent of dmpe gives $TiCl_4(dmpe)$. This complex can be readily alkylated with 1 or 2 equivalent of $PhCH_2MgCl$ to give $TiCl_3(PhCH_2)(dmpe)$ and $TiCl_2(PhCH_2)_2(dmpe)$, respectively. The corresponding thermally unstable mono *t*-butyl complex, '$TiCl_3(t\text{-}Bu)(dmpe)$', decomposes to give the dinuclear edge-sharing Ti(III) complex, $Ti_2Cl_4(\mu\text{-}Cl)_2(dmpe)_2$. The analogous, $Ti_2Cl_4(\mu\text{-}Cl)_2(depe)_2$ was prepared directly by the reaction of $TiCl_3(THF)_3$ with the corresponding phosphine. Thermal decomposition of the thermally unstable di-*t*-butyl complex '$TiCl_2(t\text{-}Bu)_2(dmpe)$' gives $Ti_3Cl_6(dmpe)_3$, which consists of an equilateral triangle of Ti(II) atoms with three coplanar μ-Cl atoms bridging the edges. Each Ti atom is further coordinated by a chelating dmpe ligand and a chloride ion, with Ti–Ti distances of 2.872(3) Å.[30]

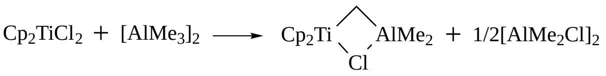
Highly stericly hindered alkyl complexes $(Me_3CCH_2)_3TiSi(SiMe_3)_3$ and $(Me_3SiCH_2)_3TiSi(SiMe_3)_3$ were prepared by the reaction of $(Me_3CCH_2)_3TiCl$ and $(Me_3SiCH_2)_3TiCl$, respectively, with $LiSi(SiMe_3)_3(THF)_3$. The structures of $(Me_3CCH_2)_3TiSi(SiMe_3)_3$ and $(Me_3SiCH_2)_3TiSi(SiMe_3)_3$ were determined by X-ray diffraction show that the three alkyl groups on the metal centers are staggered with respect to the trimethylsilyl groups on the central silicon atoms.[31]

Dialkyltitanium(IV) complexes R_2TiX_2 (R = Bu, *i*Pr, X = Cl, O*i*Pr), react with olefins, acetylenes, azoarenes, aldehydes, ketones, amides, and imines, to undergo in high-yield epimetalation of the multiple bond with TiX_2 giving transient 3-membered titanacycles. Treatment of alkynes with R_2TiX_2 followed by hydrolytic work-up gave cis-alkenes with high selectivity. In a similar manner treatment of benzophenone with R_2TiX_2 followed by hydrolytic work-up gave benzopinacol and benzhydrol.[32]

5 ALKYLIDENE AND TITANACYCLOBUTANE COMPLEXES

Tebbe's Reagent (*see Tebbe's Reagent*), a stable, soluble dimethylaluminum chloride−titanocene methylidene complex, is prepared from Cp_2TiCl_2 and $(AlMe_3)_2$, as shown in equation (7). Tebbe's reagent has been successfully utilized as an alkene metathesis (*see Metathesis*) catalyst and readily adds methylene to aldehydes, ketones, and esters. Treatment of Tebbe's reagent, in the presence of base, with alkenes or alkynes leads to titanacyclobutanes or titanacyclobutenes, as shown in Scheme 1. For monosubstituted titanacyclobutanes, the substituent prefers the β-position. Addition of a second β substituent to the metallacycles (*see Metallacycle*) results in significant destabilization of the metallacycles.[33] Bickelhapt and coworkers have developed an alternative preparation for $[Cp_2Ti{=}CH_2]$. Thus, treatment of Cp_2TiCl_2 with $(BrMg)_2CH_2$ gives $[Cp_2Ti{=}CH_2]$, which reacts with alkenes and alkynes to give titanacyclobutane and titanacyclobutene complexes in

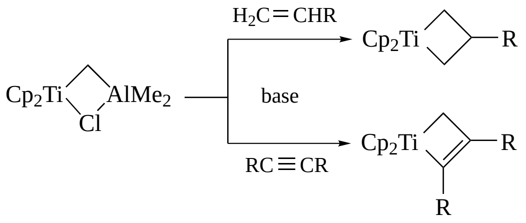
a manner similar to that of Tebbe's reagent.[34]



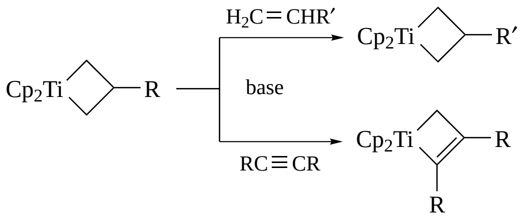
(7)

Metal alkylidene complexes (*see Schrock-type Carbene Complexes*) have been proposed as intermediates in many catalytic reactions, including alkene metathesis (*see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***), alkene and alkyne polymerization, methylenation of carbonyl compounds, and cyclopropanation of alkenes.[35–39]

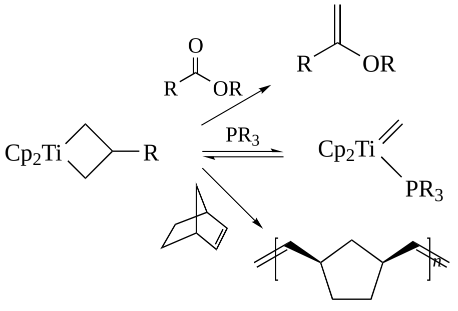
Titanacyclobutanes serve as ready sources of [$Cp_2Ti=CH_2$], reacting with alkenes and alkynes to give titanacyclobutane and titanacyclobutene complexes, as shown in Scheme 2, via slow formation of an alkene–methylidene intermediate which is rapidly trapped by the alkene or alkyne (equation 8). Titanacyclobutanes also transfer methylene groups to carbonyl groups, effect ring-opening polymerization of strained



Scheme 1

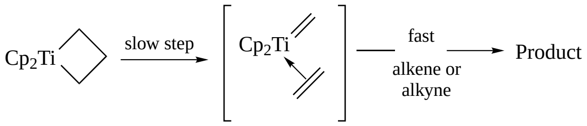


Scheme 2



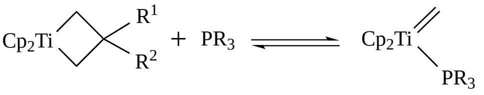
Scheme 3

cyclic alkenes (*see Ring Opening Metathesis Polymerization Reactions*), and form dinuclear methylene complexes (Scheme 3).[35,36,39]



(8)

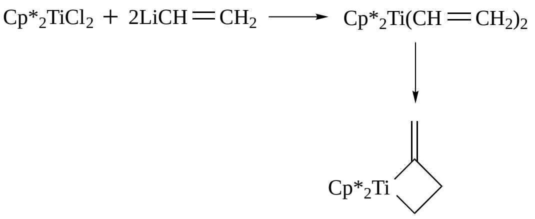
Titanocene methylidene phosphine complexes $Cp_2Ti=CH_2L$ ($L = PMe_3$, PMe_2Ph, PEt_3) have been generated by the thermolysis of titanocene metallacyclobutanes in the presence of excess phosphine (equation 9). These titanocene methylidene phosphine complexes have been found to react with alkenes, alkynes, and CO to form metallacyclobutanes, metallacyclobutenes, and a ketene complex, respectively. The phosphine ligand is labile, and an equilibrium mixture is rapidly established if a second phosphine is added.[40]



(9)

$R^1 = R^2 = Me$; $R^1 = Me$, $R^2 = Pr$; $PR_3 = PMe_3, PMe_2Ph, PEt$

Treatment of $Cp^*_2TiCl_2$ with 2 equivalents of vinyllithium gives the corresponding divinyl complex $Cp^*_2Ti(CH=CH_2)_2$ at low temperature. However, at room temperature, $Cp^*_2Ti(CH=CH_2)_2$ undergoes rearrangement quantitatively to give a titanacyclobutane with an exocyclic methylidene group (**4**) (equation 10).[41,42]

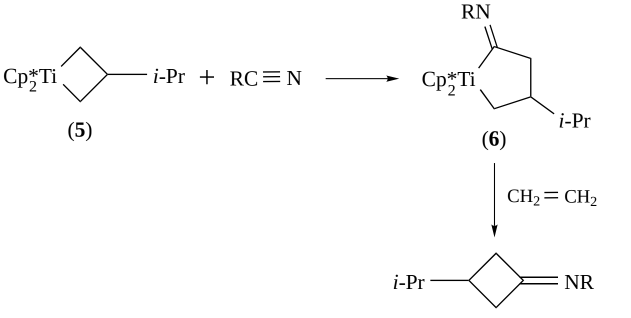


(10)

(**4**)

Migratory insertion (*see Migratory Insertion*) reaction of isonitriles, RN≡C, ($R = C_6H_{11}$, *t*-Bu) with 3-isoproplbis(pentamethylcyclopentadineyl)titanacyclobutane (**5**) gives the iminoacyl titanium complexes (**6**) (R = *t*-Bu, cyclohexyl) in 90–92%. Treatment of (**6**) ($R = C_6H_{11}$) with $CH_2=CH_2$ in tolune at 10 psi gave 94% cyclobutanimine (**7**). Treatment of (**6**) ($R = C_6H_{11}$, *t*-Bu) with 60 psi of CO at −78 °C gives the Cp^*_2Ticyclopentenamidolate complex in

high yield.[43]



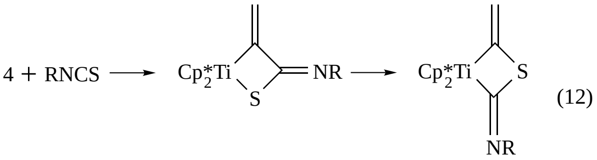
(5) (6) (7)

(11)

Addition of aryldiazoalkanes to $Cp^*_2Ti(C_2H_4)$ gives η^2-N_2-titanium aryldiazoalkane complexes $Cp^*_2Ti(N_2CHAr)$. Unlike most diazoalkane complexes, they release dinitrogen thermally to give transient carbene complexes which when trapped with styrene gives the titanacyclobutane complexes $Cp^*_2Ti(CHArCHPhCH_2)$. The addition of t-BuN≡C results in a coordination change of the diazoalkane fragment from η^2 to η^1 to give $Cp^*_2Ti(\eta^1$-$N^2CHPh)(t$-BuN≡C). The bound t-BuN≡C ligand exchanges with free t-BuN≡C in solution.[44]

Addition of (trimethylsilyl)diazomethane to $Cp^*_2Ti(\eta^2$-$C_2H_4)$ gives the η^2-N_2-diazoalkane complex $Cp^*_2Ti(N_2CHSiMe_3)$. $Cp^*_2Ti(N_2CHSiMe_3)$ loses N_2 in solution under mild conditions to give the fulvene complex $Cp^*(\eta^6$-$C_5Me_4CH_2)TiCH_2SiMe_3$. Thermolysis of $Cp^*_2Ti(N_2CHSiMe_3)$ in the presence of 1-alkenes yields the trans-α,β,-disubstituted titanacyclobutane complexes $Cp^*_2Ti(CH(SiMe_3)CH(R)CH_2)$.[45]

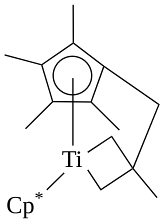
The titanocene vinylidene intermediate $Cp^*_2Ti(=C=CH_2)$ formed by ethane or methane elimination from titanacyclobutane (**4**) or $Cp^*_2Ti(CH=CH_2)Me$, respectively, reacts with isothiocyanates, RNCS (R = C_6H_{11}, Ph or t-Bu), by a [2 + 2] cycloaddition, to give the titanathietane complexes (**8**). In all cases, the regioisomer in which the S atom is bonded to Ti is found as the primary product. Upon heating in the presence of pyridine, a rearrangement of (**8**) to the regioisomeric titanacyclobutane derivative (**9**) was observed (equation 12).[46]



(8) (9)

(12)

Treatment of $Cp^*(C_5Me_4CH_2)TiCl$ with 2-methylallyl Gringard gives to $Cp^*(\eta^5{:}\eta^2$-$C_5Me_4CH_2CMe(CH_2)_2)Ti$ (**10**), with a titancyclobutane tethered to the Cp* ligand by a



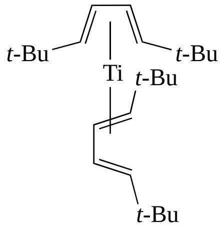
(**10**)

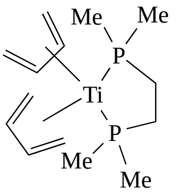
methylene bridge. Thermolysis of (**10**) gives a new fulvene complex $(C_5Me_4CH_2)(\eta^5{:}\eta^1$-$C_5Me_4CH_2CMe_2CH_2)Ti$.[47]

α-H elimination (*see α-Elimination*) from $(C_5Me_4CH_2CH_2NMe_2)Cp^*Ti(CH=CH_2)(CH_3)$ gives $(C_5Me_4CH_2CH_2NMe_2)Cp^*Ti=C=CH_2$, which further reacts to give the fulvene complexes $(C_5Me_3(CH_2CH_2NMe_2)CH_2)TiCH=CH_2$ and $(C_5Me_4CH_2CH_2NMe_2)(C_5Me_4CH_2)TiCH=CH_2$. The analogous α-H elimination from $(C_5Me_4CH_2CH_2NMe_2)Cp^*Ti(CH=CH_2)_2$ gives $(C_5Me_4CH_2CH_2NMe_2)Cp^*Ti=C=CH_2(\eta^2$-$CH_2=CH_2)$, which rearranges to a titanacyclobutane with an exocyclic methylidene group analogous to (**4**).[48]

6 DIENE COMPLEXES LACKING OTHER π-LIGANDS

The homoleptic (*see Homoleptic Compound*) titanium diene complex $(\eta^4$-t-BuCH=CHCH=CHBu-$t)_2Ti$ (**11**) has been prepared by the condensation of electron-beam vaporized titanium with an excess of 1,4-di-t-butylbuta-1,3-diene[49] (*see **Metal Vapor Synthesis of Transition Metal Compounds***). The bis-diene dmpe complex $Ti(dmpe)(\eta^4$-$C_4H_6)_2Ti$ (**12**) has been prepared by the reduction of $TiCl_4(dmpe)$ with Na/Hg in the presence of butadiene, and by the reduction of $TiCl_4$ with $CH_2=CHLi$ in the presence of dmpe.[50–52]





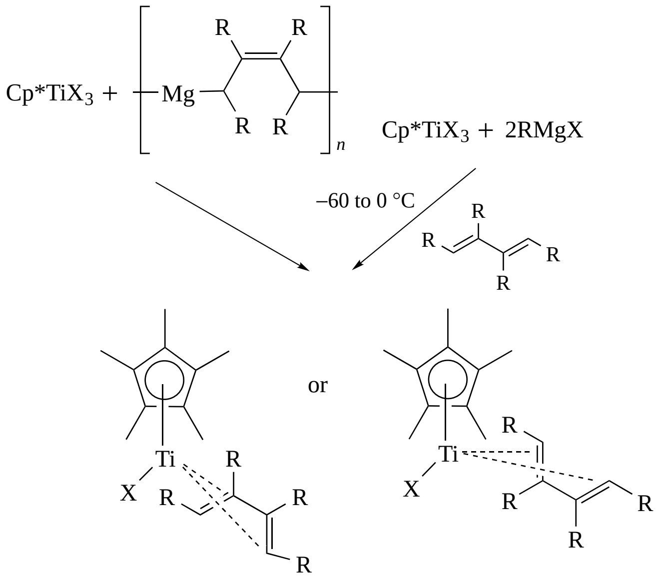
(**11**) (**12**)

Reaction of *trans*-$TiMe_2(dmpe)_2$ with 1,3-butadiene and trans, trans-1,4-diphenyl-1,3-butadiene at −20 °C give the titanium(II) butadiene complexes $TiMe_2(\eta^4$-$C_4H_6)(dmpe)$ and $TiMe_2(\eta^4$-$C_4H_4Ph_2)(dmpe)$, respectively. The NMR of spectra $TiMe_2(\eta^4$-$C_4H_6)(dmpe)$ and $TiMe_2(\eta^4$-$C_4H_4Ph_2)(dmpe)$ are consistent with structures in which the Me groups are mutually cis, which was verified by X-ray crystallography

for the $TiMe_2(\eta^4\text{-}C_4H_4Ph_2)$(dmpe). These molecules are fluxional on the NMR timescale ($\Delta H^{\ddagger} = 9.1 \pm 0.2$ kcal/mol and $\Delta S^{\ddagger} = 3 \pm 1$ eu) for $TiMe_2(\eta^4\text{-}C_4H_4Ph_2)$(dmpe). When the reaction of $TiMe_2(dmpe)_2$ and 1,3-butadiene was allowed to continue at −20 °C for more that 12 h, a second titanium complex is formed, which has been identified as (1-octa-1,6-diene-1,8-diyl) $(TiMe_2)_3$, (1-octa-1,6-diene-1,8-diyl)(dmpe). Both $Ti(\eta^4\text{-}C_4H_6)_2$(dmpe) and $TiMe_2(\eta^4\text{-}C_4H_4Ph_2)$(dmpe) exhibit the butadiene ligands bound as true dienes, unlike the structure observed for many other early transition metal butadiene complexes.[53]

7 DIENE COMPLEXES CONTAINING OTHER π-LIGANDS

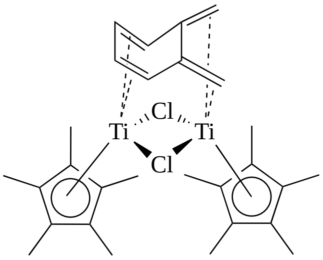
Mixed cyclopentadienyl–diene titanium complexes, Cp*TiX(diene) (X = Cl, Br, I), have been prepared in 30–60% yield by the stoichiometric reaction of $CpTiX_3$ with (2-butene-1,4-diyl)magnesium derivatives or by the reduction of $CpTiX_3$ with RMgX (R = *i*-Pr, *t*-Bu, Et; X = Cl, Br, I) in the presence of conjugated dienes, as shown in Scheme 4. The butadiene, 1,3-pentadiene, and 1,4-diphenylbutadiene complexes of Cp*TiX exhibit a unique prone (endo) conformation (**13**), while the isoprene, 2,3-dimethylbutadiene, and 2,3-diphenylbutadiene complexes prefer the supine (exo) conformation (**14**). Reduction of Cp*TiX(diene) with RMgX or Mg gives a low-valent species, which catalyzes a highly selective (>99%) tail-to-head linear dimerization of isoprene and 2,3-dimethylbutadiene.[54,55]



(**13**) prone *endo* (**14**) supine *exo*

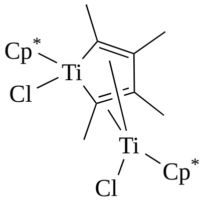
Scheme 4

Addition of $[o\text{-}(CH_2)_2C_6H_4]Mg(THF)_2$ to Cp^*TiCl_3 in toluene gives the expected *o*-xylidene complex $Cp^*TiCl[o\text{-}(CH_2)_2C_6H_4]$. However, reaction of $[o\text{-}(CH_2)_2C_6H_4]Mg(THF)_2$ with Cp^*TiCl_3 in THF leads to the dinuclear bis(diene)titanium complex (**15**), in which two Cp*TiCl fragments bond to *o*-xylidene through its exo- and endocyclic diene systems via σ^2 and η^4 bonding modes, respectively.[56]



(**15**)

Diene–cyclopentadienyl titanium halide complexes react readily with unsaturated organic molecules. For example, reaction of $Cp^*TiCl(\eta^4\text{-}CH_2{=}CH(Me)CH(Me){=}CH_2)$ with symmetrical alkynes RC≡CR (R = Me, Ph) leads to reductive coupling (*see Reductive Coupling*) of the alkynes to give metallacyclo-2,4-pentadiene products Cp*Ti(C(Ph)=C(Ph)C(Ph)=C(Ph))Cl and the dinuclear metallacycle $[Cp^*TiCl]_2(C_4Me_4)$ (**16**).[57] In an analogous manner, treatment of $Cp^*Ti(CH_2{=}C(Me)C(Me){=}CH_2)Cl$ with 2,6-xylyl isocyanide at −30 °C gives the dimeric complex $(Cp^*TiCl)_2[\mu\text{-}N_2C_2(2,6\text{-xylyl})_2]$ (**17**) in 47% yield. Lesser amounts of (**18**) and (**19**) are also formed in this reaction, as shown in Scheme 5.[58]

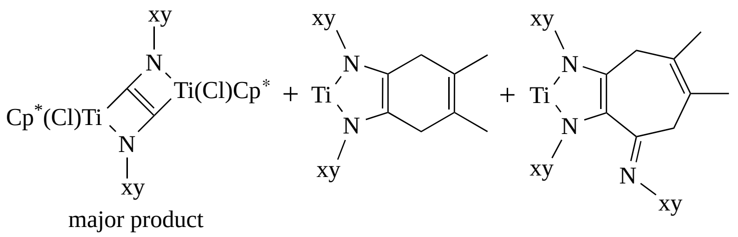


(**16**)

The cyclooctatetraene–diene complex $[(\eta^4\text{-}C_4H_6)cot]Ti$ has been reported and has been shown by ^1H NMR spectra to adopt an *s-cis*-η^4-butadiene conformation.[59]

Reduction of $TiCl_4(THF)_2$ with 2 equivalents of Mg in the presence of 2 equivalents of a sterically demanding 1-aza-1,3-diene, $ArN{=}CHC(CH_3){=}CAr$ (Ar = 1,5 $(i\text{-pr})_2C_6H_3$), gives the homoleptic early transition metal 1-aza-1,3-diene complex, $Ti(1\text{-aza-1,3-diene})_2$. X-ray diffraction analysis of this complex shows Ti–N distances of 1.949(2) and 1.939(2) Å and Ti–C distances of 2.317(3) and 2.132(3) Å. The subsequent addition of MeLi and elimination of methane

$$Cp^{*}Ti(CH_2{=}C(Me)C(Me){=}CH_2) + 2\ (2,6\text{-Xylyl})N{\equiv}C \longrightarrow$$



major product

(**17**) (**18**) (**19**)

xy = Xylyl

Scheme 5

results in the formation of a novel metallacyclic titanium alkylidene complex, which affords the opportunity to compare of Ti–C σ- bond (2.163(3)) Å and Ti=C-bond (1.978(3) Å) distances within the same molecule.[60]

Reaction of $TiCl_4THF_2$ with Na_2[MePhN=C–C=NPhMe] (Ph = C_6H_5, 4-MeC_6H_4 and 2-MeC_6H_4) or by reduction of $TiCl_4THF_2$ with Mg in presence of 2 equivalent of MePhN=C–C=NPhMe give the corresponding homoleptic 1,4-diaza-1,3-diene complexes. The endiamide complexes are thermally stable and very sensitive to oxygen and water. An X-ray crystal structure reveals the Ti atom in theses complexes is in a strongly distorted tetrahedral environment. The two 5-membered metallacyclic rings are folded along the N,N' axis. Temperature-dependent ^{1}H NMR spectra indicate a rapid intramolecular inversion of this nonplanar ring system in solution even at room temperature. Reduction of $TiCl_4THF_2$ with Mg in presence of excess DAD [PhRN=C–C=NRPh (DAD; R = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$)] gives the blue-violet complexes $(DAD)_3Ti$.[61]

8 ARENE COMPLEXES

8.1 Bis-arene Complexes

Bis-arene titanium complexes (*see Arene Complexes*) such as $(\eta^6\text{-}C_6H_6)_2Ti$ were first prepared by Green and coworkers by the reaction of titanium atoms with arenes on a liquid nitrogen cooled surface (equation 13).[62] A wide range of aromatic ligands have been incorporated in bis-arene titanium complexes by metal vapor synthesis, including highly sterically hindered arenes ($(\eta^6\text{-}t\text{-}Bu_3C_6H_3)_2Ti$) and heterocyclic arenes ($(\eta^6\text{-}2,6\text{-}Me_2C_5H_3N)_2Ti$).[63] Bis-arene titanium complexes are diamagnetic and exhibit sandwich structures (*see Sandwich Compound*) with essentially mutually parallel eclipsed planar arene ligands. However, $(\eta^6\text{-}2,6\text{-}Me_2C_5H_3N)_2Ti$ exhibits an unusual staggered configuration with a nitrogen center–titanium center'–nitrogen' torsional angle of 140.1°.[64,65]

$$C_6H_6 + \text{Ti vapor} \longrightarrow (\eta^6\text{-}C_6H_6)_2Ti \quad (13)$$

Since bis-arene titanium complexes were initially prepared by metal-atom chemistry, 'conventional' chemical synthesis of bis-arene titanium complexes has been developed. Treatment of $TiCl_4(THF)_2$ with K(Ph–Ph)$_2$ and K(4,4′-t-Bu_2Ph–Ph)$_2$ gives K[Ti(η^6-Ph–Ph)$_2$] (equation 14) and K[Ti(η^6-4,4′-t-Bu_2Ph–Ph)$_2$], respectively, which are isolated as the corresponding K([2.2.2]cryptand) or K(15-crown-5)$_2$ bis(arene)titanates. Oxidation of these complexes with I_2 gives the corresponding bis-arene complexes (equation 15).[66] Ultrasound-mediated reduction of $TiCl_4(THF)_2$ or $TiCl_3(THF)_3$ with K[BEt_3H] in benzene, toluene, p-xylene, or mesitylene gives the corresponding bis(η^6-arene)titanium complexes directly (equation 16).[67]

$$TiCl_4(THF)_2 + K(Ph{-}Ph)_2 \longrightarrow K[Ti(\eta^6\text{-}Ph{-}Ph)_2] \quad (14)$$

$$K[Ti(\eta^6\text{-}Ph{-}Ph)_2] + I_2 \longrightarrow Ti(\eta^6\text{-}Ph{-}Ph)_2 \quad (15)$$

$$TiCl_4(THF)_2 \text{ or } TiCl_3(THF)_3 \xrightarrow[C_6H_6\ )))]{K[BEt_3H]} (\eta^6\text{-}C_6H_6)_2Ti \quad (16)$$

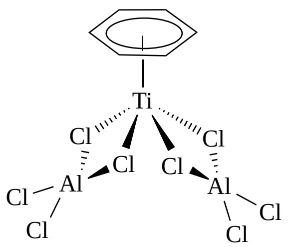
8.2 Monoarene complexes

Treatment of $[(Me_2PCH_2)_3Si\text{-}t\text{-}Bu]TiCl_3(THF)$ with sodium naphthalenide in THF gives $(\eta^6\text{-}C_{10}H_8)Ti[(Me_2PCH_2)_3Si\text{-}t\text{-}Bu]$ in 40% yield.[68]

Diamagnetic titanium(II) arene complexes $(\eta^6\text{-}C_6H_6)Ti[(\mu\text{-}X)_2(AlX_2)]_2$ (X = Cl, Br, I) (**20**) have been prepared by the reduction of TiX_4 (X = Cl, Br, I) with Al in the presence of $AlCl_3$ in C_6H_6 (equation 17). The arene ligands in these complexes are η^6 coordinated to the titanium, which exhibits square pyramidal coordination with four halides of

two AlX_4 anions forming the basal square plane.

$$C_6H_6 + AlCl_3 + Al \longrightarrow (\eta^6\text{-}C_6H_6)Ti[(\mu\text{-}Cl)_2(AlCl_2)]_2 \quad (17)$$



(**20**)

Treatment of (η^6-arene)Ti[(μ-X)$_2$(AlX$_2$)]$_2$ (X = Br, I) complexes with CO at low temperature gives the corresponding dicarbonyl derivatives [(η^6-arene)Ti(CO)$_2$[(μ-X)(AlX$_2$)]]AlX$_4$ (equation 18). Treatment of (η^6-arene)Ti(CO)$_2$[(μ-X)$_2$(AlX$_2$)]$_2$ (X = Cl, Br) with CpTl and 1 atm of CO at room temperature leads to the loss of the arene ligand and gives $Cp_2Ti(CO)_2$ in good yields (equation 19).[69]

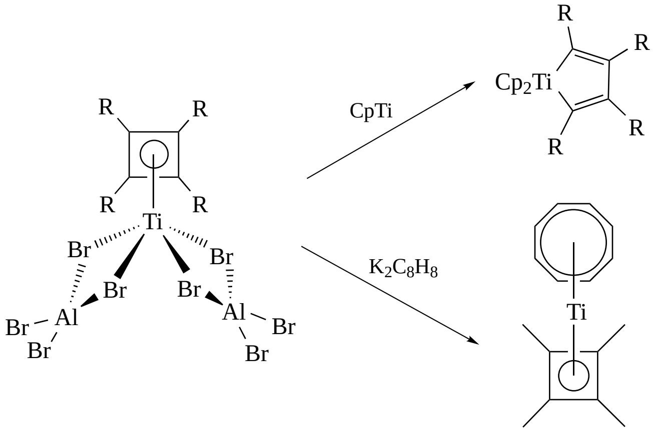
$$(\eta^6\text{-arene})Ti[(\mu\text{-}Br)_2(AlBr_2)]_2 + CO \longrightarrow (\eta^6\text{-arene})Ti(CO)_2[(\mu\text{-}Br)(AlBr_2)] \quad (18)$$

$$(\eta^6\text{-arene})Ti(CO)_2[(\mu\text{-}Br)(AlBr_2)] + CpTl \longrightarrow Cp_2Ti(CO)_2 \quad (19)$$

Reaction of Ti(η^6-MePh)[(μ-X)$_2$(AlX$_2$)]$_2$ (X = Cl, Br) with alkynes RC≡CR (R = Me, Ph) gives tetramethyl- and tetraphenylcyclobutadiene complexes, Ti(η^4-C$_4$R$_4$)[(μ-X)$_2$(AlX$_2$)]$_2$ (R = Ph, X = Cl, Br; R = Me, X = Br), in good yield. The titanium atom in Ti(η^4-C$_4$Ph$_4$)[(μ-Br)$_2$(AlBr$_2$)]$_2$ is found to have approximately square pyramidal coordination, with the apical position occupied by the symmetrically bonded tetraphenylcyclobutadiene ring with four bromines of two $AlBr_4$ anions forming the base of the pyramid. Treatment of Ti(η^4-C$_4$Ph$_4$)[(μ-Br)$_2$(AlBr$_2$)]$_2$ with CpTl and K$_2$cot forms Cp$_2$Ti[C(Ph)=C(Ph)C(Ph)=C(Ph)] and (cot)Ti(η^4-C$_4$Ph$_4$), respectively, as shown in Scheme 6. Ti(η^6-MePh)[(μ-X)$_2$(AlX$_2$)]$_2$ (X = Cl, Br) has been shown to cyclotrimerize (*see Cyclodimerization & -trimerization Reactions*) alkynes at 89 °C.[70]

Reduction of TiCl$_4$(dmpe) or Cp*TiCl$_3$ with K or Na anthracene in THF gave [Ti(η^6-C$_{14}$H$_{10}$)(η^4-C$_{14}$H$_{10}$)(dmpe)] and [Cp*Ti(η^4-C$_{14}$H$_{10}$)(η^2-C$_{14}$H$_{10}$)]$^-$, respectively. Treatment of [Ti(η^6-C$_{14}$H$_{10}$)(η-C$_{14}$H$_{10}$)(dmpe)] and [Cp*Ti(η^4-C$_{14}$H$_{10}$)(η^2-C$_{14}$H$_{10}$)]$^-$ with carbon monoxide in THF at −55 °C led to loss of the anthracene ligands to give Ti(CO)$_3$(dmpe)$_2$ and Cp*[Ti(CO)$_4$]$^-$ in 57% and 62% yields, respectively.[71]

A small number of titanium complexes with heterocyclic ligands have been prepared. Reaction of TiCl$_4$(THF)$_2$ with 2,3,4,5-tetramethyl-1-trimethylstannyl phosphole in CH$_2$Cl$_2$/pentane followed by reduction with Mg in the presence of CO gives (η^5-2,3,4,5-C$_4$Me$_4$P)Ti(CO)$_2$ in 39% yield.[72] Reaction of TiCl$_4$ with Li(C$_5$H$_5$BMe), 2-(Me$_3$Si)C$_5$H$_5$BMe, or 2-(Me$_3$Sn)C$_5$H$_5$BMe gives TiCl$_3$(η^6-C$_5$H$_5$BMe) in excellent yield. Cp TiCl$_2$(η^6-C$_5$H$_5$BMe) was prepared in an analogous manner starting with CpTiCl$_3$ in place of TiCl$_4$.[73] The addition of potassium-pyrrole to [K(15-crown-5)$_2$]$_2$[Ti(CO)$_4$(η^3-BH$_4$)] gives [K(15-crown-5)$_2$]$_2$[(η^5-C$_4$H$_4$N)Ti(CO)$_4$)].[25]



Scheme 6

9 CYCLOPENTADIENYL COMPLEXES OF TITANIUM(IV)

The vast majority of the organometallic chemistry of titanium is based upon complexes that incorporate one or two cyclopentadienyl or substituted cyclopentadienyl groups as ancillary ligands. Cyclopentadienyl (*see Cyclopentadienyl*) and substituted cyclopentadienyl ligands are ubiquitous in the organometallic chemistry of titanium. Bis(cyclopentadienyl)- and substituted bis(cyclopentadienyl)titanium dichloride complexes have been prepared by treatment of TiCl$_4$, or TiCl$_3$ followed by an oxidative work-up, with a wide range of cyclopentadienyl and substituted cyclopentadienyl salts of several metals, including Li$^+$, Na$^+$ (equation 20), MgX$^+$, Mg^{2+}, Tl$^+$, and Pb^{2+}. Bu$_2$TiCl$_2$, generated in hydrocarbon media at −78 °C by treating TiCl$_4$ with 2 equivalent of BuLi, functions a strong bases toward cyclopentadiene, substituted cyclopentadiene, and indene giving Cp$_2$TiCl$_2$ derivatives in high yield (equation 21).[74] Treatment of Ti(NMe$_2$) and Ti(NEt$_2$)$_4$ the cyclopentadiene derivatives to give metallocenes (*see Metallocene Complexes*) (equation 22).[75] Modifications of this reaction have recently been widely used to prepare substituted Cp complexes including *ansa*-metallocenes and constrained geometry complexes.

$CpTiCl_3$ is conveniently prepared by treatment of $TiCl_4$ with $CpSiMe_3$ (equation 23).[76] The synthesis and reactivity bis(cyclopentadienyl)titanium through the mid- 90s has been extensively reviewed by Bechaus up.[77] The synthesis of chiral titanocene derivatives has been reviewed by Halterman.[78]

$$2RCpNa + TiCl_4 \longrightarrow RCp_2TiCl_2 \quad (20)$$

$$Bu_2TiCl_2 + C_5H_6 \longrightarrow Cp_2TiCl_2 \quad (21)$$

$$Ti(NMe_2)_4 + C_5H_6 \longrightarrow Cp_2Ti(NMe_2)_2 \quad (22)$$

$$CpSiMe_2 + TiCl_4 \longrightarrow CpTiCl_3 \quad (23)$$

$Cp^*_2TiCl_2$ is readily prepared by reaction of 2 equivalent of $Na[C_5Me_5]$ with $TiCl_3$, followed by oxidative work-up (equation 24).[79] The mono-ring complexes Cp^*TiX_3 (X = Cl, Br) are best prepared, in nearly quantitative yield, by the treatment of TiX_4 with $(C_5Me_5)SiMe_3$ (equation 25).[80]

$$2Na[C_5M_5] + TiCl_3 \longrightarrow Cp^*_2TiCl_2 \quad (24)$$

$$TiCl_4 + (C_5Me_5)SiMe_3 \longrightarrow Cp^*TiCl_3 \quad (25)$$

Treatment of Cp_2TiCl_2 with 1 equivalent of Grignard reagent (*see Grignard Reagents*) provides a convenient route for the preparation of the mono(σ-hydrocarbyl) complexes, Cp_2TiRCl (R = Me, Et, *n*-Pr, *n*-Bu, *i*-Bu, *n*-C_5H_{11}, CH_2Bu-*t*, CH_2Ph, CH_2SiMe_3, and Ph) (equation 26). Treatment of Cp_2TiCl_2 with 2 equivalent of MeLi or MeMgX leads to Cp_2TiMe_2 in good yield (equation 27). Cp_2TiMe_2 undergoes decomposition at room temperature rapidly in light and more slowly in the dark. Similar routes have been used to prepare other bis-alkyl and -aryl complexes; however, the stability of these complexes varies widely. $Cp_2Ti(Et)_2$ decomposes below 40 °C, while $Cp_2Ti(n\text{-}Bu)_2$ decomposes above −50 °C in solution. $Cp_2Ti(R)_2$ compounds not containing β-hydrogens exhibit considerably greater stability. Thus, $Cp_2Ti(CH_2SiMe_3)_2$ and Cp_2TiPh_2 exhibit good stability at room temperature; however, they undergo thermolysis in refluxing benzene, which has been well studied. Treatment of Cp_2TiCl_2 with 2 equivalent of the more sterically demanding $LiCHPh_2$ or $LiCH(SiMe_3)_2$ leads to reduction of the titanium center to give $Cp_2TiCHPh_2$ (equation 28) and $Cp_2TiCH(SiMe_3)_2$, respectively, while treatment of Cp_2TiCl_2 with 1 equivalent of $LiCH(SiMe_3)_2$ gives Cp_2TiCl (equation 29).[81]

$$Cp_2TiCl_2 + RMgX \longrightarrow Cp_2TiClR \quad (26)$$

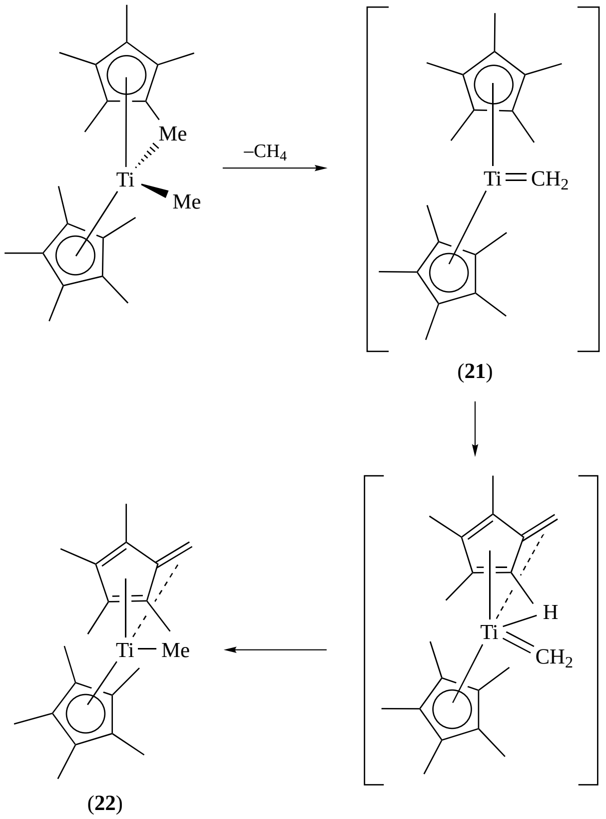
$$Cp_2TiCl_2 + 2MeMgX \longrightarrow Cp_2TiMe_2 \quad (27)$$

$$Cp_2TiCl_2 + 2LiCH(SiMe_3)_2 \longrightarrow Cp_2TiCH(SiMe_3)_2 \quad (28)$$

$$Cp_2TiCl_2 + LiCH(SiMe_3)_2 \longrightarrow Cp_2TiCl \quad (29)$$

In contrast to the preparation of Cp_2TiClR (see above), treatment of $Cp^*_2TiCl_2$ with 1 equivalent of Me, Et, or Pr, Grignard or lithium reagents gives a mixture of Ti^{III} and Ti^{IV} complexes.[42]

The replacement of the cyclopentadienyl group with the strongly electron-donating and sterically more demanding pentamethylcyclopentadienyl group has been found to impart enhanced solubility and increased kinetic stability to many transition metal complexes. This enhanced stability is typified by the difference in stability of Cp_2TiMe_2 and $Cp^*_2TiMe_2$. While Cp_2TiMe_2 undergoes decomposition at room temperature rapidly in light and more slowly in the dark, $Cp^*_2TiMe_2$ is sufficiently stable to be stored at room temperature for an extended time. Cp_2TiMe_2 is thought to decompose via α-hydrogen elimination to give products which have not been fully characterized. Bercaw has established that upon heating to 110 °C, $Cp^*_2TiMe_2$ undergoes α-hydrogen abstraction or α-hydrogen elimination (*see α-Elimination*) followed by loss of methane to give the methylidene intermediate (**21**) (equation 30). This intermediate titanium methylidene complex undergoes hydrogen migration from a ring methyl group to the methylidene to give the turquoise fulvene complex $Cp^*(\eta^6\text{-}C_5Me_4CH_2)TiMe$ (**22**).[82] Thermolysis of $(\eta^5\text{-}C_5Me_4H)_2TiMe_2$ at 130 °C gives the analogous fulvene complex $(\eta^5\text{-}C_5Me_4H)(\eta^6\text{-}C_5Me_3HCH_2)TiMe$.[83]

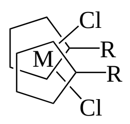


(30)

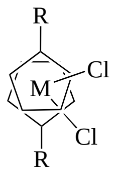
9.1 Bulky Ligands

Considerable work in recent years has been devoted to the synthesis of ring-substituted derivatives of bis(η^5-cyclopentadienyl)titanium dihalides. The ring orientation in

the bis(η^5-alkylcyclopentadienyl)titanium dihalide derivatives that have been structurally characterized, to date, can be divided into two categories, which are illustrated schematically by (**23**) and (**24**) (Table 1).



(**23**)



(**24**)

Several groups have investigated the incorporation of 1,3-di-*t*-butylcyclopentadienyl ligands in mono- and bis-cyclopentadienyltitanium complexes. The sterically congested compounds (η^5-1,3-*t*-$Bu_2C_5H_3)_2TiCl_2$ and (η^5-1,3-*t*-$Bu_2C_5H_3)TiCl_3$ are prepared in good yields by treating $TiCl_4$ or $TiCl_3$ with 2 or 1 equivalent of [1,3-*t*-$Bu_2C_5H_3$]Li, respectively.[85,86]

Reduction of (η^5-1,3-*t*-$Bu_2C_5H_3)_2TiCl_2$ with K metal in pentane gives the paramagnetic titanium(III) complex (η^5-1,3-*t*-$Bu_2C_5H_3)_2TiCl$ in high yield.[87] Treatment of (η^5-1,3-*t*-$Bu_2C_5H_3)_2TiCl_2$ with $LiBH_4$ in Et_2O leads to reduction of the titanium center to give (η^5-1,3-*t*-$Bu_2C_5H_3)_2TiBH_4$. The Ti$\cdots$B bond length is found to be 2.41 Å and the H–Ti–H bond angle is 58.2°.[88]

Bis- and tris(trimethylsilyl)cyclopentadienyl derivatives, Ti[η^5-1,3-$(SiMe_3)_2C_5H_3]_2Cl_2$ and [η^5-1,2,4-$(Me_3Si)_3C_5H_2$] $TiCl_3$, have been prepared in good yield by treating $TiCl_3$ with Li[1,3-$(SiMe_3)_2C_5H_3$] or Li[1,2,4-$(Me_3Si)_3C_5H_2$], respectively, followed by oxidative work-up.[89,90]

Reaction of $TiCl_3(THF)_3$ with 1 equivalent of the sterically demanding Li[*i*-PrC_5Me_4] in THF, followed by oxidation with HCl, affords (η^5-*i*-$PrC_5Me_4)TiCl_3$ in 66% yield. Treatment of (η^5-*i*-$PrC_5Me_4)TiCl_3$ with CpTl in refluxing benzene forms (Cp)(η^5-*i*-$PrC_5Me_4)TiCl_2$ in 95% yield. The highly sterically congested complex (η^5-*i*-$PrC_5Me_4)_2TiCl_2$ is prepared in 93% yield by reaction of $TiCl_3(THF)_3$ with 2 equivalent. of Li[*i*-PrC_5Me_4] in THF, followed by oxidation with HCl. The ring centroid–titanium–ring centroid angle of 137.4(1)° of (η^5-*i*-$PrC_5Me_4)_2TiCl_2$ is identical, within experimental error, to that found in $Cp^*_2TiCl_2$; however, the Cl–Ti–Cl bond angle of 88.81° is unusually acute (see Table 1).[84]

Table 1 Structural Parameters for RCp_2TiCl_2 Complexes[84]

	Structure type	Cp–M–Cp (°)	Cl–M–Cl (°)
(η^5-$C_5H_5)_2TiCl_2$	Staggered	131.0 (av.)	94.5 (av.)
(η^5-$C_5Me_5)_2TiCl_2$	Staggered	137.4	92.94(4)
(η^5-$MeC_5H_4)_2TiCl_2$	(**23**)	130.2	93.15(8)
(η^5-*i*-$PrC_5H_4)_2TiCl_2$	(**23**)	132.9	92.5(1)
(η^5-*t*-$BuC_5H_4)_2TiCl_2$	(**24**)	131.5	92.5(5)
(η^5-$Me_3SiC_5H_4)_2TiCl_2$		131.02	91.63
(η^5-*i*-$PrC_5Me_4)_2TiCl_2$	(**24**)	137.4	88.81
(η^5-isodiCp$)_2TiCl_2$		131.0	92.94

Treatment of $TiCl_3$ with Li(Ph_4C_5H) or K(Ph_4C_5H) gives $(Ph_4C_5H)_2TiCl$, which, upon treatment with HCl/THF or AgCl, affords the highly sterically hindered complex $(Ph_4C_5H)_2TiCl_2$.[91] In contrast to the less sterically hindered $[Cp_2TiCl]_2$, $(Ph_4C_5H)_2TiCl$ crystallizes as well-separated monomeric units with the tetraphenylcyclopentadienyl rings staggered, with a ring centroid–metal–ring centroid angle of 136.4°, and a short Ti–Cl bond length of 2.312(2) Å. Solution EPR (*see Electron Paramagnetic Resonance*) studies show evidence for free $(C_5Ph_4H)_2TiCl$ ($g = 1.957$) and a THF adduct ($g = 1.979$). Reduction of a THF solution of $(Ph_4C_5H)_2TiCl$ with sodium naphthalenide under argon and CO yields a species with IR absorptions at 1966 and 1892 cm^{-1}, which suggests the formation of $(C_5Ph_4H)_2Ti(CO)_2$.[92]

Reaction of $CpTiCl_3$ with K(C_5Ph_5) or K(C_5Ph_4H) in THF gives Cp(η^5-$Ph_5C_5)TiCl_2$ and Cp(η^5-$Ph_4C_5H)TiCl_2$, respectively. The Ti–C bond lengths for the C_5Ph_5 group in Cp(η^5-$Ph_5C_5)TiCl_2$ are found to be considerably longer than those for the C_5H_5 group; average bond lengths are 2.53(3) and 2.39(4) Å, respectively.[93]

9.2 Functionalized Ligands

Cyclopentadienyl ligands incorporating potentially chemically reactive functional groups have also been used in the preparation of bis(cyclopentadienyl)titanium dihalides. For example, reaction of (methoxycarbonylcyclopentadienyl)thallium with $CpTiCl_3$ or $TiCl_4$ gives Cp(η^5-$MeOC(O)C_5H_4)TiCl_2$ and (η^5-$MeOC(O)C_5H_4)_2TiCl_2$, respectively, in good yield. Reductive carbonylation of these complexes affords Cp(η^5-$MeOC(O)C_5H_4)Ti(CO)_2$ and (η^5-$MeOC(O)C_5H_4)_2Ti(CO)_2$, respectively, in good yield.[94]

Treatment of $TiCl_4$ with 2 equivalent of Li[ClC_5H_4] or Tl[ClC_5H_4] forms (η^5-$ClC_5H_4)_2TiCl_2$, while treatment of $CpTiCl_3$ with Tl[ClC_5H_4] gives Cp(η^5-$ClC_5H_4)TiCl_2$ in good yields. Reductive carbonylation of (η^5-$ClC_5H_4)_2TiCl_2$ and Cp(η^5-$ClC_5H_4)TiCl_2$ leads to the corresponding dicarbonyl derivatives.[94,95]

Several groups have prepared titanium-based metalloligands incorporating phosphine-substituted cyclopentadienyl ligands as the first step in the synthesis of new bimetallic complexes. Treatment of $CpTiCl_3$ with Tl($Ph_2PC_5H_4$) affords Cp(η^5-$(Ph_2P)C_5H_4)TiCl_2$ in 95% yield. Reductive carbonylation of Cp(η^5-$Ph_2PC_5H_4)TiCl_2$ gives Cp(η^5-$Ph_2PC_5H_4)Ti(CO)_2$. Both of these phosphine-substituted titanocene complexes react with $Cp(CO)_2(THF)Mn$ to give the corresponding bimetallic complexes $CpMn(CO)_2${(Cp)(η^5-$Ph_2PC_5H_4)TiCl_2$} and $CpMn(CO)_2${Cp(η^5-$Ph_2PC_5H_4$)Ti$(CO)_2$} in good yield.[96]

Reaction of Li[$Ph_2PC_5Me_4$] with $CpTiCl_3$ and $TiCl_3$ followed by treatment with CCl_4 leads to the formation of Cp(η^5-$Ph_2PC_5Me_4)TiCl_2$ and (η^5-$Ph_2PC_5Me_4)_2TiCl_2$,

respectively, in good yield.[97] In an analogous manner, reaction of $Tl[Ph_2PC_5Me_4]$ and $Tl[Me_2PC_5Me_4]$ with Cp^*TiCl_3 forms $[\eta^5\text{-}Ph_2PC_5Me_4]_2TiCl_2$ and $[\eta^5\text{-}Me_2PC_5Me_4]_2TiCl_2$, respectively, in good yield.[98] The metalloligand $[\eta^5\text{-}(Ph_2P)C_5Me_4]_2TiCl_2$ reacts readily with $Mo(CO)_4$cod, $Mo(CO)_5$THF, and $Mo(CO)_6$ to give in each case [cyclic]$[(\eta^5\text{-}Ph_2PC_5Me_4)_2TiCl_2]Mo(CO)_4$ as the sole product. The long Mo–Ti distance of 5.194(1) Å in this complex rules out any metal–metal interaction.[96]

The reaction of $(CpTiCl_2)_n$ and Cp^*TiCl_2(THF) with $Li(C_5Me_4CH_2CH_2NMe_2)$ gives $(C_5Me_4CH_2CH_2NMe_2)$ CpTiCl and $(C_5Me_4CH_2CH_2NMe_2)Cp^*TiCl$, respectively, which are oxidized by $PbCl_2$ to give $(C_5Me_4CH_2CH_2NMe_2)$ $CpTiCl_2$ and $(C_5Me_4CH_2CH_2NMe_2)Cp^*TiCl_2$, respectively. The nitrogen of the NMe_2 group in $(C_5Me_4CH_2CH_2NMe_2)$ CpTiCl was found to bond with the Ti (Ti–N, 2.437(3) Å), while the NMe_2 group in $(C_5Me_4CH_2CH_2NMe_2)Cp^*TiCl_2$ was found not be coordinated to the titanium in the solid state by single-crystal X-ray diffraction.[48]

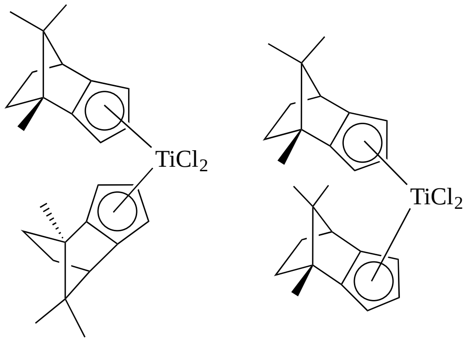
Chlorosilyl-cyclopentadienyl titanium complexes have been prepared, as starting materials allowing further modification. Treatment of MCl_4 with two equivalents of $C_5H_5(SiClMe_2)$ in toluene under reflux and in the presence of two equivalents of NEt_3 gives $(\eta^5\text{-}C_5H_4SiClMe_2)_2TiCl_2$.[99] $[Ti(\eta^5\text{-}C_5Me_4SiMeCl_2)Cl_3]$ and $[Ti(\eta^5\text{-}C_5Me_4SiMeHCl)Cl_3]$, are prepared by the treatment of $TiCl_4$ with the trimethylsilyl derivatives of the corresponding cyclopentadienes. Methylation of these complexes with MeMgCl gives the corresponding Me complexes $[Ti(\eta^5\text{-}C_5Me_4SiMe_2R)XMe_2]$ (R = H, Cl; Me; R = X = Me).[100]

$K[C_5Me_4\text{-P-}t\text{-Bu}(NEt_2)]$ and $K[t\text{-BuC}_5H_3\text{-P-}t\text{-Bu}(NEt_2)]$ are efficiently transmetalated by Me_3SnCl, subsequent reaction with $TiCl_4(L)_2$ (L = THF, tetrahydrothiophene, Me_3P) gives the half-sandwich complexes (*see Half-sandwich Complexes*) $[Me_4Cp\text{-P-}t\text{-Bu}(NEt_2)]TiCl_3$ and $[t\text{- BuC}_5H_3\text{-P-}t\text{-Bu}(NEt_2)]TiCl_3$, respectively in moderate yields. Treatment of $[t\text{- BuC}_5H_3\text{-P-}t\text{-Bu(Cl)}]$ with $TiCl_4$ in the presence of Et_3N at low temperature gives the half-sandwich complex $[t\text{-BuC}_5H_3\text{-P-}t\text{-Bu(Cl)}]TiCl_3$ quantitative yield.[101]

9.3 Annulated Cyclopentadienyl Ligands

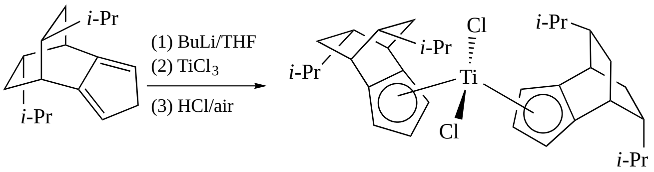
Considerable effort has been directed to the stereoselective synthesis of annulated cyclopentadienyl complexes of the group 4 transition metals. C_1 asymmetric and C_2 symmetric annulated cyclopentadienyl ligands have been used to prepare chiral organotitanium complexes, which are now being actively studied as catalysts for asymmetric synthesis and olefin polymerization (*see* ***Asymmetric Synthesis by Homogeneous Catalysis***).

Halterman and Vollhardt[102] and Paquette and coworkers[103] have prepared bis(annulated cyclopentadienyl)titanium complexes, and have separated (**25**) and (**26**) when starting from the chiral natural product camphor. They have shown that use of complex (**25**) as a catalyst precursor for asymmetric hydrogenation of 2-phenylbutene forms 2-phenylbutane quantitatively at up to 34% *ee*.

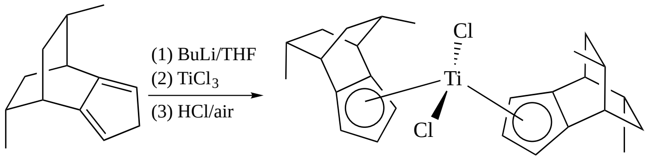


(**25**) (**26**)

The C_2 symmetric chiral cyclopentadienes (+)-(1R, 7R, 8R, 10R)-8,10-diisopropyltricyclo[5.2.2.0^{2,6}]undeca-2,5-diene (Me_2-BCO-CpH) and (−)-(1S, 7S, 8R,10R)-8,10-dimethyltricyclo[5.2.2.0^{2,6}]undeca-2,5-diene (BCO-CpH) have been metalated and treated with $TiCl_3$, followed by oxidative work-up, to give enantiomerically pure $(Me_2\text{-BCO-Cp})_2TiCl_2$ and $(BCO\text{-Cp})_2TiCl_2$ in 45 and 55% yield, respectively (equations 31 and 32).[104]



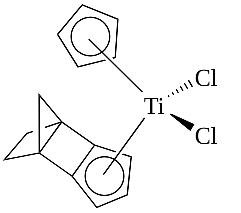
(31)



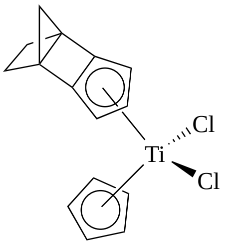
(32)

Paquette and coworkers have extensively studied the complexation of C_1 symmetric annulated cyclopentadienides with $TiCl_3$, $TiCl_4$, $CpTiCl_3$, and Cp^*TiCl_3 to give the corresponding complexes. Reaction of lithium isodicyclopentadienide (isodiCpLi) with $CpTiCl_3$, $MeCpTiCl_3$, or Cp^*TiCl_3 proceeds under conditions which are kinetically controlled and take place with complete bifacial stereoselectivity depending upon temperature (with endo complexation occurring at −78 °C and exo complexation occurring at room temperature and above).[105] For example, treatment of $CpTiCl_3$ with isodiCpLi at −78 °C gives (**27**), while the same reaction at room temperature gives (**28**). Paquette and coworkers have prepared each of the three possible diisodicyclopentadienyltitanium dichlorides with a high degree of selectivity. The pronounced influence

of reaction temperature on stereoselectivity is further demonstrated by reacting $TiCl_3$ with the isodiCpLi at 25 °C, followed by oxidative work-up, to obtain the exo,exo isomer, or reacting at −64 °C for the endo,endo isomer. In the exo,exo isomer, the cyclopentadienyl rings are almost eclipsed and the norbornane substituents on the rings are oriented away from each other. The Cl–Ti–Cl and ring centroid−Ti−ring centroid angles of 92.94 and 131.0°, respectively, are within the normal range for Cp_2TiCl_2 complexes (see Table 1). *Exo*-isodiCp$TiCl_3$ was synthesized specifically by treatment of $TiCl_4$ with isodiCp$SiMe_3$. Reaction of *exo*-isodiCp$TiCl_3$ with isodiCpLi at −78 °C leads to the endo,exo isomer selectively.[106,107] The three diastereomeric $(isodiCp)_2TiCl_2$ complexes were prepared. Treatment of the exo,exo $(isodiCp)_2TiCl_2$ with MeLi gives $(isodiCp)_2TiClMe_2$. However, treatment of the endo,endo and endo,exo $(isodiCp)_2TiCl_2$ does not lead to stable products under analogous conditions. Treatment of all three $(isodiCp)_2TiCl_2$ isomers with C_6F_5Li gives the corresponding air stable, $(isodiCp)_2Ti(C_6F_5)Cl$.[108] Reduction of exo,exo $(isodiCp)_2TiCl_2$ gives exo,exo $(isodiCp)_2TiCl$, or in the presence of BMTA $(isodiCp)_2TiCl(Me_3SiC{\equiv}CSiMe_3)$.[109]

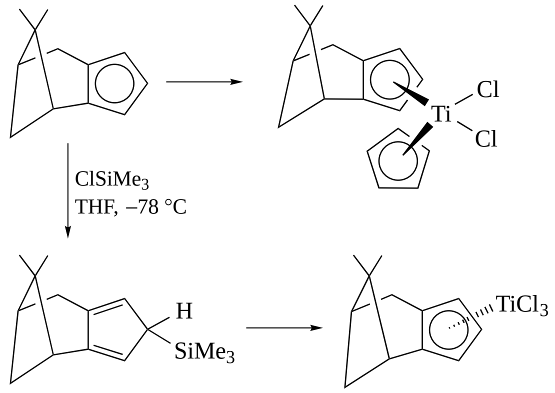


(**27**)



(**28**)

Paquette has shown that lithium salts of annulated cyclopentadienides coordinate to a metal atom predominantly or exclusively from a single π surface. Paquette has proposed that this facial selectivity is controlled by the locus of the lithium counterion and the state of aggregation of the reactive organometallic species. Recently, Paquette and Sivik have shown that it is possible to take advantage of the high stereoselectivity of *C*-silylation of annulated cyclopentadienides and the strict inversion of configuration that occurs during electrophilic condensation of these silanes with titanium chloride reagents, as shown in Scheme 7.[110]

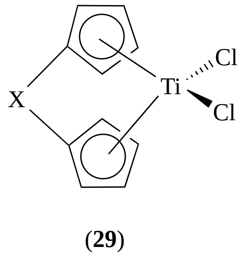


Scheme 7

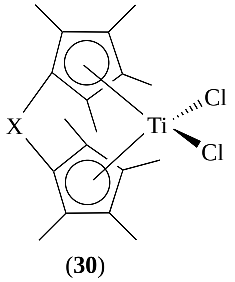
9.4 *ansa*-Metallocenes

There has been considerable interest in the synthesis of *ansa*-metallocenes of the group 4 transition metals because of their potential use as reagents or catalysts in organic synthesis. The bridging of the two rings in an *ansa*-metallocene can, if the bridge is short enough, cause significant changes in the ring centroid−Ti−ring centroid angle and give a more open coordination geometry. In addition, the bridging of the two rings can 'lock' substituents on the two rings relative to each other.

Many *ansa*-metallocene complexes of titanium are best prepared by treatment of $TiCl_3$ or $TiCl_3THF_3$ with the dianion of a bridged dicyclopentadienyl ligand, followed by an oxidative work-up. Simple *ansa*-metallocenes (**29**) have been prepared with hydrocarbon bridges ($CH_2CH_2CH_2$,[111] CMe_2CMe_2,[112] CMe_2[113]) rigid hydrocarbon bridges, $C(=CH_2)C=CNR_2$,[114] and hetero atom containing bridges, $SiMe_2$,[115] $Me_2Si(CH_2)_3SiMe_2$,[116] $Me_2SiN(R)SiMe_2$,[117] $Me_2SiOSiMe_2$.[99] *ansa*-metallocenes incorporating permethylated cyclopentadienyl rings (**30**) have been prepared with CMe_2[118] $GeMe_2$,[119,120] PPh[121] bridges and a smaller number of *ansa*-metallocene have been prepared the incorporate one Cp and one Cp* bridged by $SiMe_2$,[122] $GeMe_2$[122,123] Treatment of the lithium slats 1,2-bis(1-indenyl)benzenes with $TiCl_3$ followed by oxidation gives the phenyl-bridged *ansa*-bis(indenyl)titanium dichloride in good yield.[124] Several *ansa*-metallocenes bridged at the 7,7′-positions of the indenyl moiety have been prepared.[125]



(**29**)



(**30**)

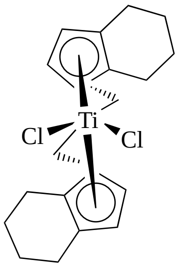
A small number of alkene-linked *ansa*-metallocenes are known for titanium. Thus reaction of $Na_2(C_5H_4)C(R){=}C(R)(C_5H_4)$ with $TiCl_4$ or $TiCl_3THF_3$ affords the corresponding alkene-bridged *ansa*-titanocene dichlorides. There is no indication of interaction between the alkene π-system and the titanium center.[126]

ansa-Metallocenes of titanium dichloride undergo many of the same reactions as the unbridged analogs. For example, reduction of $(Me_2SiCp_2)TiCl_2$ with Na/Hg gives the corresponding dimeric titanium(III) *ansa*-metallocene $[(Me_2SiCp_2)TiCl]_2$. Treatment of $[(Me_2SiCp_2)TiCl]_2$ with PMe_2Ph or reduction of $(Me_2SiCp_2)TiCl_2$ with Na/Hg in the presence of PMe_2Ph forms $(Me_2SiCp_2)TiCl(PMe_2Ph)$. Alkylation of $(Me_2SiCp_2)TiCl(PMe_2Ph)$ leads to the titanium(III) alkyls $[(Me_2SiCp_2)TiR(PMe_2Ph)]$.[127]

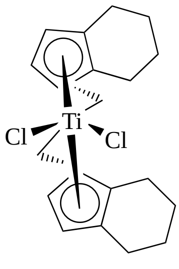
ansa-Metallocenes have been prepared in which the two cyclopentadienyl rings are differently substituted. For example, treatment of $TiCl_4$ with the unsymmetrical dianions $(C_5H_4)CHR(Cp')^{2-}$ (R = Me, CMe_3; Cp′ = Cp, indenyl, fluorenyl) affords the corresponding *ansa*-metallocenes $[(C_5H_4)CHR(Cp')]TiCl_2$.[128]

ansa-Metallocenes and, in particular, chiral *ansa*-metallocenes have generated considerable interest because of their use as reagents and catalysts to carry out stereoselective polymerization, hydrogenation, alkylation of ketones, and aminoalkylation of alkynes.

Addition of a substituent, such as an alkyl group or a fused ring, to the cyclopentadienyl group in *ansa*-metallocenes leads to the possibility of racemic and meso complexes. For example, ethylenebis(1-indenyl) and ethylenebis(tetrahydro-1-indenyl) complexes prepared by Brintzinger and coworkers have been isolated in both the racemic form (**31**) and meso form (**32**).[129–131]



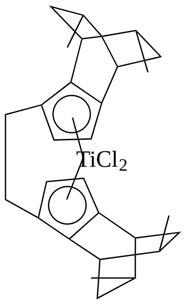
(**31**) racemic



(**32**) *meso*

Titanium *ansa*-metallocenes incorporating a $SiMe_2$ or CMe_2CMe_2 bridge and a Ph or 1-naphthyl substituent in one β-position of each Cp ring have been prepared as a mixture of racemic and meso complexes.[132] Synthesis of the racemic and meso diastereomers of disubstituted tetramethylethanediyl-bridged titanocene derivatives $Me_4C_2(1\text{-}C_5H_3\text{-}3\text{-}R)_2TiCl_2$ (R = t-Bu, $SiMe_3$, i-Pr, α,α-dimethylbenzyl, or 1-phenylcyclohexyl) is accomplished by reductive coupling of the appropriately substituted 6,6-dimethylfulvenes with Mg/CCl_4 and reaction of the resulting di-Grignard reagents with $TiCl_3\cdot 3THF$, followed by oxidative work-up.[133]

Several titanium *ansa*-metallocenes have been prepared which incorporate chiral centers in the backbone as a way of influencing the stereoselectivity of *ansa*-metallocene formation. Chiral backbones that have been prepared and used in this fashion include $(1R,2R)$-*trans*-1,2-bis(1-indenylmethyl)cyclopentane,[134] (S,S)-2,3-butylene-1,1′-bis(indenyl),[135] and 2,3-bis[3-(1,1-dimethylethyl)-1,3-cyclopentadien-5-yl]-2,3-dimethylbutane.[136] Chiral *ansa*-metallocene such as $(\eta^5{:}\eta^5\text{-}C_5Me_4SiMe_2C_5H_3R^*)TiCl_2$ (R^* = menthyl, neomenthyl) incorporating a chiral group on one of the Cp rings have been prepared.[137] Chiral *ansa* complexes utilizing annulated cyclopentadienyl ligands have also been prepared.[138] Chiral *ansa*-metallocene complexes based upon biphenyl and binaphthyl bridges have been prepared.[139–144] The chiral annulated *ansa*-metallocenes such as (+)-[ethylene-1,2-bis[η^5-$(1R,7R,8R,10R)$-8,10-dimethyltricyclo[5.2.2.02,6]-2,5-undecadien-4-yl]]titanium dichloride (**33**) has been prepared.[145]



(**33**)

Collins and coworkers have developed two synthetic routes for the preparation of chiral [1,2-ethylenebis(η^5-3-alkylcyclopentadienyl)]titanium dichlorides (R = Me, Et, i-Pr, t-Bu) in 80–85% yields as a mixture of racemic and meso-titanocene dichlorides.[146] In more recent work, the addition of a methyl group to the cyclopentadienyl rings has allowed Collins and coworkers to prepare a series of [1,2-ethylene-1,1′-bis(4-R-2-methylcyclopentadienyl)] titanium dichlorides (R = Me, i-Pr, t-Bu) stereoselectively to give the racemic isomers.[147]

Biscyclopentadienly incorporating reactive functional groups on each Cp ring have been utilized to prepare *ansa*-metallocenes. Thus, treatment of $(\eta^5\text{-}C_5H_4SiClMe_2)_2TiCl_2$ with a stoichiometric amount of water with selective hydrolysis of the Si–Cl bonds to gives the tetramethyldisiloxane-bridged dicyclopentadienyl complexes $[(\eta^5\text{-}C_5H_4)SiMe_2OSiMe_2(\eta^5\text{-}C_5H_4)]TiCl_2$.[99] In an analogous manner, treatment of $(Cp\text{-}P\text{-}t\text{-}BuCl)_2CMe_2$ with one equivalent of $TiCl_4$ in the presence of Et_3N gives complex $[(Cp\text{-}P\text{-}t\text{-}BuCl)_2CMe_2]TiCl_2$.[101]

Cationic *ansa*-(η^5-cyclopentadienyl)(η^6-arene) titanium derivatives have been prepared with both Cp and Cp* derivatives. Treatment of $TiCl_4$ with $C_5H_4(R)SiMe_3$ (R = CMe_2Ph, CMe_2CH_2Ph, $CHPh_2$) gives the corresponding half-sandwich complexes $(\eta^5\text{-}C_5H_4R)TiCl_3$ Alkylation of $(\eta^5\text{-}C_5H_4R)TiCl_3$ gives $(\eta^5\text{-}C_5H_4R)TiMe_3$ which upon treatment with $[Ph_3C]^+$ $[B(C_6F_5)_4]^-$ in dichloromethane at low temperature gives the cationic $[(\eta^5\text{-}C_5H_4R)TiMe_2]^+$ *ansa* complexes; with π-coordination of the Ph ring with one-

and two-carbon bridges.[148] An analogous permethyl complex $[(\eta^5,\eta^6\text{-}C_5H_4CMe_2Ar)TiMe_2][MeB(C_6F_5)_3]$ is prepared by treatment of $(\eta^5\text{-}C_5H_4CMe_2Ar)TiMe_3$ (Ar = 3, 5-$Me_2C_6H_3$) with $B(C_6F_5)_3$. Treatment of $(\eta^5\text{-}C_5H_4CMe_2Ar)TiMe_3$ with $B(C_6F_5)_3$ in bromobenzene give the unusual dimeric Ti(III) dicationic *ansa*-metallocene, $\{[(\eta^5,\eta^6\text{-}C_5H_4CMe_2Ar)Ti(\mu\text{-}Br)]_2\}[B(C_6F_5)_4]_2$.[149]

9.5 Cationic Bis(cyclopentadienyl)titanium Complexes

Since cationic titanium complexes have been proposed as intermediates in alkene polymerization by soluble Cp_2TiCl_2/AlR_3-based Ziegler–Natta catalysts (*see Ziegler–Natta Catalysts*), there has been considerable interest in the synthesis and reactivity of cationic titanium complexes (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***).

The reaction of Cp_2TiCl_2 with $AgAsF_6$ or the reaction of Cp_2TiF_2 with AsF_5, in SO_2, gives $Cp_2Ti(AsF_6)_2$ in quantitative yields.[150] The reaction of $Cp_2Ti(AsF_6)_2$ in SO_2 with HCN, ICN, $AsMe_3$, or As_2Me_4 affords the new cationic titanocene complexes $[Cp_2Ti(HCN)_2][AsF_6]_2$, $[Cp_2Ti(ICN)_2][AsF_6]_2$, $[Cp_2Ti(AsMe_3)_2][AsF_6]_2$, and $[Cp_2Ti(As_2Me_4)]_2[AsF_6]_4$.[151] Treatment of Cp_2TiCl_2 with 2 equivalent of $AgSbF_6$ in SO_2 gives $Cp_2Ti(SbF_6)_2$ and AgCl quantitatively.[152]

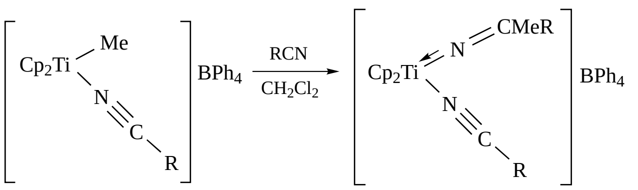
Treatment of $Cp_2Ti(O_2CPh)_2$ with H_2SO_4 or H_2SeO_4 in Ac_2O forms $[Cp_2Ti(H_2O)_2]SO_4$ and Cp_2TiSeO_4 in 85 and 78% yield, respectively. Reaction of Cp_2TiCl_2 with 4 M H_2SO_4 and $K_2Cr_2O_7$ gives $[Cp_2Ti(H_2O)_2]Cr_2O_7$ in 50% yield. Cp_2TiSeO_4 and $[Cp_2Ti(H_2O)_2]Cr_2O_7$ are found to be explosive when heated or mechanically agitated.[153]

$[Cp^*_2Ti(DMF)Cl]CF_3SO_3$ and $[Cp^*_2Ti(DMF)_2](CF_3SO_3)_2$ have been prepared by reaction of $Cp^*_2TiCl_2$ with CF_3SO_3Ag in DMF. The structures of $[Cp^*_2Ti(DMF)Cl]CF_3SO_3$ and $[Cp^*_2Ti(DMF)_2](CF_3SO_3)_2$ have been determined by X-ray diffraction, and the titanium atom in each of these complexes was found to have the expected, approximately tetrahedral, coordination geometry typical for $Cp^*_2Ti^{IV}$ complexes.[154]

The reaction of $Cp_2Ti(CF_3SO_3)_2$ with bipy or phen forms $[Cp_2Ti(bipy)](CF_3SO_3)_2$ and $[Cp_2Ti(phen)](CF_3SO_3)_2$, respectively. An X-ray structure determination indicates that the Ti atoms are to a first approximation tetrahedrally coordinated, and the atoms of the bipy or phen chelate ligands are nearly coplanar.[155]

Reaction of Cp_2TiCl_2 with Zn in the presence of MeCN gives $[Cp_2Ti(MeCN)_2]_2[ZnCl_4]$. Treatment of $[Cp_2Ti(MeCN)_2][BPh_4]$ with PMe_3 in a stepwise fashion forms $[Cp_2Ti(MeCN)(PMe_3)][BPh_4]$ initially, and then $[Cp_2Ti(PMe_3)_2][BPh_4]$ upon addition of excess PMe_3. Similar reaction of $[Cp_2Ti(MeCN)_2][BPh_4]$ with excess PEt_3 gives only the monosubstitution product $[Cp_2Ti(MeCN)(PEt_3)][BPh_4]$. PCy_3 and PPh_3 fail to react with $[Cp_2Ti(MeCN)_2][BPh_4]$.[156]

Nitrile complexes of the type $[Cp_2TiMe(N{\equiv}CR)]BPh_4$ (R = Me, Pr, *t*-Bu, Ph) react with excess nitrile in CH_2Cl_2 at room temperature to give azaalkenylidine complexes, $[Cp_2Ti(N{=}CMeR)(N{\equiv}CR)]BPh_4$, in quantitative yield by migratory insertion (*see Migratory Insertion*) of nitrile into the Ti–Me bond (equation 33). The indenyl complexes $[Ind_2Me(N{\equiv}CR)]BPh_4$ are more reactive with nitriles than are the corresponding cyclopentadienyl complexes $[Cp_2TiMe(RCN)]BPh_4$. The structure of $[(C_9H_7)_2Ti(NCMePh)(NCPh)]BPh_4$ has been determined by X-ray crystallography. The Ti–azavinylidene arrangement is linear, with a short Ti–N double bond; the Me and Ph substituents adopt a Me-outside conformation in the plane bisecting the indenyl–Ti–indenyl angle. The indenyl ring centroid–titanium–indenyl ring centroid angle is 135.8(6)°.[157]



R = Me, Ph, *t*-Bu, *n*-Pr

(33)

$[Cp_2TiMe(L)]BPh_4$ (L = MeCN, PrCN, *t*-BuCN, PhCN, Me_3P, Me_2PPh, $MePPh_2$, Bu_3P, py) have been prepared in high yields by treating $Cp_2TiMeCl$ with L and $NaBPh_4$ in polar solvents (equation 34). In a similar manner, treatment of $Ind_2TiMeCl$ with L (L = MeCN, PrCN, *t*-BuCN, PhCN, Me_3P, Me_2PPh) and $NaBPh_4$ gives the corresponding complexes $[Ind_2TiMe(L)]BPh_4$. The nitrile complexes readily undergo substitution with pyridine or PMe_3, but fail to react with $PhC{\equiv}CR$ (R = $SiMe_3$, Me, Ph). Treatment of $[Cp_2TiMe(MeCN)]BPh_4$ with 1 atm of CO forms the η^2-acyl complex $[Cp_2Ti(\eta^2\text{-}COMe)(MeCN)]BPh_4$ in which the nitrile ligand has been retained. Addition of *t*-BuNC to $[Cp_2TiMe(MeCN)]BPh_4$ in acetonitrile gives $[Cp_2Ti(\eta^2\text{-}C(Me){=}N\text{-}t\text{-}Bu)(C{\equiv}N\text{-}t\text{-}Bu)(MeCN)]BPh_4$.[158]

$$Cp_2TiMeCl + L + NaBPh_4 \longrightarrow [Cp_2TiMe(L)]BPh_4 + NaCl \quad (34)$$

$$L = MeCN, PrCN, t\text{-}BuCN, Me_3P, Me_2PPh, MePPh_2, Bu_3P, Py$$

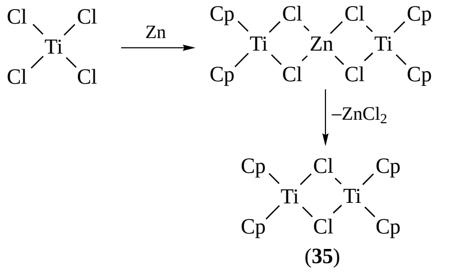
Reaction of Cp_2TiMe_2 and Ind_2TiMe_2 with $(PhNMe_2H)BPh_4$ or $(Bu_3NH)BPh_4$ in CD_2Cl_2 forms the corresponding base-free cationic 14-electron alkyltitanium complexes $[Cp_2TiMe]BPh_4$ and $[Ind_2TiMe]BPh_4$. Treatment of $[Ind_2TiMe]BPh_4$ with Et_2O forms black crystals of $[Ind_2TiMe(OEt_2)]BPh_4$, whereas reaction of $[Cp_2TiMe]BPh_4$ with MeCN yields $[Cp_2TiMe(NCMe)]BPh_4$. $[Cp_2TiMe]BPh_4$ and $[Ind_2TiMe]BPh_4$ catalytically polymerize ethylene.[159] The oxidation of Cp^*_2TiMe with $AgBPh_4$ in THF gives $[Cp^*_2TiMe(THF)]BPh_4$.[160]

The reaction of $CpTiCl_3$ with $AgAsF_6$ and $AgSbF_6$ in SO_2 at −50 °C forms $CpTi(AsF_6)_3{\cdot}SO_2$ and $CpTi(SbF_6)_3{\cdot}SO_2$.

$CpTi(AsF_6)_3{\cdot}SO_2$ and $CpTi(SbF_6)_3{\cdot}SO_2$ are Lewis acid adducts of $CpTiF_3$. $CpTi(AsF_6)_3{\cdot}SO_2$ and $CpTi(SbF_6)_3{\cdot}SO_2$ decompose in solution at room temperature and slowly at $-50\,°C$, but are nonexistent in the solid state.[161]

10 CYCLOPENTADIENYL COMPLEXES OF TITANIUM(III)

Dang and Geise have reviewed the reduction of Cp_2TiCl_2 to $[Cp_2Ti(\mu\text{-}Cl)]_2$. This reduction has been carried out using Al, K, Na, Zn, or lithium and sodium amalgams.[162] Alternatively, treatment of Cp_2TiCl_2 with $LiAlH_4$, $NaBH_4$, MgH_2, bulky Grignard reagents (*see Grignard Reagents*), and organoaluminum and organolithium reagents also leads to Ti^{III} species. Electrochemical and photochemical procedures to produce Ti^{III} have also been investigated.[163] In the reduction of Cp_2TiCl_2 with Zn the intermediate $(Cp_2Ti(\mu\text{-}Cl)_2)_2Zn$ has been isolated and characterized (equation 35).[164] The reduction of Cp_2TiCl_2 with Mg in THF in the presence of P_4 leads to $(Cp_2Ti(\mu\text{-}Cl)_2)_2Mg(THF)_2$ and $(Cp_2Ti(\mu\text{-}Cl)_2Mg(THF)_2(\mu\text{-}Cl)_2)_2$, which have been characterized also. Reaction of $(Cp_2Ti(\mu\text{-}Cl)_2)_2Mg(THF)_2$ and $(Cp_2Ti(\mu\text{-}Cl)_2Mg(THF)_2(\mu\text{-}Cl)_2)_2$ with PMe_3 forms $Cp_2Ti(PMe_3)Cl$, which upon reduction with Mg in the presence of PMe_3 gives $Cp_2Ti(PMe_3)_2$.[165]



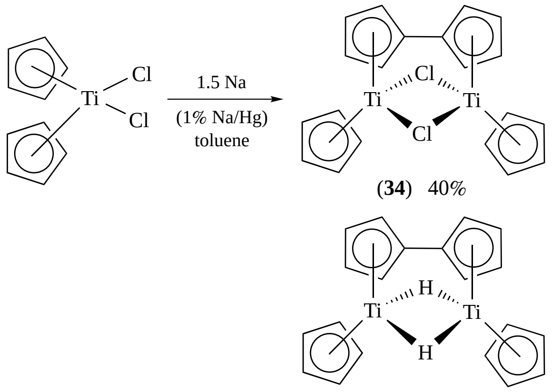
(35)

(35)

Treatment of Cp_2TiCl_2 and $CpTiCl_3$ with $[Li[\mu\text{-}P(SiMe_3)_2](THF)_2]_2$ in THF at room temperature leads to the reduced species $Cp_2TiCl(THF)$ and $CpTiCl_2(THF)$, respectively, in high yields.[166]

Reaction of $Cp_2Ti(CO)_2$ with Cp_2TiBr_2 or Cp_2TiCl_2 in C_6H_6 forms $[Cp_2TiBr]_2$ and $[Cp_2TiCl]_2$, respectively, in 90% yield.[167] An ESR study of the reaction solution of the reaction of $Cp_2Ti(CO)_2$ with Cp_2TiBr_2 indicates the presence of $[Cp_2TiBr]$ in equilibrium with the dimer, as well as the presence of the unstable intermediate $[Cp_2Ti(CO)Br]$.[168]

Reduction of Cp_2TiCl_2 with 1.5 equivalent of Na(Hg) gives a mixture of the dinuclear fulvalene complexes $[CpTi(\mu\text{-}Cl)]_2(\mu\text{-}\eta^5{:}\eta^5\text{-}C_{10}H_8)$ (**34**) and $[CpTi(\mu\text{-}H)]_2(\mu\text{-}\eta^5{:}\eta^5\text{-}C_{10}H_8)$ ('titanocene') (**35**) in 40% yield each (equation 36). Both compounds contain Ti^{III} species, which undergo quick oxidation upon exposure to air, yielding $[CpTiCl]_2(\mu\text{-}O)(\mu\text{-}\eta^5{:}\eta^5\text{-}C_{10}H_8)$. Reduction of $[CpTi(\mu\text{-}Cl)]_2(\mu\text{-}\eta^5{:}\eta^5\text{-}C_{10}H_8)$ with $LiBHEt_3$ gives $[CpTi(\mu\text{-}H)]_2(\mu\text{-}\eta^5{:}\eta^5\text{-}C_{10}H_8)$.[169]



(**34**) 40%

(**35**) 40%

(36)

The chemistry of the Ti–C bond in Cp_2TiR has been reviewed.[170] The paramagnetic, 15-electron, d^1 titanium complexes Cp^*_2TiR (R = Me, Et, Pr, CH_2-*t*-Bu, CH_2Ph, η^3-C_3H_5, η^3-C_4H_7, $CH{=}CH_2$, $C{\equiv}CMe$, Ph) have been prepared by the reaction of Cp^*_2TiCl with the corresponding anion (equation 37). The ethyl and *n*-propyl complexes, Cp^*_2TiEt and Cp^*_2TiPr, have also been prepared by the addition of ethylene or propylene, respectively, to Cp^*_2TiH (equation 38). Treatment of Cp^*_2TiR with CO at approx. $-70\,°C$ in pentane or toluene leads to the formation of the corresponding η^2-acyl complexes, which are thermally stable up to $0\,°C$ (equation 39). Above $0\,°C$, these acyl complexes are unstable, leading to $Cp^*_2Ti(CO)_2$ and unidentified paramagnetic products. Treatment of Cp^*_2TiMe with *t*-BuN≡C gives the corresponding η^2-iminoacyl complex $Cp^*_2Ti(CMe{=}N\text{-}t\text{-}Bu)$. Reaction of CO_2 with Cp^*_2TiR, in which the R group does not contain a β-hydrogen, gives the corresponding carboxylate complexes $Cp^*_2Ti(\eta^2\text{-}O_2CR)$. However, treatment of alkyl complexes Cp^*_2TiR, in which the R group bears a β-hydrogen, with CO_2 forms the formate complex $Cp^*_2Ti(\eta^2\text{-}O_2CH)$ as the dominant product (equation 40). This formate complex is produced by β-H transfer to the incoming CO_2 and extrusion of an alkene. These Cp^*_2TiR complexes are surprisingly unreactive toward $CH_2{=}CH_2$, with Cp^*_2TiMe recovered unchanged even after treatment with 10 atm of $CH_2{=}CH_2$ at 50 °C for 100 h.[171]

$$Cp^*_2TiCl + MR \longrightarrow Cp^*_2TiR + MCl \quad (37)$$

$$Cp^*_2TiH + H_2C{=}CHR \longrightarrow Cp^*_2TiCH_2CH_2R \quad R = H, Me \quad (38)$$

$$Cp^*_2TiR + CO \longrightarrow Cp^*_2Ti(\eta^2\text{-}COR) \quad (39)$$

$$Cp^*_2TiR + CO_2 \longrightarrow Cp^*_2Ti(\eta^2\text{-}O_2CR)$$
$$\text{or } Cp^*_2Ti(\eta^2\text{-}O_2CH) \text{ if R contains a } \beta\text{-H} \quad (40)$$

Further studies have been carried out on Cp^*_2TiMe and Cp^*_2TiEt. Reaction of Cp^*_2TiMe and Cp^*_2TiEt with HO_2C-*i*-Pr, HOEt, or HC≡CMe forms $Cp^*_2TiO_2C$-*i*-Pr, Cp^*_2TiOEt, and $Cp^*_2TiC{\equiv}CMe$, respectively, and RH. Reaction of Cp^*_2TiMe

with neat MeC≡CMe gives $Cp^*_2TiC(Me){=}CMe_2$ via migratory insertion (*see Migratory Insertion*); however, PhC≡CPh and $Me_3SiC{\equiv}CSiMe_3$ are unreactive toward Cp^*_2TiMe.

The β-H atom of the ethyl group in Cp^*_2TiEt exhibits agostic bonding (*see Agostic Bonding*) with the titanium. Cp^*_2TiEt reacts with t-BuC≡N, $Me_2C{=}O$, and alkynes via a Cp^*_2TiH intermediate to give products of migratory insertion into the Ti–H bond of Cp^*_2TiH.[172]

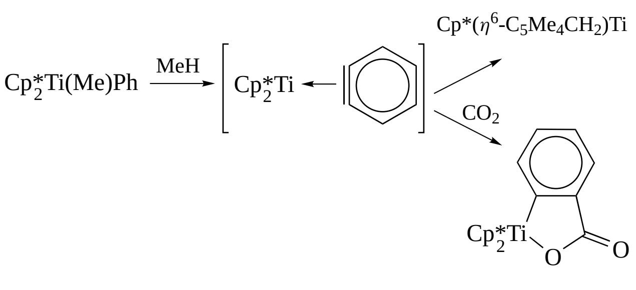
Oxidative alkylation of Cp^*_2TiX (X = OMe, Cl, N=CH-t-Bu) and Cp^*_2TiMe by $CdMe_2$ or $ZnMe_2$ forms the diamagnetic complexes $Cp^*_2Ti(Me)X$ and $Cp^*_2TiMe_2$, respectively, and cadmium or zinc metal (equation 41). Oxidative alkylation of Cp^*_2TiR (R = Et, $CH{=}CH_2$, Ph) with $CdMe_2$ or $ZnMe_2$ forms a statistical mixture of $Cp^*_2Ti(Me)R$, $Cp^*_2TiMe_2$, and $Cp^*_2TiR_2$.[173] Oxidation of Cp^*_2TiR with $PbCl_2$ gives $Cp^*_2Ti(R)Cl$ (R = Me, Et, Pr, $CH{=}CH_2$, Ph, OPr) in good yield (equation 42).

$$Cp^*_2TiX + CdMe_2 \text{ or } ZnMe_2 \longrightarrow Cp^*_2TiXMe \quad (41)$$

$$Cp^*_2TiR + PbCl_2 \longrightarrow Cp^*_2Ti(R)Cl \quad (42)$$

Thermolysis of $Cp^*_2Ti(Me)CH{=}CH_2$, prepared by the reaction of $Cp^*_2Ti(CH{=}CH_2)Cl$ with MeLi, gives $Cp^*(\eta^6\text{-}C_6Me_4CH_2)TiCH{=}CH_2$ via a vinylidene intermediate, $Cp^*_2Ti{=}C{=}CH_2$, formed by a rate-limiting vinylic α-hydrogen abstraction. $Cp^*_2Ti(Me)Ph$ undergoes thermally induced decomposition to give $Cp^*(\eta^6\text{-}C_6Me_4CH_2)TiPh$ and methane. This thermolysis occurs via *ortho*-hydrogen abstraction from the phenyl ligand, giving an o-phenylene intermediate, which can be trapped by CO_2 to yield the titanacycle, as shown in Scheme 8.[18]

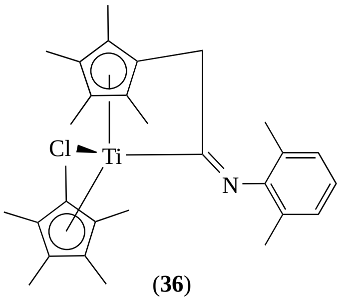
Thermolysis of Cp^*_2TiR (R = Me, Et, n-Pr, C_2H_3, CH_2-t-Bu, Ph) forms $Cp^*(\eta^6\text{-}C_5Me_4CH_2)Ti$ in high yield as the exclusive organometallic product, along with RH (equation 43). Kinetic measurements and deuterium-labeling studies show that this decomposition is catalyzed by Cp^*_2TiH, which is formed either by β-hydrogen elimination (*see β-Hydride Elimination*) from a titanium alkyl $Cp^*_2TiCH_2CH_2R$ at low temperature or by hydrogenolysis of Cp^*_2TiR or $Cp^*(\eta^6\text{-}C_5Me_4CH_2)Ti$, deriving dihydrogen by elimination from $Cp^*(\eta^6\text{-}C_5Me_4CH_2)Ti$ at elevated temperatures. Permethyltitanocene, Cp^*_2Ti, is found not to be an intermediate in these thermolysis reactions.[174]



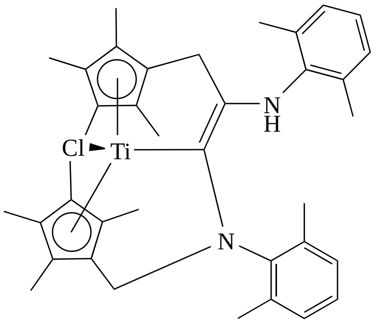
Scheme 8

$$Cp^*_2TiR \xrightarrow{\Delta} Cp^*(\eta^6\text{-}C_5Me_4CH_2)Ti + RH \quad (43)$$

Treatment of $Cp^*(\eta^6\text{-}C_5Me_4CH_2)Ti$ with $PbCl_2$ gives $Cp^*(\eta^6\text{-}C_5Me_4CH_2)TiCl$, which reacts with C≡N(2,6-$Me_2C_6H_3$) to give the η^1-iminoacyl complex (**36**). Reaction of iminoacyl (**28**) with a second equivalent of isonitrile gives (**37**).[175]



(**36**)



(**37**)

The titanocene(III) complexes $Cp_2TiX(PMe_3)$ (X = F, Cl, Br, I, Me, SMe) are readily prepared by *comproportionation* reactions of $Cp_2Ti(PMe_3)_2$ and Cp_2TiX_2. The products are characterized by EPR spectroscopy.[176]

11 CYCLOPENTADIENYL COMPLEXES OF TITANIUM(II)

Bis-cyclopentadienyltitanium(II) species are unstable 14-electron d^2 species, with one lone-electron pair and two vacant valence orbitals. The reactivity of 'Cp_2Ti' has been compared to carbenes. The interactions between the occupied and unoccupied orbitals can explain why 'Cp_2Ti' reacts with unsaturated compounds to give metallacycles (*see Metallacycle*).

Murry first prepared $Cp_2Ti(CO)_2$ via the high-pressure carbonylation of $Cp_2Ti(\eta^1\text{-}C_5H_5)_2$ (equation 44).[177] The reduction and carbonylation of Cp_2TiCl_2 to give $Cp_2Ti(CO)_2$

was first achieved with Mg in the presence of CO. *Reductive carbonylation* (*see Reductive Carbonylation*) of Cp_2TiCl_2 or $Cp^*_2TiCl_2$ with Mg, activated with $HgCl_2$, and CO in THF affords $Cp_2Ti(CO)_2$ (equation 45) and $Cp^*_2Ti(CO)_2$, respectively, in good yield.[178] In recent years a wide range of ring-substituted biscyclopentadienyl derivatives have been reductively carbonylated. This work has recently been reviewed by Sikora *et al.*[179]

$$Cp_2Ti(\eta^1\text{-}C_5H_5)_2 + CO(\text{high pressure}) \longrightarrow Cp_2Ti(CO)_2 \quad (44)$$

$$Cp_2TiCl_2 + CO \xrightarrow{Mg/HgCl_2} Cp_2Ti(CO)_2 \quad (45)$$

Rausch and coworkers have shown that $Cp_2Ti(CO)_2$ reacts reversibly with PF_3, under irradiation, to give $Cp_2Ti(PF_3)_2$ (equation 46). In contrast, treatment of $Cp_2Ti(CO)_2$ with PEt_3 or PPh_3 gives $Cp_2Ti(CO)PEt_3$ and $Cp_2Ti(CO)PPh_3$, respectively, in good yield (equation 47). $Cp_2Ti(CO)PEt_3$ can serve as a convenient source of $[Cp_2Ti(CO)]$. Thus, treatment of $Cp_2Ti(CO)PEt_3$ with alkynes, RC≡CR (R = Ph, C_6F_5), or alkenes, $RO_2CCH{=}CHCO_2R$ (R = Me, Et), leads to the corresponding alkyne and alkene complexes, $Cp_2Ti(CO)(\eta^2\text{-}RC{\equiv}CR)$ and $Cp_2Ti(CO)(\eta^2\text{-}RO_2CCH{=}CHCO_2R)$, respectively, in good yields (equation 48).[180]

$$Cp_2Ti(CO)_2 \underset{\text{Hexane}}{\overset{h\nu,\ PF_3}{\rightleftharpoons}} Cp_2Ti(CO)PF_3 \underset{\text{Hexane}}{\overset{h\nu,\ PF_3}{\rightleftharpoons}} Cp_2Ti(PF_3)_2 \quad (46)$$

$$Cp_2Ti(CO)_2 + PEt_3 \xrightarrow[\text{hexane}]{h\nu \text{ or } \Delta} Cp_2Ti(CO)PEt_3 \quad (47)$$

$$Cp_2Ti(CO)PEt_3 + PhC{\equiv}CPh \longrightarrow Cp_2Ti(CO)(\eta^2\text{-}PhC{\equiv}CR) \quad (48)$$

Rausch and coworkers have also developed a convenient, high-yield synthesis for $Cp_2Ti(PMe_3)_2$, which has often been referred to as stabilized 'titanocene' (*see Titanocene*), by utilizing Mg to reduce Cp_2TiCl_2 in the presence of PMe_3 (equation 49).[181]

$$Cp_2TiCl_2 + Mg + PMe_3 \longrightarrow Cp_2Ti(PMe_3)_2 \quad (49)$$

The unique phosphine–carbon dioxide complex $Cp_2Ti(CO_2)PMe_3$ is prepared by treatment of $Cp_2Ti(PMe_3)_2$ with dry CO_2 at −180 °C (equation 50). Slow thermal decomposition of $Cp_2Ti(CO_2)PMe_3$ at room temperature leads principally to $Cp_2Ti(CO)_2$.[182]

$$Cp_2Ti(PMe_3)_2 \xrightarrow[-180\,^\circ C]{CO_2} Cp_2Ti(CO_2)PMe_3 \quad (50)$$

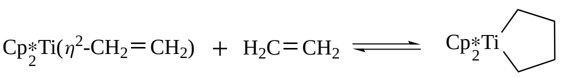
The titanium alkene complex $Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ can be prepared in greater than 80% yield by the Na/Hg reduction of $Cp^*_2TiCl_2$ in toluene under 700 torr of ethylene (equation 51), or in nearly quantitative yield by the addition of ethylene to $[Cp^*_2Ti]_2(\mu\text{-}N_2)$ (equation 52).[183] Alternatively, treatment of $Cp^*_2TiEtCl$ with MeLi, KCH_2Ph, or $LiCH{=}CH_2$ leads to $Cp^*_2Ti(\eta^2\text{-}C_2H_4)$ in quantitative yield and the formation of RH via β-hydride elimination (*see β-Hydride Elimination*).[39] This titanium ethylene complex undergoes facile displacement of the ethylene by two-electron donors. For example, reaction of $Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ with CO or MeNC leads to quantitative displacement of alkene to give $Cp^*_2Ti(CO)_2$ (equation 53) or the thermally unstable $Cp^*_2Ti(CNMe)_2$, respectively.[183]

$$Cp^*_2TiCl_2 + C_2H_4(700\text{ torr}) \xrightarrow{Na/Hg} Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2) \quad (51)$$

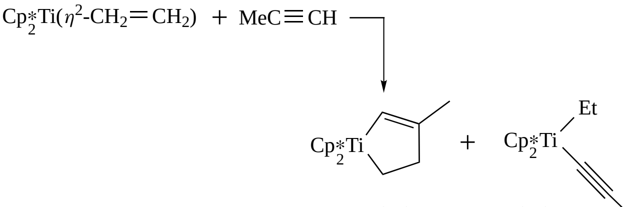
$$[Cp^*_2Ti](\mu\text{-}N_2) + 2C_2H_4 \longrightarrow Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2) \quad (52)$$

$$Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2) + 2CO \longrightarrow Cp^*_2Ti(CO)_2 \quad (53)$$

$Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ undergoes a reversible reaction with $CH_2{=}CH_2$ to give the corresponding unstable titanacyclopentane complex (equation 54). Addition of MeC≡CH to $Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ at −50 °C gives a mixture of metallacycle (*see Metallacycle*) (**38**) and the propynyl ethyl tautomer (**39**) (equation 55), which over several days rearranges to (**38**). Treatment of $Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ with *t*-BuC≡CH affords rapidly and quantitatively the *t*-butylacetylide ethyl complex $Cp_2Ti(Et)(C{\equiv}C\text{-}t\text{-}Bu)$ (**40**). In contrast to this result, reaction of $Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ with 2-butyne over 8 h at 25 °C gives quantitatively the metallacycle $Cp^*_2Ti(C(Me){=}C(Me)CH_2CH_2)$ (equation 56). However, reaction of $Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ with diphenylacetylene yields the alkyne complex $Cp^*_2Ti(\eta^2\text{-}PhC{\equiv}CPh)$ (equation 57). Reaction of $Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ with 1 equivalent of acetonitrile at −50 °C results in quantitative formation of the metallacycloimine complex $Cp^*_2Ti(N{=}C(Me)CH_2CH_2)$, which above −10 °C establishes an equilibrium with its metallacycloenamine tautomer (equation 58). Addition of CO_2 to $Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2)$ at −78 °C gives $Cp^*_2Ti(OC(O)CH_2CH_2)$ (equation 59).[184]

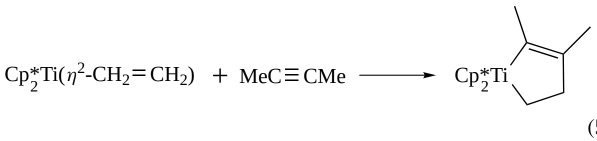


(54)



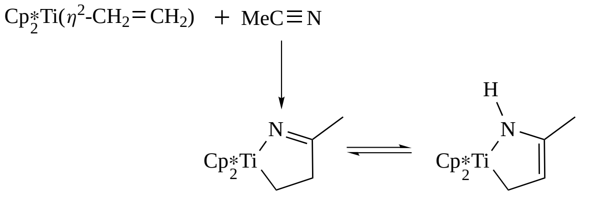
(**38**) (**39**)

(55)

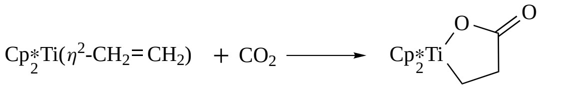


(56)

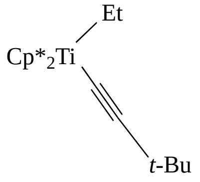
$$Cp^*_2Ti(\eta^2\text{-}CH_2{=}CH_2) + PhC{\equiv}CPh \longrightarrow Cp^*_2Ti(\eta^2\text{-}PhC{\equiv}CPh) \quad (57)$$



(58)



(59)



(**40**)

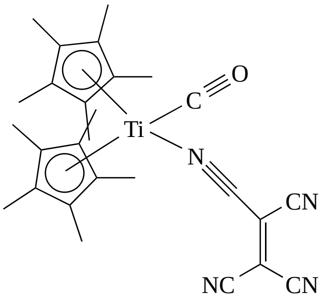
$Cp_2Ti(\eta^2-Me_3SiC{\equiv}CSiMe_3)$, which is readily prepared in large quantities by the reduction of Cp_2TiCl_2 with magnesium in the presence of $Me_3SiC{\equiv}CSiMe_3$, serves as ready sources of The chemistry of $Cp_2Ti(\eta^2-Me_3SiC{\equiv}CSiMe_3)$ has been extensively reviewed by Rosenthal and coworkers.[185,186]

$Cp_2Ti(\eta^2-Me_3SiC{\equiv}CSiMe_3)$ can release $Me_3SiC{\equiv}CSi$ Me_3 quantitatively under mild conditions to give the unstable highly reactive 'Cp_2Ti', which can then react with a wide range of unsaturated molecules. Treatment of $Cp_2Ti(\eta^2-Me_3SiC{\equiv}CSiMe_3)$ with one equivalent of PhC≡CPh leeds to exchange of the acetylene to give $Cp_2Ti(\eta^2$-PhC≡CPh), which on treatment with additional PhC≡CPh gives the corresponding metallocycle Cp_2Ti[C(Ph)=C(Ph)C(Ph)=C(Ph)]. This reaction is very general, working with a wide range of substituted Cp derivatives and a wide range of substituted and disubstituted acetylenes including α,ω-diynes, $RC{\equiv}C(CH_2)_nC{\equiv}CR$ to give bicyclic titanacyclopentadienies.

Thermolysis of $Cp_2Ti(\eta^2-Me_3SiC{\equiv}CSiMe_3)$ in the absence of substrate gives $[CpTi(\mu-H)]_2(\mu-\eta^5:\eta^5-C_{10}H_8)$ (**35**), while thermolysis of $[C_5Me_4(SiMe_3)]_2Ti(\eta^2-Me_3SiC{\equiv}CSiMe_3)$ gives on dissociation of $Me_3SiC{\equiv}CSiMe_3$ in the absence of other ligands, stable, free $[C_5Me_4(SiMe_3)]_2Ti$, which cannot be prepared directly by the reduction of $[C_5Me_4(SiMe_3)]_2$ $TiCl_2$.

Reaction of $Cp_2Ti(\eta^2-Me_3SiC{\equiv}CSiMe_3)$ with $B(C_6F_5)_3$ in toluene leads via electrophilic substitution on one of the Cp rings to the zwitterionic titanium(III) complex $CpTi[\eta^5-C_5H_4B(C_6F_5)_3]$. Treatment of $Cp_2Ti(\eta^2-Me_3SiC{\equiv}CSiMe_3)$ with fullerene gives the unique fullerene complex $Cp_2Ti(\eta^2-C_{60})$.

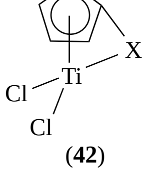
$Cp_2Ti(CO)_2$ and $Cp_2^*Ti(CO)_2$ react instantaneously with TCNE (tetracyanoethene) and TCNQ (7,7,8,8-tetracyano-*p*-quinodimethane) to give the corresponding highly air-sensitive monocarbonyl TCNE (**41**) and TCNQ complexes. The Cp_2^*Ti(CO)(TCNE) and Cp_2^*Ti(CO)(TCNQ) complexes were characterized in the oxidized and reduced forms through cyclic voltammetry, EPR, IR, and UV-visible spectroelectrochemistry. While oxidation at rather low potentials yields labile carbonyltitanium(IV) species of the TCNE and TCNQ ligands, the reduction occurs stepwise at unusually negative potentials, first on the ligand (to yield coordinated $TCNE^{2-}$ and $TCNQ^{2-}$) and then on the metal, to form Ti(II).[187]



(**41**)

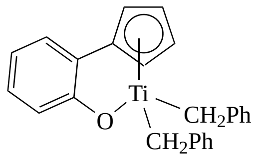
12 CONSTRAINED GEOMETRY TITANIUM COMPLEXES

Constrained geometry titanium complexes (**42**), also know as *ansa* half-sandwich complexes, are currently of great scientific and technological interest as precursors to a new generation of high activity, high selectively Ziegler–Natta (*see Ziegler–Natta Catalysts*) type α-olefin polymerization catalysts. A wide range of constrained geometry titanium complexes incorporating a η^5-cyclopentadienly derivative with a remote η^1-hetero atom tethered via a wide range of bridging groups have been prepared. These complexes incorporate rigid bridges such as phenolates and carboranes and flexible hydrocarbon chains, or a single intervening C, Si, B, or P attached to a N, O, or P. The vast majority of these complexes have been evaluated for their potential for upon activation with MAO, and so on, for Ziegler–Natta type α-olefin polymerization (*see* ***Oligomerization & Polymerization by Homogeneous Catalysis***).



(**42**)

A verity of synthetic methods have been developed for the preparation cyclopentadienyl-phenoxytitanium



(**43**)

derivatives. Reaction of $TiCl_4$ with the corresponding dilithio salts 2-(3,4-diphenylcyclopentadienyl)-6-phenylphenol derivatives gives the corresponding constrained geometry complexes.[188] Treatment of $TiCl_4$ with one equivalent of a 2-tetramethylcyclopentadienyl phenol derivative to give a coordination intermediates, followed by treatment with 2 equivalent of *n*-BuLi at low temperature gives tetramethylcyclopentadienyl-phenoxytitanium dichlorides in moderate yields.[189] Treatment of $Ti(CH_2Ph)_4$ with 2-(tetramethylcyclopentadienyl)-4-methylphenol at 60° in toluene cleanly gives (η^1-$OC_6H_3(CH_3)$-η^5-C_5Me_4)$Ti(CH_2Ph)_2$ (**43**). In solution at room temperature, the two benzyl groups of (**37**) are magnetically equivalent; however, in the solid state, X-ray diffraction reveals that one benzyl group is coordinated in a normal η^1-fashion and the other in an η^2 mode. Low-temperature NMR-scale reactions of (**37**) with $B(C_6F_5)_3$ and Ph_3C^+ $B(C_6F_5)_4^-$ indicate the formation of the corresponding cationic complexes.[190] Several of the cyclopentadienyl-phenoxytitanium datives have been structurally characterized by single-crystal X-ray diffraction and the Cp(cent)-Ti-O angle in all cases was found to be approximately 107°.[188–190]

The analogous indenyl-phenoxytitanium complexes have recently been reported, and structurally characterized, with the Ind(cent)-Ti-O angle of approximately 105°. Treatment of $Ti(NMe_2)_4$ with one equivalent 2-(inden-3-yl)-4,6-di-*tert*-butylphenol and its 1,2-di-Me, 2,4,7-tri-Me, and 1,2,4,7-tetra-Me derivatives gives the corresponding bis(dialkylamido) complexes such as, [Ti(η^1-OC_6H_2{η^5-Ind}-2-$Bu^t{}_2$-4,6)$(NMe_2)_2$].[191] Thermolysis of [η^5-$C_5H_4CMe_2$-2-$C_6H_4OCH_3$]$TiCl_3$ gives [η^5:η^1-$C_5H_4CMe_2$-2-C_6H_4O]$TiCl_2$ which is analogous to 37 with a CMe_2 group between the Cp ring and the phenoxide.[192]

A verity of carborane (*see Carborane*)-appended cyclopentadienyl constrained geometry complexes have been prepared. [η^5:η^1-$Me_2Si(C_5Me_4)(C_2B_{10}H_{10})$]$TiCl_2$ was prepared via salt metathesis and amine elimination reactions utilizing the linked *o*-carboranyl ligand, $Me_2Si(C_5Me_4H)(C_2B_{10}H_{11})$.[193] $Me_2C(C_5H_4)(C_2B_{10}H_{10})$]$Ti(NR_2)_2$ $Me_2Si(C_5H_4)(C_2B_{10}H_{10})$] $Ti(NR_2)_2$ (R = Me, Et), were prepared in good yield via amine elimination reactions of $Ti(NMe_2)_4$ and the corresponding neutral ligands in toluene. Treatment of [η^5:σ-$Me_2C(C_5H_4)(C_2B_{10}H_{10})$]$Ti(NMe_2)_2$ with excess Me_3SiCl gives [η^5:σ-$Me_2C(C_5H_4)(C_2B_{10}H_{10})$]$TiCl(NMe_2)$.[194] Treatment of $Ti(NMe_2)_4$ with carboranyl-thiol-appended cyclopentadiene ligand, 1-SH-2-[HCpCH(Ph)]-closo-1,2-$C_2B_{10}H_{10}$, gives the corresponding Ti complex [1-(σ-S)-2-(η^5-$C_5H_4CH(Ph)$-1,2-$C_2B_{10}H_{10}$)]$Ti(NMe_2)_2$, which undergoes exclusively monohalogenation at titanium with Me_3SiCl or Me_3NHCl, giving [1-(σ-S)-2-(η^5-$C_5H_4CH(Ph)$-1,2-$C_2B_{10}H_{10}$)]$TiCl(NMe_2)$ in 71% yield.[195] Treatment of $Ti(NMe_2)_4$ with 1 equivalent of *i*-$Pr_2NB(C_9H_7)(C_2B_{10}H_{11})$, gives deborated product (η^5-$C_2B_9H_{11}$)$Ti(NMe_2)_2(HNMe_2)$. Salt metathesis reaction between $TiCl_4(THF)_2$ and Li_2[*i*$Pr_2NB(C_9H_6)(C_2B_{10}H_{10})$] $(Et_2O)_2$ afforded [η^5:σ-*i*-$Pr_2NB(C_9H_6)(C_2B_{10}H_{10})$]$TiCl_2$. Alternatively, [$\eta^5$:$\sigma$-*i*-$Pr_2NB(C_9H_6)(C_2B_{10}H_{10})$]$TiCl_2$ was also prepared by the treatment of $TiCl_3(THF)_3$ with one equivalent of Li_2[*i*-$Pr_2NB(C_9H_6)(C_2B_{10}H_{10})$]$(Et_2O)_2$ followed by addition of 0.5 equivalent of $PbCl_2$ in THF.[196] In an analogous manner, treatment of $Ti(NMe_2)_4$ with a series of nido-7,8-$(NMe_2CH_2)_2$-7,8-$C_2B_9H_{11}$ dicarbollide ligands gives mono- and trimetallic titanium complexes [η^5:η^1-$(NMe_2CH_2)C_2B_9H_9CH_2NMe_2$]$Ti(NMe_2)_2$ and [η^5:η^1-[$(NMe_2CH_2)C_2B_9H_9CH_2NMe_2$]$Ti(NMe_2)$]$_2$($\mu_3$-O)[$Ti(NMe_2)_2$].[197]

Constrained geometry titanium complexes with cyclopentadienyl derivatives bridged to the Ti via a Si–N linkage have been prepared and extensively studied as precursors to Ziegler–Natta type polymerization catalysts. Treatment of (η^5-$C_5H_4SiMe_2Cl$)$TiCl_3$ with primary aryl amines H_2NR (R = C_6H_5, 2,6-$Me_2C_6H_3$, 2-Me-6-*i*-Pr-C_6H_3) gives the constrained geometry derivatives (η^5:η^1-$C_5H_4SiMe_2NR$)$TiCl_2$. (η^5:η^1-$C_5H_4SiMe_2N$-2,6-$Me_2C_6H_3$)$TiCl_2$ is converted to (η^5:η^1-$C_5H_4SiMe_2N$-2,6-$Me_2C_6H_3$)TiR_2 (R = Me, CH_2Ph, CH_2SiMe_3, NMe_2), by treatment with the appropriate Grignard or organolithium reagents.[198] Marks and coworkers have reported that the treatment of constrained geometry precursors such as $C_5H_5Si(Me_2)NHCMe_3$ with *n*-BuLi to give the dianion followed treatment with $TiCl_3THF_3$, oxidation with $PbCl_2$ and alkylation with MeLi to give Me_2Si(η^5-Me_4C_5)(*t*-BuN)$TiMe_2$, is time consuming and leads to only poor yields. However, they found that treatment of $C_5H_5Si(Me_2)NHCMe_3$ with $Ti(CH_2Ph)_4$ in aromatic or saturated hydrocarbon solvents at 60° gives Me_2Si(η^5-Me_4C_5)(*t*-BuN)$Ti(CH_2Ph)_2$, in 90% isolated yield in 12 h.[199] Treatment of (η^5:η^1-$C_5Me_4SiMe_2NR'$)$Ti(CH_2Ph)_2$ (R′ = Me, *i*-Pr, *t*-Bu) with $B(C_6F_5)_3$ or $[Ph_3C][B(C_6F_5)_4]$ in bromobenzene gives the corresponding cationic monbenzyl complex [(η^5:η^1-$C_5Me_4SiMe_2NR'$)$Ti(CH_2Ph)$]$^+$. Solution NMR studies suggest that the benzyl titanium cations contain a fluxional η^2-coordinated benzyl ligand.[200]

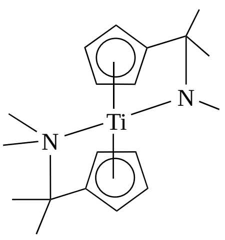
A series of heteroatom substituted indenyl constrained geometry complexes [(η^5-C_9H_5X)($SiMe_2$-*t*-Bu)TiR_2] (X = 2-OEt, 2-NMe_2, 3-OMe, 3-NC_4H_4; R = Cl, Me) were prepared in moderate yield by treatment of the dilithium salt of the ligand with $TICl_3THF_3$ in THF followed by treatment with $PbCl_2$.[201]

Reactions of [Ti(η^5-$C_5Me_4SiMeXCl$)Cl_3] with two equiv. of LiNH-*t*-Bu afforded the *ansa*-silyl-η-amido compounds (η^5:η^1-C_5Me_4SiMeX-N-*t*-Bu)$TiCl_2$ (X = H, Cl). Methylation of (η^5:η^1-C_5Me_4SiMeX-N-*t*-Bu)$TiCl_2$ with MgClMe gives

(η^5:η^1-C_5Me_4SiMeX-N-t-Bu)$TiMe_2$.[100] Treatment of (η^5-1,3-t-$Bu_2C_5H_3$)(η^5-$C_5H_4SiClMe_2$)$TiCl_2$, with two equiv. of LiNH-t-Bu in toluene at 50–60° gives (η^5-1,3-t-$Bu_2C_5H_3$)(η^5:η^1-$C_5H_4SiMe_2$N-t-Bu)TiCl.[99]

Treatment of {η^5:η^1-$C_5R_4SiMe_2$N-t-Bu}$TiMe_2$ (R = H, Me) with $HOCMe_2CH_2CH_2CH{=}CH_2$ gives a mixture of {η^5-$C_5R_4SiMe_2$NH-t-Bu}$TiMe_2$($OCMe_2CH_2CH_2CH{=}CH_2$) and {η^5:η^1-$C_5R_4SiMe_2$N-t-Bu}TiMe($OCMe_2CH_2CH_2CH{=}CH_2$). Treatment of a mixture of {η^5-$C_5R_4SiMe_2$NH-t-Bu}$TiMe_2$($OCMe_2CH_2CH_2CH{=}CH_2$) and {η^5:η^1-$C_5R_4SiMe_2$N-t-Bu}TiMe($OCMe_2CH_2CH_2CH{=}CH_2$) with $B(C_6F_5)_3$ gives the chelated olefin complexes [{η^5:η^1-$C_5R_4SiMe_2$N-t-Bu}Ti($OCMe_2CH_2CH_2CH{=}CH_2$)][$MeB(C_6F_5)_3$] which serves as a model for the Ti-olefin interaction in the putative $[\{\eta^5{:}\eta^1\text{-}C_5R_4SiMe_2N\text{-}t\text{-Bu}\}Ti(R')(olefin)]^+$ intermediates in constrained geometry Ti-catalyzed olefin polymerization. A similar reaction with [Ph_3C][$B(C_6F_5)_4$] yields [{η^5:η^1-$C_5Me_4SiMe_2$N-t-Bu}Ti($OCMe_2CH_2CH_2CH{=}CH_2$)][$B(C_6F_5)_4$].[202]

Treatment of $TiCl_4$ with Li[(C_5H_4)CMe_2NMe_2] followed by treatment with CH_3Li gives [$CpCMe_2NMe_2$]$Ti(CH_3)_2$. The reaction of [$CpCMe_2NMe_2$]$Ti(CH_3)_2$ with $B(C_6F_5)_3$ gives a reactive metallocene cation complex that instantaneously undergoes CH activation at a N-CH_3 group to yield the metallacyclic constrained geometry complex (**44**).[203]

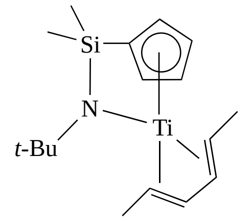


(**44**)

Treatment of $Ti(NMe_2)_4$ with (C_5H_5)CH_2(2-C_4H_3NH) gives [(η^5:η^1-C_5H_4)CH_2(2-C_4H_3N)]$Ti(NMe_2)_2$ via amine elimination. In an analogous manner treatment of $Ti(NMe_2)_4$ with 1,3- and 1,4-{CH_2(2-C_4H_3NH)}$_2C_5H_4$ gives [(η^5:η^1:η^1)-1,3-{CH_2(2-C_4H_3N)}$_2$(η^5-C_5H_3)]$TiNMe_2$.[204]

Reduction of (η^5:η^1-$C_5Me_4SiMe_2$NR)$TiCl_2$ (R = t-Bu, Ph) with BuLi in the presence of various 1,3-dienes gives the unique constrained geometry diene complexes, (η^5:η^1-$C_5Me_4SiMe_2$NR)Ti(diene) complexes (**45**). The diene coordination mode (π, formally Ti(II), or metallacyclic, formally Ti(IV)) and the activity for olefin polymerization are highly sensitive to the identity of R.[205] Treatment of (η^5:η^1-$C_5Me_4SiMe_2$NR)$TiCl_2$ (R = t-Bu, CHMe(1-$C_{10}H_7$)) with butadienemagnesium gives butadiene complexes analogous to (**39**) in good yield. The isomer which has the s-cis-butadiene ligand oriented with its open side toward the amido group (prone) is favored.[206]

Treatment of $Ti(NMe_2)_4$ with $C_5H_5B(NR_2)$NHPh (R = i-Pr, $SiMe_3$) and C_9H_2B(N-i-Pr_2)NHPh gives the

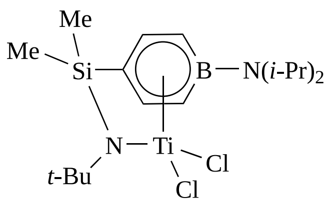


(**45**)

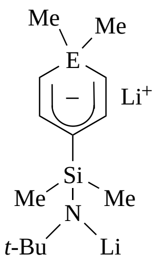
boron–nitrogen bridged constrained geometry titanium complexes (η^5:η^1-$C_5H_4B(NR_2)$NPh)$Ti(NMe_2)_2$ and (η^5:η^1-C_9H_6B(N-i-Pr_2)NPh)$Ti(NMe_2)_2$ in good yields via the amine elimination reaction. Subsequent deamination-chlorination with excess Me_3SiCl gives the corresponding dichloro complexes (η^5:η^1-$C_5H_4B(NR_2)$NPh)$TiCl_2$ and (η^5:η^1-C_9H_6B(N-i-Pr_2)NPh)$TiCl_2$, respectively. Reaction of the analogous ligand precursors containing more bulky R groups at nitrogen C_5H_5B(N-i-Pr_2)N(H)R (R = Cy, t-Bu) with $Ti(NMe_2)_4$ gives the half-sandwich complexes (*see Half-sandwich Complexes*) (η^5-C_5H_4B(N-i-Pr_2)N(H)R)$Ti(NMe_2)_3$ (R = Cy, t-Bu) rather than the corresponding bridged complexes.[207]

Treatment of Li_2[$C_5H_4C(Me_2)$PR] and Li_2[C_5H_4CH(t-Bu)PR] (R = Cy and Ph) with $Cl_2Ti(NR'_2)_2$ (R′ = Me, Et) gives the corresponding constrained geometry complexes (η^5:η^1-$C_5H_4C(Me_2)$PR)$Ti(NR'_2)_2$ and (η^5:η^1-C_5H_4CH(t-Bu)PR)$Ti(NR'_2)_2$ with a C–P bridge as red oils in good yield.[208] The analogous Si–P bridged complex, (η^5:η^1-$C_5Me_4SiMe_2$Pcy)$Ti(NMe_2)_2$, was prepared moderate yield by treatment of Li_2[$C_5Me_4SiMe_2$P(cyclohexyl)] with $Cl_2Ti(NMe_2)_2$.[209] Treatment of (t-BuCpP(-t-Bu)Cl)$TiCl_3$ with LiN(H)-t-Bu in the presence of Et_3N leads to the formation of the constrained geometry complex (η^5:η^1-t-BuCpP(-t-Bu)N-t-Bu)$TiCl_2$ in high yield.[101]

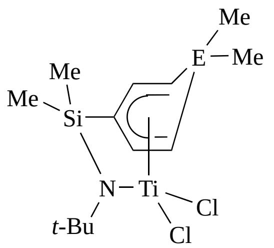
Constrained geometry complexes with other π ligands have also been prepared. Treatment of (4-Dimethylsilyl-*tert*-butylamido)-N,N-diisopropyl-1-aminoboratabenzene with two equivalents of t-BuLi followed by treatment with $TiCl_4$ gives (4-Dimethylsilyl-*tert*-butylamido)-N,N-diisopropyl-1-aminoboratabenzene titanium dichloride complexes (**46**).[210] Treatment of $TiCl_3THF_3$ with dianions (**47**) at low temperature followed by $PbCl_2$ gives the corresponding constrained geometry complexes (**48**) based on the dimethylcyclohexadienyl and dimethylsilacyclohexadienyl ligands.[211]



(**46**)



(**47**)



(**48**)

E = $SiMe_2$, CMe_2

13 CYCLOHEPTATRIENYL COMPLEXES

Reduction of $TiCl_4$ in the presence of PMe_3, $Me_2PCH_2PMe_2$, and $Me_2NCH_2CH_2NMe_2$ with an excess of cycloheptatriene gives $(\eta^7\text{-}C_7H_7)Ti(PMe_3)_2Cl$, $(\eta^7\text{-}C_7H_7)Ti(Me_2PCH_2PMe_2)Cl$, and $(\eta^7\text{-}C_7H_7)Ti(Me_2NCH_2CH_2NMe_2)Cl$, respectively.[212,213]

14 CYCLOPENTADIENYL–CYCLOHEPTATRI ENYL COMPLEXES

The mixed cyclopentadienyl–cycloheptatrienyl ('5–7') titanium complex $Cp(\eta^7\text{-}C_7H_7)Ti$ has been prepared in 33–40% yield by the reduction of $CpTiCl_3$ with isopropylmagnesium bromide or Mg in the presence of cycloheptatriene.[1] Reduction of Cp^*TiCl_3 in THF with Mg in the presence of cycloheptatriene gives $Cp^*(\eta^7\text{-}C_7H_7)Ti$ in 68% yield.[214] Titanium '5–7' complexes exhibit sandwich structures (*see Sandwich Compound*) with the five-membered and seven-membered rings nearly parallel to each other.

Metalation of $Cp(\eta^7\text{-}C_7H_7)Ti$ with *n*-butyllithium occurs predominantly at the seven-membered ring (equation 60). Dimetalation of $Cp(\eta^7\text{-}C_7H_7)Ti$ to give $(\eta^5\text{-}C_5H_4Li)(\eta^7\text{-}C_7H_6Li)Ti(TMEDA)_2$ has been achieved in 61% yield by treatment with 2 equiv. of BuLi/TMEDA. The dimetalated complex $(\eta^5\text{-}C_5H_4Li)(\eta^7\text{-}C_7H_6Li)Ti(TMEDA)_2$ reacts with a wide range of electrophilies, including MeI, Me_3SiCl, CO_2, and R_2PCl, to give the corresponding disubstituted complexes $(\eta^5\text{-}C_5H_4X)(\eta^7\text{-}C_7H_6X)Ti$ (X = Me, Me_3Si, CO_2^-, Me_2P, Ph_2P) in good yield (equation 61).[215]

$$Cp(\eta^7\text{-}C_7H_7)Ti \xrightarrow[\text{2. MeI}]{\text{1.}n\text{-BuLi}} \underset{95\%}{Cp(\eta^7\text{-}MeC_7H_6)Ti} + \underset{5\%}{MeCp(\eta^7\text{-}C_7H_7)Ti} \quad (60)$$

$$Cp(\eta^7\text{-}C_7H_7)Ti \xrightarrow[\text{2. 2 MeI}]{\text{1.}n\text{-BuLi/TMEDA}} (\eta^5\text{-}MeC_5H_4)(\eta^7\text{-}MeC_7H_6)Ti \quad (61)$$

Rausch and coworkers have extensively studied the use of $(\eta^5\text{-}C_5H_4PR_2)(\eta^7\text{-}C_7H_6PR_2)$ (R = Me, Ph) complexes as metalloligands. Reactions between $(\eta^5\text{-}C_5H_4PMe_2)(\eta^7\text{-}C_7H_6PMe_2)Ti$ and $M(CO)_6$ (M = Cr, Mo) in refluxing xylene result in the formation of chelated heterobimetallic complexes, $[(\eta^5\text{-}C_5H_4PMe_2)(\eta^7\text{-}C_7H_6PMe_2)Ti]M(CO)_4$ (M = Cr, Mo) in high yields, whereas a reaction between $(\eta^5\text{-}C_5H_4PMe_2)(\eta^7\text{-}C_7H_6PMe_2)Ti$ and $Fe_2(CO)_9$ under similar conditions gives the nonchelated product $[(\eta^5\text{-}C_5H_4PMe_2)(\eta^7\text{-}C_7H_6PMe_2)Ti][Fe(CO)_4]_2$. Treatment of bis(1,5-cod) nickel with 2 equiv. of $(\eta^5\text{-}C_5H_4PMe_2)(\eta^7\text{-}C_7H_6PMe_2)Ti$ in toluene at room temperature leads to displacement of the cod ligands and formation of $[(\eta^5\text{-}C_5H_4PMe_2)(\eta^7\text{-}C_7H_6PMe_2)Ti]_2Ni$ in 78% yield.[215]

The metalloligand $(\eta^5\text{-}C_5H_4PPh_2)(\eta^7\text{-}C_7H_6PPh_2)Ti$ reacts with a variety of metal carbonyls in refluxing toluene to produce a series of chelated heterobimetallic compounds, including $[(\eta^5\text{-}C_5H_4PPh_2)(\eta^7\text{-}C_7H_6PPh_2)Ti]M(CO)_4$ (M = Cr, Mo), $[(\eta^5\text{-}C_5H_4PPh_2)(\eta^7\text{-}C_7H_6PPh_2)Ti](CpCo)$, and $[(\eta^5\text{-}C_5H_4PPh_2)(\eta^7\text{-}C_7H_6PPh_2)Ti]Fe(CO)_3$. The crystal structure of the hemitoluene solvate of $[(\eta^5\text{-}C_5H_4PPh_2)(\eta^7\text{-}C_7H_6PPh_2)Ti]Cr(CO)_4$ has been determined. The phosphino groups are both on the same side of the molecule and coordinated to the Cr atom (Cr–P(av.) = 2.43(2) Å). The Ti–C(η^7) and Ti–C(η^5) distances average 2.19(1) and 2.31(2) Å, respectively, with an observed centroid(C5)–Ti–centroid(C7) angle of 173.5°, compared to a centroid(C5)–Ti–centroid(C7) angle of 175.8° in the parent bisphosphine.[216]

Treatment of $Mn_2(CO)_{10}$ with 2 equiv. of $(\eta^5\text{-}C_5H_4PPh_2)(\eta^7\text{-}C_7H_6PPh_2)Ti$ in refluxing toluene results in carbonyl group displacement, metal–metal bond cleavage, and hydrogen abstraction to give $HMn(CO)_3[(\eta^5\text{-}C_5H_4PPh_2)(\eta^7\text{-}C_7H_6PPh_2)Ti]$ in 57% yield. The Mn atom exhibits a distorted octahedral geometry with *cis* phosphines. The coordination geometry in the titanium complex backbone is relatively unaffected by the coordination of manganese.[217]

Treatment of $(\eta^5\text{-}C_5H_4Li)(\eta^7\text{-}C_7H_6Li)Ti \cdot 2TMEDA$ with two equivalents of dimethyldisulfide, diphenyldisulfide, and diphenyldiselenide and gives $(\eta^5\text{-}C_5H_4SCH_3)(\eta^7\text{-}C_7H_6SCH_3)Ti$, $(\eta^5\text{-}C_5H_4SPh)(\eta^7\text{-}C_7H_6SPh)Ti$, and $(\eta^5\text{-}C_5H_4SePh)(\eta^7\text{-}C_7H_6SePh)Ti$, respectively in low yield. The crystal structure of $(\eta^5\text{-}C_5H_4SPh)(\eta^7\text{-}C_7H_6SPh)Ti$, indicates that the five and seven-membered rings are essentially coplanar, and the two phenylthio substituents are in a trans-orientation.[218]

Treatment of $(\eta^7\text{-}C_7H_7)Ti(\eta^5\text{-}C_5H_5)$ with dithioacetic acid, CH_3CS_2H, leads to loss of the cycloheptatrienyl to give $(\eta^5\text{-}C_5H_5)Ti(S_2CCH_3)_3$.[219]

15 CYCLOPENTADIENYL–CYCLOOCTA TETRAENE COMPLEXES

Mixed '5–8' titanium complexes have been prepared by reduction of Cp^*TiCl_3 and $CpTiCl_3$ with Mg in THF in the presence of cyclooctatetraene to give $Cp^*(\eta^8\text{-}C_8H_8)Ti$

and $Cp(\eta^8-C_8H_8)Ti$ in 31 and 38% yield, respectively. Alternatively, reaction of Cp^*TiCl_3 with $K_2C_8H_8$ in THF gives $Cp^*(\eta^8-C_8H_8)Ti$ in 34% yield.[214]

16 CYCLOOCTATETRAENE COMPLEXES

Treatment of $TiCl_4(THF)_2$ with 2 equiv. of $Li_2[C_8H_6(SiMe_3)_2]$ and in THF gives $[Ti\{C_8H_6(SiMe_3)_2\}_2]$. The X-ray structure of $[Ti\{C_8H_6(SiMe_3)_2\}_2]$ indicates one ring is η^8 bound while the other is less readily classified, being intermediate between the η^3 structure found for $[Zr\{C_8H_6(SiMe_3)_2\}_2]$ and the η^4 structure found in $Ti(C_8H_8)_2$. In a variable-temperature solution NMR study on $[Ti\{C_8H_6(SiMe_3)_2\}_2]$, the two rings only become equivalent on the NMR timescale above 328 K.[220] In contrast, treatment of $TiCl_3(THF)_3$ with one equivalent of 1,4-bis(trimethylsilyl)cyclooctatetraene dianion (COT″) gives a mixture of $(COT'')_2Ti$, $[(COT'')Ti]_2(\mu-Cl)_3$ and $\{[\eta^8-1,4-(SiMe_3)_2C_8H_6]Ti(\mu-Cl)\}_2(THF)$.[221]

The reduction of $[(\eta^8-C_8H_8)Ti(THF)(\mu-Cl)]_2$ with magnesium in the presence of bis(trimethylsilyl)acetylene (BTMSA) gives $[(\eta^8-C_8H_8)Ti]_2[\mu-\eta^2{:}\eta^2-Me_3SiC{\equiv}CSiMe_3]$ in high yield. The crystal structure of $[(\eta^8-C_8H_8)Ti]_2[\mu-\eta^2{:}\eta^2-Me_3SiC{\equiv}CSiMe_3]$ revealed that BTMSA serves as a four-electron ligand to two equivalent $(\eta^8-C_8H_8)Ti$ units. The average C–C distance of 1.51 Å in the acetylene ligand is close to that of a sp^3 carbon–carbon single bond, however, the high thermal stability and a large down-field chemical shift of the acetylenic carbon atoms (δ292.8 ppm) suggests unusually high π-back-bonding in the Ti–acetylene bond. In contrast, the reduction of $[(\eta^8-C_8H_8)Ti(THF)(\mu-Cl)]_2$ by magnesium in the presence of diphenylacetylene gave $(\eta^8-C_8H_8)Ti(\eta^4-C_4Ph_4)$ and hexaphenylbenzene.[222]

17 OTHER η^5-LIGANDS

Seminal work by Ernst and coworkers has shown that the pentadienyl ligand $\eta^5-C_5H_7$ and its alkylated congeners are versatile ligands, possessing features of both Cp and allyl ligands. Treatment of $TiCl_2$, prepared in situ by the reduction of $TiCl_4$ with Mg, with potassium 2,4-dimethylpentadienide gives $(\eta^5-2,4-Me_2C_5H_5)_2Ti$ (equation 62). Complexes $(\eta^5-2,4-t-Bu_2C_5H_5)_2Ti$ and $(\eta^5-2,4-(SiMe_3)_2C_5H_5)_2Ti$ have been prepared in a similar manner. Somewhat surprisingly, these 14-electron open-sandwich compounds have been found to be low-spin (diamagnetic), whereas Cp^*_2Ti possesses two unpaired electrons.[223] The three bis(pentadienyl) complexes have staggered pentadienyl groups. Addition of CO or phosphines leads to the diamagnetic 16-electron complexes $(\eta^5-2,4-Me_2C_5H_5)_2TiL$ (L = CO ($\nu_{CO} = 1942\ cm^{-1}$), PMe_3, PEt_3, $P(OMe)_3$, PMe_2Ph) (equation 63) in which the pentadienyl ligands are syn eclipsed. $(\eta^5-C_5H_7)_2TiPEt_3$ can be prepared directly by treatment of '$TiCl_2$' with 2 equiv. of $[C_5H_7]^-$ and 1 equiv. of PEt_3.[224]

$$2K(2,4-Me_2C_5H_3) + TiCl_2 \longrightarrow (\eta^5-2,4-Me_2C_5H_3)_2Ti \quad (62)$$

$$(\eta^5-2,4-Me_2C_5H_3)_2Ti + L \longrightarrow (\eta^5-2,4-Me_2C_5H_3)_2TiL \quad (63)$$

The bis(6,6-dimethylcyclohexadienyl)titanium bent-sandwich complex $(\eta^5-6,6-Me_2C_6H_5)_2Ti$ has been prepared in 50% yield by treatment of $TiCl_3(THF)_3$ or $TiCl_4(THF)_2$ with 6,6-dimethylcyclohexadienylpotassium (K(dmCh)). Carbonylation of $(dmCh)_2Ti$ at 1 atm and 25 °C gives the thermally sensitive cherry-red carbonyl adduct $(dmCh)_2TiCO$ ($\nu_{CO} = 1904\ cm^{-1}$) in 95% yield. The carbonyl complex $(dmCh)_2TiCO$ has C_{2v} symmetry, with a dmCh–Ti–dmCh angle of 155°. Treatment of $(dmCh)_2Ti$ with PF_3, PMe_3, or $P(OMe)_3$ at low temperature in solution leads to adducts; however, the lability of these adducts does not allow direct characterization.[225]

Bis(η^5-cyclooctadienyl)Ti complexes form monoadducts with both CO and the cage phosphite $P(OCH_2)_3CEt$. The 16 electron titanium complexes are diamagnetic, exhibiting broad ^1H NMR spectra indicating that the phosphite complex undergoes rapid, reversible ligand dissociation. Structural data reveal a high degree of steric crowding in these complexes, while the IR data for the bis(η^5-cyclooctadienyl)Ti carbonyl complex indicates that the edge-bridged dienyl ligands are substantially stronger electron donors than typical pentadienyl ligands, comparable to the Cp ligand.[226]

The reactions of $CpTiCl_2(PR_3)_2$ (R = Me, Et) with 2 equiv. of KC_5H_7 or $K(2,4-C_7H_{11})$ (C_7H_{11} = dimethylpentadienyl) gives the corresponding diamagnetic 16 electron Cp(pendadienyl)$TiPR_3$ complexes. A single-crystal X-ray diffraction study of Cp $(\eta^5-2,4-C_7H_{11})TiPEt_3$ revealed that the Ti–C bond lengths for the open dienyl ligand are much shorter than those for the Cp ligand, 2.240(3) versus 2.346(4) Å, indicative of stronger Ti–C_7H_{11} bonding. Reaction of $Cp(\eta^5-2,4-C_7H_{11})TiPEt_3$ with MeCN leads to loss of the PEt_3 ligand and coupling to the 2,4-C_7H_{11} ligand. Thus, the C_7H_{11} ligand is bound more strongly than the Cp ligand (*see Ligand*), yet more reactive. The phosphine ligands in these complexes are readily replaced by treatment with $P(OMe)_3$ or $P(OEt)_3$. Treatment of $CpTi(\eta^5-2,4-C_7H_{11})(PEt_3)$ with CO leads to thermally unstable monocarbonyl and dicarbonyl complexes.[227]

Pentadienyl complexes $[\eta^5-1,3-C_5H_3(t-Bu)_2]Ti(\eta^5-2,4-C_7H_{11})(PMe_3)$, $Ti[\eta^5-1,3-C_5H_3(t-Bu)_2](\eta^5-C_5H_7)(PR_3)$ (R = Me or Et) and $[\eta^5-1,3-C_5H_3(SiMe_3)_2]Ti(\eta^5-2,4-C_7H_{11})(PMe_3)$ (C_7H_{11} = dimethylpentadienyl) containing bulky Cp ligands have been prepared. The X-ray structure of $[\eta^5-1,3-C_5H_3(t-Bu)_2]Ti$ $(\eta^5-C_5H_7)PMe_3$ revealed a markedly shorter Ti–C bonds for the open dienyl ligand as compared to the cyclic one.[228] Structural data have been obtained for these complexes, and for $Ti(\eta^5-2,4-C_7H_{11})_2(PEt_3)$. The presence of the coordinated phosphines in all cases led to the adoption of the expected syn-eclipsed geometries, with the phosphines

positioned by the open dienyl edges. These phosphine ligands cause substantial alterations of the bonding patterns in these species, relative to ligand-free complexes. Most notably, the shortest M–C distances involve the central dienyl carbon atoms.[229]

18 ALKOXIDES AND RELATED COMPLEXES

Rothwell and Wolczanski have developed considerable titanium organometallic chemistry utilizing sterically hindered alkoxides as ancillary ligands.

Wolczanski and coworkers have shown that the tritox ligand t-Bu_3CO, with a cone angle (*see Cone Angle*) of 125 °C, which is slightly smaller than the 136° cone angle for Cp, can serve to sterically 'saturate' titanium and allow the development of considerable organometallic chemistry. Reaction of 2 equiv. of Li(tritox) with $TiCl_3$ gives '$(tritox)_2TiCl$', which appears to be monomeric, in contrast to the Cp analog $[Cp_2TiCl]_2$ (equation 64). Treatment of '$(tritox)_2TiCl$' with excess CCl_4 gives $(tritox)_2TiCl_2$, which can also be prepared directly, in 51% yield, by reaction of $TiCl_4$ with 2 equiv. of Li(tritox) (equation 65). Similarly, $(tritox)TiCl_3$ is prepared in 57% yield by treatment of $TiCl_4$ with 1 equiv. of Li (tritox) (equation 66).

$$2Li(tritox) + TiCl_3 \xrightarrow[\text{hexane}]{Et_2O} \text{'}(tritox)_2TiCl\text{'} + 2LiCl \quad (64)$$

$$\text{'}(tritox)_2TiCl\text{'} + CCl_4 \longrightarrow (tritox)_2TiCl2 \quad (65)$$

$$Li(tritox) + TiCl_4 \xrightarrow{Et_2O} (triox)TiCl_3 + LiCl \quad (66)$$

In a manner analogous to the reactivity of Cp_2TiCl_2, treatment of $(tritox)_2TiCl_2$ with 2 equiv. of MeLi gives $(tritox)_2TiMe_2$ in 76% yield (equation 67). In an analogous manner, treatment of $(tritox)TiCl_3$ with 3 equiv. of MeLi gives $(tritox)TiMe_3$ in 60% yield (equation 68). $(Tritox)_2TiMe_2$ exhibits high thermal stability, with less than 10% decomposition observed over 2 weeks in a benzene solution at 100 °C.[230]

$$(triox)_2TiCl_2 + 2LiMe \xrightarrow{Et_2O} (triox)_2TiMe_2 + 2LiCl \quad (67)$$

$$(triox)TiCl_3 + 3LiMe \xrightarrow{Et_2O} (triox)TiMe_3 + 3LiCl \quad (68)$$

Reaction of $(tritox)_2TiMe_2$ with dry O_2 for 8–30 h gives $(tritox)_2Ti(OMe)_2$ in 87% yield. Reaction of $(tritox)TiMe_3$ with O_2 gives three different methoxide complexes, depending upon the stoichiometry of the reagents (equations 69–71).[231]

$$(triox)TiMe_3 + \frac{1}{2}O_2 \longrightarrow \frac{1}{n}[(triox)TiMe_2(OMe)]_n \quad (69)$$

$n = 1$ in solution, 2 in solid state

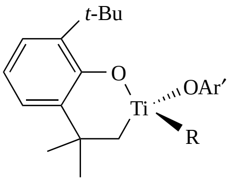
$$(triox)TiMe_3 + O_2 \longrightarrow (triox)TiMe(OMe)_2 \quad (70)$$

$$(triox)TiMe_3 + \frac{3}{2}O_2 \longrightarrow (triox)Ti(OMe)_3 \quad (71)$$

Rothwell and coworkers have shown that treatment of $Ti(CH_2Ph)_4$ with 2 equiv. of 2,6-di-t-butylphenol gives the deep-red complex $Ti(2,6\text{-}t\text{-}Bu_2C_6H_3O)_2(CH_2Ph)_2$ in 25–40% yield (equation 72). Thermolysis of $Ti(2,6\text{-}t\text{-}Bu_2C_6H_3O)_2(CH_2Ph)_2$ at 120 °C in hydrocarbon solvents leads to cyclometalation (*see Cyclometalation*) to give $Ti[2,6\text{-}(t\text{-}Bu)(CMe_2CH_2)C_6H_3O](2,6\text{-}t\text{-}Bu_2C_6H_3O)(CH_2Ph)$ (**47**) (equation 73). Reaction of $Ti(CH_2SiMe_3)_4$ with 2,6-t-$Bu_2C_6H_3OH$ at 25 °C for several days gives no observable reaction; however, warming the reaction mixture to 80 °C affords $Ti[2,6\text{-}(t\text{-}Bu)(CMe_2CH_2)C_6H_3O](2,6\text{-}t\text{-}Bu_2C_6H_3O)(CH_2SiMe_3)$.[232] Complexes $Ti(2,6\text{-}Ph_2C_6H_3O)_2R_2$ (R = Me, CH_2SiMe_3, CH_2Ph, Ph) and $Ti(2,6\text{-}Ph_2C_6H_3O)_3R$ (R = Me, CH_2SiMe_3) are obtained by treating the corresponding homoleptic (*see Homoleptic Compound*) alkyl TiR_4 with 2,6-diphenylphenol in the proper stoichiometry. X-ray crystallographic analysis of $Ti(2,6\text{-}Ph_2C_6H_3O)_2(Ph)_2$ and $Ti(2,6\text{-}Ph_2C_6H_3O)_3(CH_2SiMe_3)$ demonstrates that the Ti atoms in these complexes are in a pseudotetrahedral environment with short Ti–O distances (1.794(3)–1.806(2) Å) and large Ti–O–C angles (153–179°).[233]

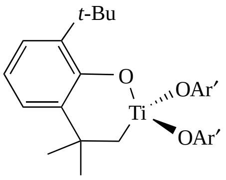
$$Ti(CH_2Ph)_4 + 2(2,6\text{-}t\text{-}Bu_2C_6H_3OH) \longrightarrow Ti(2,6\text{-}t\text{-}Bu_2C_6H_3O)(CH_2Ph)_2 \quad (72)$$

$M(OAr')_2R_2 \xrightarrow{\Delta}$



(**49**)

HOAr′ | Δ (73)



(**71**)

Mixed (alkyl)(aryl oxide) complexes of $(ArO)_2Ti(CH_2Ph)_2$ (Ar = $2,6\text{-}Ph_2C_6H_3$, $2,6\text{-}i\text{-}Pr_2C_6H_3$) have been found to undergo migratory insertion (*see Migratory Insertion*) with organic isocyanides to give η^2-iminoacyl derivatives (equation 74). Reaction of $(ArO)_2Ti(CH_2Ph)_2$ with 2,6-dimethylphenyl isocyanide leads initially to the monoiminoacyl derivative $(ArO)_2Ti(\eta^2\text{-}2,6\text{-}Me_2C_6H_3N{=}CCH_2Ph)(CH_2$

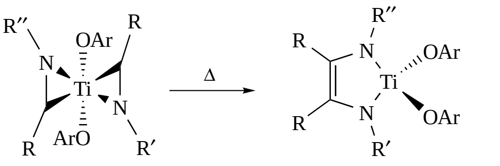
Ph) and finally to the bis-insertion product $(ArO)_2Ti(\eta^2\text{-}2,6\text{-}Me_2C_6H_3N{=}CCH_2Ph)_2$ (equation 75).[234] Mild thermolysis of $(ArO)_2Ti(\eta^2\text{-}2,6\text{-}Me_2C_6H_3N{=}CCH_2Ph)_2$ in hydrocarbon solvents gives the corresponding enediamido complexes (equation 76). Treatment of the alkyl–iminoacyl–aryl oxide complexes with 200–1000 psi of CO forms enamidolate complexes (equation 77).[235]

$$(ArO)_2Ti(CH_2Ph)_2 \xrightarrow{RN\equiv C} (ArO)_2Ti(\eta^2\text{-}2,6\text{-}Me_2C_6H_3N{=}CCH_2Ph)(CH_2Ph) \quad (74)$$

$$(ArO)_2Ti(\eta^2\text{-}RN{=}CCH_2Ph)(CH_2Ph) \xrightarrow{RN\equiv C} (ArO)_2Ti(\eta^2\text{-}RN{=}CCH_2Ph)_2$$

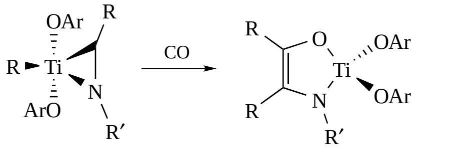
$Ar = 2,6\text{-}Ph_2C_6H_3,\ 2,6\text{-}i\text{-}Pr_2C_6H_3;\ RN\equiv C = 2,6\text{-}Me_2C_6H_3N\equiv C$

(75)



(76)

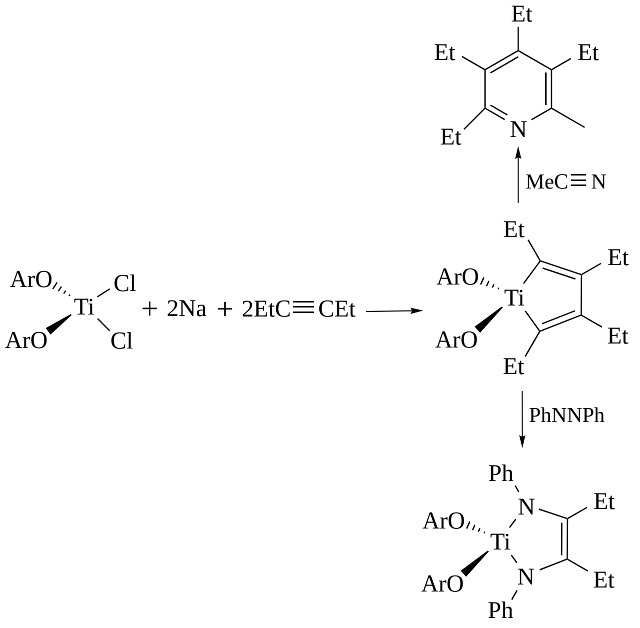
$Ar = 2,6\text{-}i\text{-}Pr_2C_6H_3$; $R = CH_2Ph$, $R' = Ph$, $2,6\text{-}Me_2C_6H_3$, t-Bu; $R'' = 2,6\text{-}Me_2C_6H_3$, t-Bu



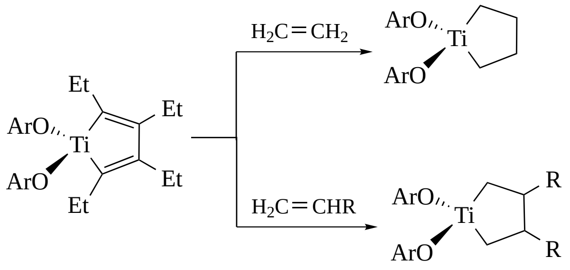
(77)

$Ar = 2,6\text{-}i\text{-}Pr_2C_6H_3$; $R = CH_2Ph$, $R' = t$-Bu;

Reduction of $Ti(2,6\text{-}Ph_2C_6H_3O)_2Cl_2$ (which can be prepared by the reaction of $TiCl_4$ with $2,6\text{-}Ph_2C_6H_3OH$)[236] with sodium amalgam at room temperature in the presence of $EtC\equiv CEt$ gives a new titanacyclopentadiene complex in 89–90% yield. Titanocycles supported by aryl oxide ligation undergo fragmentation and isomerization and are more reactive than the corresponding bis(cyclopentadienyl)titanacyclopentadiene complexes, as shown in Scheme 9. Treatment of $(2,6\text{-}Ph_2C_6H_3O)Ti(EtC{=}CEtCEt{=}CEt)$ with 3-hexyne at 110 °C gives hexaethylbenzene catalytically. $(2,6\text{-}Ph_2C_6H_3O)Ti(EtC{=}CEtCEt{=}CEt)$ reacts rapidly with MeCN to produce the corresponding pyridine. Addition of $PhN{=}CMeCMe{=}NPh$ or azobenzene to $(2,6\text{-}Ph_2C_6H_3O)Ti(EtC{=}CEtCEt{=}CEt)$ gives the corresponding enediamido complexes $(RO)_2Ti(PhNCMe{=}CMeNPh)$ and $(RO)_2Ti(PhNCEt{=}CEtNPh)$, respectively.[237] Exposure of $(2,6\text{-}Ph_2C_6H_3O)Ti(EtC{=}CEtCEt{=}CEt)$ to ethylene in solution leads rapidly to the formation of the saturated titanacyclopentane $(2,6\text{-}Ph_2C_6H_3O)_2Ti(CH_2CH_2CH_2CH_2)$ and 1,2,5,6-tetraethyl-1,3-cyclohexadiene, as shown in Scheme 10.[238]



Scheme 9



R = Me, Et

Scheme 10

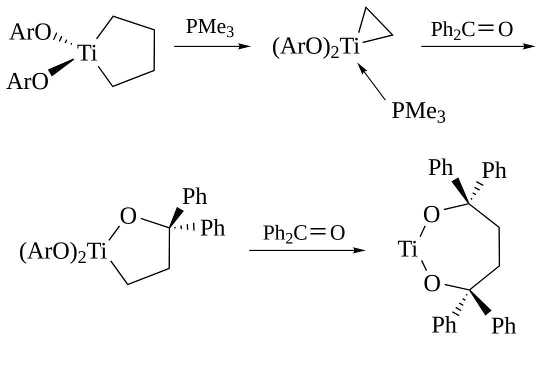
Treatment $(2,6\text{-}Ph_2C_6H_3O)Ti(EtC{=}CEtCEt{=}CEt)$ with olefins gives a variety of stable titanacyclopentane derivatives and one equivalent of substituted 1,3-cyclohexadiene. Reduction of the $(O\text{-}2,6\text{-}Ph_2C_6H_3)_2TiCl_2$ or $(O\text{-}2,3,5,6\text{-}Ph_4C_6H)_2TiCl_2$ with Na amalgam (2 Na per Ti) or 2 equiv. of BuLi in the presence of an olefin give the corresponding titanacyclopentane derivatives. These titanacyclopentane complexes undergo facile fragmentation. Addition of phosphine donor ligands gives $(O\text{-}2,6\text{-}Ph_2C_6H_3)_2Ti(\eta^2\text{-}CHR{=}CH_2)(L)$ (R = H, Me, Et, Ph,) along with 1 equiv. of free olefin. Addition of $Ph_2C{=}O$ or $PhCH{=}NR$ ($R = Ph$, CH_2Ph) to the titanacyclopentane and leads to different products depending upon the reagent and reaction conditions.[239]

Treatment of a hydrocarbon solution of $(2,6\text{-}Ph_2C_6H_3O)_2Ti(CH_2)_4$ with PMe_3 leads to the formation of the deep-purple η^2-ethylene complex $(2,6\text{-}Ph_2C_6H_3O)_2Ti(\eta^2\text{-}C_2H_2)(PMe_3)$. A single-crystal X-ray diffraction analysis

of (2,6-$Ph_2C_6H_3O)_2Ti(\eta^2$-$C_2H_2)(PMe_3)$ shows a pseudotetrahedral environment about the titanium center with the ethylene aligned perpendicular to the O–Ti–O plane. The Ti–C (ethylene) distances of 2.110 (2) and 2.148 (2) Å, as well as a C–C distance of 1.425 (3) Å, are consistent with a titanacyclopropane bonding description. Addition of Ph_2CO to (2,6-$Ph_2C_6H_3O)_2Ti(\eta^2$-$C_2H_2)(PMe_3)$ gives initially the oxatitanacyclopentane complex (2,6-$Ph_2C_6H_3O)_2Ti(OCPh_2CH_2CH_2)$, which upon addition of a second equivalent of Ph_2CO gives the dioxametallacyclic complex (2,6-$Ph_2C_6H_3O)_2Ti(OCPh_2CH_2CH_2CPh_2O)$, as shown in Scheme 11.[240]

$CpTiCl_2X$ complexes where X is a OAr, SAr, or carbazole have been prepared. Treatment of $CpTi(OAr)Cl_2$ and $Cp^*Ti(OAr)Cl_2$ where OAr is a bulky phenol derivative, with 2 equiv. of LiMe gives $CpTi(OAr)Me_2$ and $Cp^*Ti(OAr)Me_2$, respectively. Alternatively, treatment of $CpTiMe_3$ in a cold ether solution of a bulky phenol gives $CpTi(OAr)Me_2$. Reaction of $CpTiMe_3$ with 2 equiv. of less bulky phenol derivatives, HOAr′ (Ar′ = 2, 6-dimethyl-phenyl, 2,6-dimethyl-4-Br-phenyl), gives $[CpTi(OAr')_2Me]$. Reaction of the $CpTi(OAr)Me_2$ with $[B(C_6F_5)_3]$ generates the corresponding cationic complex, $[CpTi(OAr)Me][MeB(C_6F_5)_3]$. The thermally unstable cationic readily eliminates methane at room temperature giving $CpTi(OAr)(C_6F_5)(CH_2B(C_6F_5)_2)$. The solid-state structure of $CpTi(OC_6H$-2,6-Ph_2-3,5-$Me_2)(C_6F_5)$ $(CH_2B(C_6F_5)_2)$ confirms the transfer on one C_6F_5 to titanium and no interaction of the trigonal-planar boron atom with the adjacent Ti–C_6F_5 group.[241]

Treatment of $CpTiCl_3$ with 1 equiv. of substituted arylsulfide ligands (SAr = 4-Me-SC_6H_4, 2,4,6,-Me_3-SC_6H_2, 2,4,6-*i*-Pr_3-SC_6H_2, 2,4,6-Ph_3-SC_6H_2) in benzene gives $CpTi(SAr)Cl_2$. One electron reduction of $CpTi(SAr)Cl_2$ with Na/Hg gives the sulfur-bridged dimmers, $[CpTiCl(\mu$-$SAr)]_2$ (SAr = 2, 4, 6,-Me_3-SC_6H_2, 2,4,6-*i*-Pr_3-SC_6H_2, 2,4,6-Ph_3-SC_6H_2). The solid-state structures of these dimers show that the cyclopentadienyl rings are arranged in a transoid fashion about the $Ti(\mu$-$SAr)_2Ti$ core.[242] The reaction of $CpTiCl_3$ with K carbazolate (Kcb) gives $CpTi(cb)Cl_2$ which can readily be converted $CpTi(cb)Me_2$.[243]



Scheme 11

Reduction of $CpTi(OAr)Cl_2$ (OAr = 2,3,5,6-tetraphenylphenoxide) with 2 equivalent of sodium amalgam at room temperature in the presence of $Me_3C{\equiv}CH$ gives the 2,5-di(*t*-butyl)titanacyclopentadiene complex, Cp(ArO)Ti(2,5-*t*-Bu_2-C_4H_2). When Cp(ArO)Ti(2,5-*t*-Bu_2-C_4H_2) is heated at 100 °C for a few days in C_6D_6 it isomerizes to the more stable 2,4-di(*t*-butyl) regioisomer.[244]

Treatment of $[Ti(CH_2Ph)_4]$ with carbazole gives $Ti(cb)_2(CH_2Ph)_2$. $Ti(cb)_2(CH_2Ph)_2$ reacts with 2,6-dimethylphenyl isocyanide to generate the corresponding bis(iminoacyl) derivative, in which the iminoacyl is η^2-C,N binding. The reaction of the more bulky $[Ti(CH_2SiMe_3)_4]$ with cbH at 100 °C gives the alkylidene bridged dimer $[(cb)_2Ti(\mu$-$CHSiMe_3)_2Ti(cb)_2]$ which was structurally characterized. The reaction of $CpTiCl_3$ with K carbazolate (Kcb) gives $CpTi(cb)Cl_2$ which can readily be converted $CpTi(cb)Me_2$.[243]

Treatment o (2,6-Ph_2-3,5-$Me_2C_6HO)_2Ti(CH_2Ph)_2$ with $[B(C_6F_5)_3]$ gives the corresponding zwitterionic species (2,6-Ph_2-3,5Me_2-$C_6HO)_2Ti(CH_2Ph)[\eta^6$-$C_6H_5CH_2B(C_6F_5)_3]$[245]

1 INTRODUCTION

Metal carbonyl compounds are, with very few exceptions, polyatomic molecules with, as might be expected, rich and interesting infrared spectra. For a molecule $M(CO)_x(L)_y$, there will be absorptions due to the motions of the CO groups and, of course, any other ligands attached to the metal. It might seem a little myopic then to concentrate by far the greatest proportion of spectroscopic effort to the region around 2000 cm^{-1}. Around this 2000 cm^{-1} region of the IR (and Raman) spectrum, we find the 'CO-stretching' bands, ν(CO), of metal carbonyl complexes. The number, pattern, and position of these absorptions give an enormous amount of information about molecular structure, symmetry, and bonding. The 'ν(CO)' region has, since the early 1960s, been the scene of some exciting work and the arena for many arguments.

In the mid-1970s, Braterman[1] published a complete text devoted to metal carbonyl spectra and, although out of date in several areas, it remains a valuable resource, particularly in its advice on sample preparation and handling where the generally high toxicity and ready decomposition of metal carbonyl complexes causes more problems than might be usually found. Another helpful source of information, although even older, by Adams[2] contains ν(CO) information on a large number of transition metal carbonyl complexes.

Paradoxically, gaseous carbon monoxide itself is not a strong IR absorber. Yet the IR spectrum of any transition metal carbonyl complex with terminal CO groups is dominated by the very high intensity of some of the CO-stretching absorptions. Since IR intensities are proportional to the square of the dipole change associated with the vibration, the implication is that there is a large dipole change when a carbonyl group vibrates. This effect derives from the π-bonding in the M–C–O unit.[3] The stretching of a CO group bonded to a metal atom leads to a lowering of the energy of the 2π orbital, since the antibonding interaction is weakened and the orbital becomes a better acceptor. At the same time, the overlap of the carbon and the metal orbitals is increased as the M–C distance lessens. There is, therefore, a great deal of electronic flow and ebb within each vibration and, consequently, a high dipole change.

2 PRINCIPLES OF MOLECULAR FORCE FIELDS

The bonds that hold molecules together obey Hooke's law (for small distortions at least). That is, the restoring force F is proportional to the extension x

$$F = -kx \tag{1}$$

The potential energy, V, of such a system is given by

$$V = \frac{(kx^2)}{2} \tag{2}$$

The constant of proportionality (k) in both cases is the stretching force constant and, in the same way that a force constant can measure the strength of a mechanical spring, k gives a measure of the strength of a chemical bond. Indeed, the force constant measures bond strength when the atoms are near their equilibrium positions, a far more subtle measure than the dissociation energy.

The vibration of a molecule does not affect its center of mass. The vibration is equivalent to that of a single particle of reduced mass μ moving in a field of force constant k. A diatomic molecule AB (such as CO) will vibrate with a frequency ν_{AB} given by the equation

$$\nu_{AB} = \frac{1}{2\pi}\sqrt{\frac{k_{AB}}{\mu_{AB}}} \tag{3}$$

where μ_{AB} is the reduced mass of the molecule, given by

$$\mu_{AB} = \frac{(m_A \times m_B)}{(m_A + m_B)} \tag{4}$$

Rearranging equations (3) and (4), and gathering constants so that ν_{AB} is in cm^{-1} and the masses of the atoms are in

atomic mass units, gives k_{AB} in SI units of newtons per meter ($\mathrm{N\,m^{-1}}$):

$$k_{AB} = 5.8915 \times 10^{-5} \nu_{AB}^2 \mu_{AB} \qquad (5)$$

If the atoms concerned are ^{12}C and ^{16}O, then

$$k_{\mathrm{CO}} = 4.0393 \times 10^{-4} \nu_{\mathrm{CO}}^2 \qquad (6)$$

Clearly, calculating the force constant of a diatomic molecule is simple if we know its vibrational frequency.

Unfortunately, the finding of a set of force constants for a polyatomic molecule is greatly complicated by the fact that distorting one bond will affect all the other bonds in the molecule to some extent. A rigorous description of the problem of finding force constants from frequencies (and *vice versa*) in polyatomic molecules has been given by Wilson, Decius, and Cross.[4] Here a simpler, almost qualitative approach, is presented.

Equation (5) could have been written as

$$k_{AB}\mu_{AB}^{-1} - 5.8915 \times 10^{-5} \nu_{AB}^2 = 0$$

or, more conveniently,

$$k_{AB}\mu_{AB}^{-1} - \lambda_{AB} = 0 \qquad (7)$$

If the bonds in a polyatomic molecule were to vibrate in total isolation (i.e., without affecting any other bonds in the molecule), there would be a series of equations similar to equation (7):

$$\begin{aligned} k_1\mu_1^{-1} - \lambda_1 &= 0 \\ k_2\mu_2^{-1} - \lambda_2 &= 0 \\ k_3\mu_3^{-1} - \lambda_3 &= 0 \end{aligned} \qquad (8)$$

and so on.

Unfortunately, in real molecules the situation is not that simple. Stretching a bond in a polyatomic molecule has consequences for every other bond in the molecule, both in terms of the alteration of orbital energies (and by implication, the strength of the bonds) and the mechanical movement of neighbor atoms. The effects on the orbital energies can be thought of as a matrix containing all the force constants (called the F matrix). The F matrix contains **stretching force constants** along the diagonal (e.g., k_1, k_2, k_3, etc.) and off-diagonal terms, which are called **interaction constants** (k_{12}, k_{13}, k_{23}, etc.). Similarly, the matrix with inverse reduced masses (called the G matrix) contains off-diagonal terms for atoms, which are common between two bonds, although the G matrix elements linking distortions with no atom in common are zero. Short-circuiting some involved mathematics then, this reduces our overall problem to a single secular equation:

$$|FG - \lambda E| = 0 \qquad (9)$$

The off-diagonal terms in λ have been removed (simply because they do not exist), while the diagonal elements occur with coefficients of unity.

Theoretically then, given the complete structure of a molecule (from which the G matrix can be constructed) and all the force constants (the force field from which the F matrix can be constructed), we can calculate the vibrational frequencies. Unfortunately, the problem is nearly always the other way round. We invariably have the observed vibrations and need to calculate force constants. The basic problem with calculating force fields is that a nonlinear molecule of N atoms has $3N - 6$ fundamental vibrations and there are $(N^2 + N)/2$ independent force constants. Clearly then, for substantial transition metal carbonyl molecules, such as *cis*-$Cr(CO)_4(PF_3)_2$ for example, there are (even allowing for symmetry) many more force constants than observable fundamental frequencies. So, even in the most sophisticated force fields, approximations will appear in some form or the other. A 'general quadratic valence force field' (GQVFF)[5] seeks to use harmonic frequencies and to take account of all terms in the F and G matrices. In truth, the GQVFF is the only way to find a 'real' solution to equation (9). A general procedure for a GQVFF study is as follows: high-resolution IR and Raman spectra are taken; intensity data are collected; fundamental, combination, and overtone bands are analyzed; and related species are compared to establish trends and aid the assignment of fundamental vibrations. Isotopic substitution is routinely used to give a chemically identical molecule with atoms of different masses (i.e., the F matrix is unchanged but the G matrix has different elements). This, hopefully, provides sufficient additional data to ensure that the number of observed frequencies equals or is greater than the number of force constants. After all accessible information has been gathered, it is processed to give a force field. This has, for many years now, been accomplished by computer programs that can optimize a solution to a 'best fit' situation and provide some feel for the errors that are present in the measurements. This list of prerequisites for a GQVFF study limits the enthusiasm for undertaking such work. In his study of the group 6 hexacarbonyls ($Cr(CO)_6$, $Mo(CO)_6$, $W(CO)_6$), Jones[6] collected and analyzed IR and Raman spectra of the $M(^{12}C^{16}O)_6$ species in the gas phase, cyclohexane or CCl_4 solution, and as solids. He then repeated the entire process for the $M(^{12}C^{18}O)_6$ and $M(^{13}C^{16}O)_6$ species. Even then, for $Cr(CO)_6$, a 'unique solution' depended on some minor, but still fairly arbitrary, approximations.

Clearly, a method that requires such devotion will only ever attract a small number of protagonists. A different approach has been adopted for metal carbonyls, which arises from an interesting situation.

3 ENERGY FACTORED FORCE FIELDS

The vibrational spectra of metal carbonyls have absorptions that involve the M–C–O unit in the regions given in Table 1.

Notice that the ν(CO) vibrations are much higher in frequency than all other involving the M–C–O unit. Thus, it is not unreasonable to think of the ν(CO) modes as completely C–O stretching. Taking this thought one stage further, we might argue that, while coupling between different ν(CO) modes occurs (via off-diagonal terms in the F matrix), coupling between ν(CO) and any other vibration can be neglected. By this process, usually described as energy factoring, we radically reduce the sizes of the F and G matrices. In effect, we are blinkered so that we totally ignore every vibration except those assigned as 'C–O stretching' modes. In the F matrix, all terms which link the displacement of a C–O bond to the change in any other bonds (apart from another CO group) are neglected. This means that only two types of force constant remain in the F matrix: C–O stretching force constants (k_{CO}) along the diagonal, and CO–CO interaction constants ($k_{\mathrm{CO,CO}}$) as off-diagonal terms. The G matrix is reduced to an array containing the reciprocal mass of the CO group as the only elements (along the diagonal) since no two CO groups have a common atom. For the spectroscopist, a carbonyl such as $Ni(CO)_3PF_3$ might have a rich and interesting spectrum, but in trying to glean some information about the bonding within the molecule, we here would only be interested in the two sharp, intense bands in the ν(CO) region.

This approach was first described in detail by Cotton and Kraihanzel in 1962.[7] The *Cotton–Kraihanzel Force Field* (CKFF) was very quickly taken up by workers in the field and extensively used as a tool for analyzing ν(CO) frequencies to produce force constants that made chemical sense and were readily accessible. Now, with its application in metal nitrosyl[8] and dinitrogen spectroscopy[9] the CKFF often appears under the more general name of the *Energy Factored Force Field* (EFFF) or *Frequency Factored Force Field* (F^4). An equally important paper, by Haas and Sheline,[10] followed Cotton's pioneering work and investigated the mathematics rather more fully, and facilitated work on isotopic species.

However, the Cotton–Kraihanzel force field and the entire philosophy of energy factoring was sharply criticized by Jones who contended that the CKFF yielded CO force constants, which showed some consistency of pattern but which had no theoretical foundation except in 'gross approximation'.[5] The validity of the EFFF was further called into question following the GQVFF study of the group 6 hexacarbonyls.[6] The GQVFF force constants (especially the CO–CO interaction constants) calculated were *very* different from those obtained by using anharmonic frequencies in an EFFF. This meant that the proposal that (in octahedral complexes) the *cis* and *trans* CO–CO interaction constants should be related by:

$$k_{trans} = 2k_{cis} \tag{10}$$

was extremely dubious. It remained, however, a useful approximation when there were more EFFF force constants than observable frequencies and, for anharmonic frequencies at least, it seemed to work. For example, the monosubstituted octahedral complexes $M(CO)_5L$ (C_{4v} point group) have four fundamental ν(CO) modes ($2a_1 + b_2 + e$). Unfortunately, there are five force constants, which means that the problem is underdetermined with one degree of freedom. However, this can be removed by using equation (10) and a 'solution' can be obtained. If the b_2 mode is not observed (it is, strictly, IR-inactive), Cotton approximated further and reduced all the CO–CO interactions to a single parameter, k_i:

$$k_{cis} = \tfrac{1}{2}k_{trans} = k_i \tag{11}$$

Confusingly, in the light of Jones' work,[11] a number of studies by Bor[12] showed that the EFFF was capable of accurately analyzing complicated isotopic spectra. Elsewhere, Turner and coworkers were producing transition metal carbonyl fragments (e.g., $Mo(CO)_5$, $Fe(CO)_3$) in low-temperature matrices and using the EFFF to fit observed frequencies very closely to a set of force constants.[13] Like Bor, they were not using completely substituted species, but the whole range of isotopomers (e.g., $Mo(^{12}C^{16}O)_{5-x}(^{13}C^{16}O)_x x = 0–5$). Remarkably, in view of Jones' comments, an entire spectrum was regularly being fitted with an average error of less than 1 cm^{-1} with a unique set of EFFF force constants.

Obviously, there is a dilemma here. Without doubt, the EFFF can be used to fit complicated isotopic spectra with remarkable accuracy, and yet the force constants it uses appear to be at variance with the 'true' force constants. If the F matrix of the EFFF is only a gross approximation of the 'true' (viz. GQVFF) F matrix, then why does the EFFF work so well?

Isotopic substitution in metal carbonyl complexes does not alter the force constant matrix, but changes the elements along the diagonal of the simplified EFFF G matrix from the inverse reduced mass of $^{12}C^{16}O$ to the inverse reduced mass of the isotopic group (most frequently $^{13}C^{16}O$, although $^{12}C^{18}O$ was commonly used for earlier studies[14]). Relevant data for the commonly used isotopes in CO is given in Table 2.

When the molecule is completely substituted by isotopically different CO, the ν(CO) frequencies of the fully

Table 1 Vibrations associated with $M(CO)_n$ complexes

Approximate description	Range (cm^{-1})
C–O stretching ν(CO)	2150–1750
M–C–O bending δ(MCO)	700–500
M–C stretching ν(MC)	500–300
C–M–C bending δ(CMC)	150–50

Table 2 Mass data for $^{x}C^{y}O$ ($x = 12,13$; $y = 16,18$)

	$^{12}C^{16}O$	$^{13}C^{16}O$	$^{12}C^{18}O$	$^{13}C^{18}O$
Reduced mass	6.85621	7.17241	7.19987	7.54937
Reduced mass ratio	1.00000	0.97771	0.97586	0.95300

substituted molecule should be related to those of the parent (all $^{12}C^{16}O$) molecule by

$$\nu' = \left(\frac{\mu}{\mu'}\right)^{\frac{1}{2}} \nu = R\nu \tag{12}$$

where ν and ν' are the frequencies of the parent and the fully substituted molecule, respectively, and μ and μ' are the reduced masses of the $^{12}C^{16}O$ and the isotopic CO. The constant R has been called (somewhat incorrectly) the reduced mass ratio. Unfortunately, equation (12) is not found to be absolutely accurate in practice. When $^{12}C^{16}O$ is replaced by $^{13}C^{16}O$ ($R = 0.977709$), the differences between observed and calculated frequencies are generally low. However, when $^{12}C^{18}O$ ($R = 0.975855$) replaces $^{12}C^{16}O$, errors of up to 5 cm^{-1} are commonplace. Bor[15,16] used the idea of an ‘effective reduced mass ratio’, which reduces the error, but this is clearly hiding problems within the EFFF. The double assumptions that anharmonicity (up to 40 cm^{-1} in some cases) can be neglected and that M–C/C–O coupling is negligible are breaking down.

Burdett *et al.*[17] showed that, to fit isotopic spectra accurately, the EFFF needed two corrections: a factor that takes into account the particular isotope of CO used and a further correction to ameliorate the effects of using anharmonic frequencies. The effect of the neglect of M–C/C–O coupling was originally explained by Miller[18] in terms of an x-factor, which depended on the particular CO isotope being used. Anharmonicity is accounted for by another correction that could be determined from the all-$^{12}C^{16}O$ molecule and the reduced mass ratio.

The effect of these two corrections is best shown (in Table 3) by the close examination of the t_{1u} mode of various isotopomers of $Cr(CO)_6$ in methane matrices at 20 K.

The convincing fit is a considerable improvement on the simplest equation. For other carbonyls and other modes, the dramatic reduction in error is similar. However, it is not possible to apply the x-shift and the anharmonicity correction unless the GQVFF force field and the anharmonicity corrections are known. That said, some useful generalizations can be outlined:

1. the shift due to anharmonicity is always positive for $^{13}C^{16}O$, $^{12}C^{18}O$, and $^{13}C^{18}O$;
2. the x-factor shift is negative for $^{13}C^{16}O$, but positive for $^{12}C^{18}O$ and $^{13}C^{18}O$.

Table 3 Observed and calculated wavenumbers for the $t_{1u}\nu$(CO) mode of $Cr(^{a}C^{b}O)_6$ (a = 12, 13; b = 16, 18)

	$^{12}C^{16}O$	$^{13}C^{16}O$	$^{12}C^{18}O$	$^{13}C^{18}O$

[a]Used to calculate other frequencies (in methane matrices at 20 K).

The general conclusion from these observations is that $^{13}C^{16}O$ will follow the restrictions of the EFFF best because the shifts caused by anharmonicity and M–C/C–O coupling are of similar magnitude and opposite in sign. We can also see that Bor’s effective reduced mass arises through combining the corrections for M–C/C–O coupling and anharmonicity into a single parameter.

The vibrational frequencies of a fully isotopically substituted carbonyl are more or less related to those of the parent molecule in such a way that no new information about the force field can be learned. The situation is different when molecules are partially substituted; $Cr(CO)_6$ is used to illustrate the point. $Cr(^{12}C^{16}O)_6$ has three fundamental C–O stretches: a_{1g} (Raman), e_g (Raman), and t_{1u} (IR). The force constants that are required are a single stretching force constant (k_{CO}), an interaction constant for mutually *cis* CO groups (k_{cis}), and another interaction constant for mutually *trans* CO groups (k_{trans}). There are three absorptions and three fundamentals, so the force field is fully determined. If, instead of the parent molecule, we had $Cr(^{12}C^{16}O)_5(^{13}C^{16}O)$ we would have a molecule with C_{4v} symmetry and five fundamental ν(CO) bands ($3a_1 + b_2 + e$). With five observed frequencies and only three force constants the force field can be optimized to give a best fit. Access to the entire range of isotopomers in the $Cr(^{12}C^{16}O)_{6-x}(^{13}C^{16}O)_x$ series would provide many more observable absorptions than force constants. The best fit force field can be defined as that which reproduces a set of frequencies closest to those observed. From the discussion above, a $^{12}C^{16}O/^{13}C^{16}O$ mixture would be expected to give low mean errors for $^{12}C^{16}O/^{12}C^{18}O$, with $^{12}C^{16}O/^{13}C^{18}O$ giving substantially higher mean errors; this is indeed the case. When Bor’s effective reduced mass is introduced as an additional variable, the errors in $^{12}C^{16}O/^{12}C^{18}O$ and $^{12}C^{16}O/^{13}C^{18}O$ spectra become comparable with those for $^{12}C^{16}O/^{13}C^{16}O$.

A point to be made here, most forcibly, is that, although the EFFF is an *approximate* force field, it readily produces force constants that are *valid* (in the sense that they provide crucial information about chemical bonding) and *reliable*.

4 CO–CO INTERACTION CONSTANTS

Without a large number of GQVFF studies on carbonyl complexes the actual relationship between EFFF and GQVFF interaction constants will not be resolved. This does not mean, however, that the CO–CO interaction constants are of no value. Indeed, the magnitude of the interaction constant had long been thought of as a strong indicator of π-bonding within M-C-O units;[19] for a large number of tetrahedral $Ni(CO)_3(L)$, $Ni(CO)_2(L)_2$, and $Co(CO)_2(NO)(L)$ complexes there is an excellent linear correlation[20] between the CO-stretching force constant, k_{CO}, and the associated CO–CO interaction constant, k_i:

$$k_i = 203 - 0.983k_{CO} \tag{13}$$

So, while remaining as an unknown and complex mixture of GQVFF force constants, k_i must reflect systematic changes in these ‘true’ force constants. Similar straight lines are found for CO groups at 90°, 120°, and 180°. In summary, if two CO groups (with force constants k_1 and k_2) are bonded to a metal atom M, the EFFF interaction constant (k_{12}) is given by

$$k_{12} = A - B\left[\frac{(k_1 + k_2)}{2}\right] \tag{14}$$

where A and B are empirical constants (given in Table 4) for a given C–M–C bond angle. The importance of these relationships is that it removes the need for the arbitrary constraints such as those proposed by Cotton[7] and, later, by van der Kelen[21] and it provides an excellent way of removing various degrees of freedom from force fields.

Let us take the simple case of $Ni(CO)_4$ to demonstrate the usefulness of equation (14).

A dilute solution of $Ni(CO)_4$ in heptane shows a single band at 2045.7 cm^{-1} in the ν(CO) region.[22] This is the t_2 asymmetric stretch. The symmetric stretch (a_1) is Raman-active only. The EFFF force constants required for $Ni(CO)_4$ are k_{CO} and k_i (the CO-stretching force constant and the CO,CO interaction constant respectively) and it would appear impossible to calculate two force constants from one ν(CO) absorption. However, the symmetry force constant for the t_2 mode is

$$K(t_2) = k_{CO} - k_i \tag{15}$$

Table 4 Values of A and B for common C–M–C bond angles

Bond angle	A (N m^{-1})	B (dimensionless)
90	180	0.0929
109	203	0.0983
120	221	0.1115
180	241	0.1134

which, using equation (15), can be rewritten as

$$K(t_2) = k_{CO} - (A - Bk_{CO}) \tag{16}$$

This can be rearranged to give

$$k_{CO} = \frac{(K(t_2) + A)}{(1 + B)} \tag{17}$$

from which it can be calculated that $k_{CO} = 1723.9$ Nm^{-1} and $k_i = 33.6$ Nm^{-1}, and coincidentally, predicting that the a_1 stretch would occur at 2125.3 cm^{-1} (observed in the Raman spectrum at 2125.0 cm^{-1}).

It is a simple enough matter to extend this to complexes which, even if all the ν(CO) absorptions were observed, would still have more force constants than observed frequencies (i.e., underdetermined force fields). As an example, consider the force field (Table 5) of $HMn(CO)_5$ isolated in a methane matrix at 20 K which has three IR absorptions and five force constants. The close correspondence between the force constants calculated by different means is quite striking.

Carbonyl anions and cations are found not to obey equation (14) in its most simple form. They can be included in the scheme, however, if the charge is taken into account via a parameter C (the charge factor) to give the more complete relationship

$$k_{a,b} = A - B\left[\frac{(k_a + k_b)}{2} - C\right] \tag{18}$$

It is found that C (120 N m^{-1}) is independent of the structure of the molecule. If a molecule is doubly charged, the correction is $2C$. The effect of charges on the force constants of the three d^6 hexacarbonyl species $V(CO)_6{}^-$, $Cr(CO)_6$ and $Re(CO)_6{}^+$ is illustrated in Table 6.

Table 5 Energy factored force field for $HMn(CO)_5$

	Approx.^{a}	Exact^b
k_2	1656	1652.42
k_1	1692	1690.61
k_{12}	28	32.60
$k_{11(cis)}$	23	24.72
$k_{11(trans)}$	49	48.27

^{a}Using equation (14). ^{b}Best fit values from isotopic spectra. All force constants in Nm^{-1}.

Table 6 Force constants of d^6 hexacarbonyls[1]

	k$_{CO}$	k$_{cis}$	k$_{trans}$
$V(CO)_6{}^-$	1454.9	33.2	60.4
$Cr(CO)_6$	1644.2	26.1	53.6
$Re(CO)_6{}^+$	1809.2	21.8	53.2

In the light of the k_{CO}/k_i relationships of table 4. Cotton's durable approximation (equation 10) has been reevaluated and the empirical relationship

$$k_{trans} = 21.3 + 1.22k_{cis} \quad (19)$$

has been proposed.[23] This equation agrees very well with Cotton's approximation when k_{CO} is in the region of $1650\,\mathrm{N\,m^{-1}}$. Coincidentally, this is almost the same as the force constants for the group 6 hexacarbonyls.

5 CALCULATING FORCE CONSTANTS FROM ν(CO) SPECTRA

5.1 Force Constant Nomenclature and Symmetry Considerations

Before describing how force fields may be calculated, let us clarify the nomenclature used. The stretching force constants of a metal carbonyl will be numbered sequentially as k_1, k_2, k_3 and so on. The CO groups denoted by k_1 will be the most common. The CO,CO interaction constants will refer to the CO groups interacting. Thus, k_{11} arises in the F matrix where two k_1 CO groups interact. So, for a molecule such as $Fe(CO)_5$ there will be five EFFF force constants: k_1 (for the equatorial CO groups), k_2 (for the axial CO groups) and three interaction constants, k_{11}, k_{12}, k_{22}. Even where there is only one type of carbonyl group in the molecule, we will adhere to this convention for the sake of consistency.

We will, throughout this section, refer to 'symmetry force constants' (K(Γ) where Γ is the symmetry of the vibrational mode) derived directly from observed frequencies. Since we will be dealing with all-$^{12}C^{16}O$ molecules as a matter of course, these are simply found *via* a relationship analogous to equation (6):

$$K(\Gamma) = 4.0393 \times 10^{-4}\nu(\Gamma)^2_{CO} \quad (20)$$

The number of force constants required for the force fields of carbonyls depends, of course, on the number of CO groups and the point group of the complex. For example, $Mo(CO)_5$ PF_3 is treated as a C_{4v} structure based on an octahedron. This is not strictly true since the PF_3 ligand has a threefold rather than a fourfold axis of symmetry and $Mo(CO)_5$ PF_3 is, at best, C_s. However, most ligands behave more or less as single spherical entities and it is more convenient to regard them as such. However, a note of caution must be registered in that some ligands, for example the phosphites, such as $P(OMe)_3$, distort the CO framework significantly and reduce the symmetry away from the idealized situation.

Extending the example of $Mo(CO)_5PF_3$ further, this complex has four equivalent CO groups *cis* to the PF_3 ligand and a chemically distinct CO group *trans* to the PF_3. Therefore the EFFF of this complex needs two CO-stretching force constants, k_1 for the more numerous CO groups *cis* to PF_3 and k_2 for the CO group *trans* to PF_3. In the F matrix of the molecular force field these constants would occupy the positions along the diagonal. Furthermore, we need off-diagonal terms in the F matrix, that is, the interaction constants. There are three interaction constants: $k_{11(cis)}$ linking mutually cis equatorial CO groups, $k_{11(trans)}$ for mutually trans CO groups and k_{12} linking the axial CO group with the equatorial CO groups. The EFFF F matrix for this molecule is shown below:

$$F: \begin{vmatrix} k_1 & k_{11(cis)} & k_{11(trans)} & k_{11(cis)} & k_{12} \\ k_{11(cis)} & k_1 & k_{11(cis)} & k_{11(trans)} & k_{12} \\ k_{11(trans)} & k_{11(cis)} & k_1 & k_{11(cis)} & k_{12} \\ k_{11(cis)} & k_{11(trans)} & k_{11(cis)} & k_1 & k_{12} \\ k_{12} & k_{12} & k_{12} & k_{12} & k_2 \end{vmatrix} \quad (21)$$

The text below describes the force fields and possible ν(CO) absorptions of the various types of mononuclear transition metal carbonyl complex. Although it is not an exhaustive survey, most of the important groups are covered. A summary of the structures covered is given in Table 7. Where a ligand is denoted as L it is a two-electron donor (e.g., PF_3) and where it is X it is a one-electron donor (e.g., Br).

Before attempting to calculate a force field, it is best to ensure that the wavenumbers of the ν(CO) bands are accurately known and the relative intensities are also known. A very useful quantity to have at hand at the start of the process that changes frequencies into force constants is $\sum K$, the sum of all the symmetry force constants (allowing for degeneracy). For example, $\sum K$ for $Cr(CO)_6$ would be found by:

$$\sum K = K(a_{1g}) + 2K(e_g) + 3K(t_{1u}) \quad (22)$$

For any carbonyl complex $M(CO)_x(L)_y$, the mean CO-stretching force constant ($\bar{k}_{CO}$) is

$$\bar{k}_{CO} = \frac{\sum K}{x} \quad (23)$$

where x is the number of CO groups. In any iterative procedure for calculating force constants, $\bar{k}_{CO}$ is a very good starting point.

5.2 Monocarbonyls

The case of a monocarbonyl is the most simple. The force constant is given simply by

$$k_1 = 4.0393 \times 10^{-4}\nu^2_{CO} \quad (24)$$

There will be a weak feature to lower frequency due to $^{13}C^{16}O$ in natural abundance. Check that this band is in

Table 7 Energy factored force fields of mononuclear carbonyl complexes

Point group	Example	ν(CO) modes	Force constants	
			Stretching	Interaction
Monocarbonyls				
C_{nv}	$Mo(L)_5CO$	a_1	k_1	
Dicarbonyls				
D_{4h}	*trans*-$Mo(CO)_2(L)_4$	$a_{1g} + b_{2u}$	k_1	k_{11}
D_{3h}	*trans*-$Fe(CO)_2(L)_3$	$a_1' + a_2''$	k_1	k_{11}
C_{2v}	$Ni(CO)_2(L)_2$	$a_1 + b_2$	k_1	k_{11}
C_s	$Co(CO)_2(NO)(L)$	$a' + a''$	k_1	k_{11}
Tricarbonyls				
D_{3h}	*trans*-$Fe(CO)_3(L)_2$	$a_1' + e'$	k_1	k_{11}
C_{3v}	$Ni(CO)_3(L)$	$a_1 + e$	k_1	k_{11}
C_{2v}	*mer*-$Mo(CO)_3(L)_3$	$2a_1 + b_2$	k_1, k_2	k_{11}, k_{12}
C_s	*fac*-$Re(CO)_3(L)_2X$	$2a' + a''$	k_1, k_2	k_{11}, k_{12}
Tetracarbonyls				
T_d	$Ni(CO)_4$	$a_1 + t_2$	k_1	k_{11}
D_{4h}	*trans*-$Cr(CO)_4(L)_2$	$a_{1g} + b_{2g} + e_u$	k_1	$k_{11(cis)}, k_{11(trans)}$
C_{3v}	$HCo(CO)_4$	$2a_1 + e$	k_1, k_2	k_{11}, k_{12}
C_{2v}	$Fe(CO)_4(PF_3)$	$2a_1 + b_1 + b_2$	k_1, k_2	k_{11}, k_{22}, k_{12}
C_s	$Cr(CO)_4(CS)(L)$	$3a' + a''$	k_1, k_2, k_3	$k_{11}, k_{12}, k_{13}, k_{23}$
Pentacarbonyls				
D_{3h}	$Fe(CO)_5$	$2a_1' + a_2'' + e'$	k_1, k_2	k_{11}, k_{22}, k_{12}
C_{4v}	$Mn(CO)_5X$	$2a_1 + b_2 + e$	k_1, k_2	$k_{11(cis)}, k_{11(trans)}, k_{12}$
Hexacarbonyls				
O_h	$W(CO)_6$	$a_{1g} + e_g + t_{1u}$	k_1	$k_{11(cis)}, k_{11(trans)}$

the correct place by multiplying the $\nu(^{12}C^{16}O)$ frequency by 0.977709 to give that for $\nu(^{13}C^{16}O)$.

5.3 Dicarbonyls

The force field for dicarbonyls with equivalent CO groups (e.g., $Ni(CO)_2(L)_2$ complexes[24]) is straightforward, since there are as many absorptions as there are force constants. The secular equations and force constants for a C_{nv} dicarbonyl are shown in Table 8, but for different point groups the only difference is the convention of labeling the symmetric and asymmetric modes:

In general, the lower frequency (b_2) mode will be considerably stronger than the a_1 mode. The C–M–C bond angle, θ, can be estimated from the relative intensities of the a_1 and b_2 bands:

$$\theta = 2\tan^{-1}\sqrt{\frac{I(b_2)}{I(a_1)}} \qquad (25)$$

Table 8 $M(CO)_2$ dicarbonyl with C_{nv} or higher symmetry

K(Γ)	$K(a_1) = k_1 + k_{11}$
	$K(b_2) = k_1 - k_{11}$
	$\sum K = K(a_1) + K(b_2)$
Force field	$k_1 = \sum K \big/ 2$
	$k_{11} = k_1 - K(b_2)$

where $I(b_2)$ and $I(a_1)$ are the intensities of the absorptions.

An identical treatment to that above can be carried out for dicarbonyls of point group C_s (e.g., $Co(CO)_2(NO)(L)$ complexes[25]). The only difference is that the a_1 mode is now of symmetry a' and the b_2 mode is reclassified as a''. In octahedral species of the type *trans*-$M(CO)_2(L)_4$ (point group D_{4h}) and trigonal-bipyramidal structures of the type *trans*-$M(CO)_2(L)_3$ (point group D_{3h}) there are two ν(CO) vibrations, a symmetric and an asymmetric stretch.[26] The symmetric stretch is at higher frequency (by virtue of the fact that CO–CO interaction constants are always positive) and is Raman-active only. If both frequencies are known, the procedure is identical to complexes of the C_{2v} type. If Raman spectra are not available, the force constants can be estimated by using equation (18) and the asymmetric stretch.

In dicarbonyls where the CO groups are chemically different the force field is underdetermined with three force constants (k_1, k_2, and k_{12}) and only two absorptions which have the same symmetry (a′ for C_s, a for C_1). Without any further information, only equation (18) can be invoked, since

$$k_{12} = A - B\left\{\frac{[K(a)_1 + K(a)_2]}{2}\right\} \qquad (26)$$

This would, assuming a particular C–M–C bond angle to provide appropriate values of A and B, enable an approximate force field to be calculated. That said, accurate force constants can only be obtained from the isotopic spectrum.

5.4 Tricarbonyls

Tricarbonyls with D_{3h} symmetry (see Table 9) occur commonly in complexes of the type $Fe(CO)_3(L)_2$[27] (and their ruthenium and osmium analogs). There are two ν(CO) modes, an a_1' symmetric stretch, which is inactive in the IR, and an e' stretch. These two absorptions are sufficient to determine the two force constants.

The a_1' band is IR-inactive but is often present as a very weak feature. If Raman spectra are not available to confirm the location of this absorption, the force field can be determined from the isotopic spectrum. Naturally abundant $^{13}C^{16}O$ would provide for 3.3% of the molecules being isotopically substituted and this would give rise to the usual satellite bands.

Examples of tricarbonyl molecules with C_{3v} symmetry are not difficult to find (see Table 10). A multitude of $Ni(CO)_3L$[24] and *fac*-$M(CO)_3(L)_3$ (M = Cr, Mo, W)[28] complexes fall into this category. The treatment is very similar to that for the D_{3h} tricarbonyls above but, if anything, simpler since both absorptions ($a_1 + e$) are active in both the IR and Raman.

The force field is, therefore, fully determined. Since both absorptions are present in the infrared, it is unlikely that isotopic data would be required for C_{3v} tricarbonyl complexes.

Tricarbonyl complexes of C_{2v} symmetry are represented by the octahedral *mer*-$M(CO)_3(L)_3$ species[29] and equatorially substituted trigonal-bipyramid $M(CO)_3(L)_2$ complexes (see Table 11). There are three ν(CO) modes ($2a_1 + b_2$) and four force constants (k_1, k_2, k_{11}, k_{12}) in the force field. The higher frequency a_1 mode tends to be sharp and of quite low relative intensity. The b_2 mode is much stronger than the low-frequency a_1 mode, but the two may overlap. The problem is, in any case, underdetermined with one degree of freedom. If k_1 is defined as the force constant for the two equivalent CO groups and k_2 as the force constant for the single, chemically different CO group, two interaction constants (k_{11} and k_{12}) are required to complete the force field. Although a full solution of the force field is always possible using isotopic CO, a simpler solution will be found *via* equation (18).

This method of calculating the force field introduces two constraints where only one is strictly necessary. An iterative balancing of the force constants may be more illuminating. A better solution would be found using isotopic data. Given reasonable spectra showing enough satellite bands, the force field can be manipulated to give a best fit.

An important class of tricarbonyls are of C_s symmetry (see Table 12). These include such species as *fac*-$Re(CO)_3$(L−L)X where L−L is a bidentate ligand (for example, 2,2′-bipyridyl) and X is a halogen or pseudohalogen.[30] There has been considerable interest in these species recently as they have interesting catalytic[31] and photochemical[32] properties. The EFFF treatment for these complexes is very similar to that for the C_{2v} tricarbonyls.

The infrared spectrum of these complexes is like the *fac*-substituted $M(CO)_3(L)_3$ complexes where the e mode is split. The higher frequency a' mode is often relatively quite intense and the lower a' and a'' are usually quite close in frequency and, although the latter is usually more intense, overlap may make it difficult to assign them unambiguously from the IR spectrum alone. Judicious use of equation (18) usually solves assignment problems.

Table 9 $M(CO)_3$ tricarbonyl with D_{3h} symmetry

K(Γ)	$K(a_1') = k_1 + 2k_{11}$
	$K(e') = k_1 - k_{11}$
	$\sum K = K(a_1') + 2K(e')$
Force field	$k_1 = \sum K \big/ 3$
	$k_{11} = k_1 - K(e')$

	$k_{11} = k_1 - K(a'')$
	$k_2 = \sum K - 2k_1$
	$k_{12} = A - B[k_1 + k_2]/2$

5.5 Tetracarbonyls

The force field of tetrahedral $M(CO)_4$ (e.g., $Ni(CO)_4$, $[Co(CO)_4]^-$) is fully determined if the a_1 (Raman) and t_2 (IR and Raman) are both observed (see Table 13).

If the Raman spectrum is not available, the force field can be determined from the naturally occurring isotopic species (≈4.4% abundance), which belongs to the point group C_{3v}, or by using equation (18).

Most octahedral disubstituted $M(CO)_4(L)_2$ complexes have a cis isomer of C_{2v} symmetry (discussed below) and a trans isomer, which has D_{4h} symmetry if the ligand has fourfold symmetry or is a single atom (see Table 14). D_{4h} tetracarbonyl molecules have a center of symmetry and none of the vibrations appear in both IR and Raman spectra. In the CO region there are three vibrations: a_{1g} (Raman), b_{2g} (Raman), and e_u (IR). Given all three ν(CO) frequencies, the force field (k_1, $k_{11(cis)}$, and $k_{11(trans)}$) is fully determined.

The IR spectrum of complexes such as these will therefore show a single band (the e_u mode). If Raman data are unavailable, and the supposedly IR-inactive bands are not observed as weak features,[33] reasonably accurate force constants can be obtained from equation (18). More usually, asymmetry in the ligand or distortion of the force field due to solvent–CO interactions makes both the Raman-active bands very slightly allowed in the IR. Indeed, *trans*-$[(i\text{-PrO})_3P]_2Mo(CO)_4$ shows pronounced effects due to the irregular packing of the phosphite ligands. Not only are the a_{1g} and b_{2g} bands readily observable, but the e_u band is rather broader than is usually found. In the absence of such data, isotopic spectra will provide enough information to resolve the problem. The monosubstituted molecule is present at 4.4% (natural abundance). The force fields of this type of molecule invariably support Cotton's approximation (equation 10) in that:

$$K(b_{2g}) \approx k_1 \tag{27}$$

If a species $M(CO)_4$ is intermediate between tetrahedral and square planar, it belongs to the point group D_{2d}. The a_{1g}, b_{2g}, and e_u modes of the D_{4h} structure are relabeled a_1, b_2, and e, respectively. All three modes are Raman-active, although the intensity of the e mode in the Raman spectrum is likely to be low if the distortion from square planar is small. The a_1 mode remains, formally, IR-inactive. The force field can be determined by using the equations for the D_{4h} tetracarbonyl above. It has been suggested that octahedral species of the D_{4h} type show some distortion toward D_{2d}, as the 'b_{2g}' mode of these complexes is often observed in their IR spectrum. This does not explain the appearance of the 'a_{1g}' mode in the IR and it is likely that some ligands (e.g., $P(OR)_3$) cause a considerable overall reduction in symmetry.

Many $Fe(CO)_4L$, $Ru(CO)_4L$, and $Os(CO)_4L$ complexes[34] have C_{3v} symmetry, along with a large number of $Co(CO)_4L$ compounds (see Table 15).[35] On the basis of the trigonal-bipyramidal structure, these complexes have a single ligand, occupying an axial site. Typically their IR spectra show a weak, sharp absorption at high frequency (the a_1 mode that is primarily due to the symmetric breathing mode of the equatorial CO groups), a moderately strong absorption (of a_1 symmetry, due to the motion of the axial CO group), and a very strong absorption at lower frequency (the asymmetric e mode). Unfortunately, the force field is underdetermined and it is necessary to resort to equation (18) for approximate force constants or to utilize isotopic spectra for an exact solution. At natural abundance, 1.1% of the molecules will have a $^{13}C^{16}O$ group in an axial position and 3.3% will be substituted in an equatorial position. The axially substituted molecule retains the symmetry of the parent. The equatorially substituted molecule belongs to the point group C_s and has four ($3a' + a''$) ν(CO) modes. If all the parent and naturally occurring isotope bands were observed, there would be eight frequencies with which to fix four force constants. It is unlikely, however, that this would be the case as all but two of the isotope bands are likely to be very weak. The use of equation (18) to fix at least one of the interaction constants makes the calculation of an approximate force field for these molecules quite simple.

Table 13 $M(CO)_4$ tetracarbonyls with T_d symmetry

	$K(e) = k_1 - k_{11}$
	$\sum K = K(a_1)_1 + K(a_1)_2 + 2K(e)$
Force field	$k_1 = (K(e) + A)/(1 + B)$
	$k_{11} = k_1 - K(e)$
	$k_2 = \sum K - 2k_1$
	$k_{12} = A - B[k_1 + k_2]/2$

Table 16 $M(CO)_4$ tetracarbonyls with C_{2v} symmetry

K(Γ)	$a_1: \begin{vmatrix} k_1 + k_{11} - K & 2k_{12} \\ 2k_{12} & k_2 + k_{22} - K \end{vmatrix} = 0$
	$K(b_1) = k_1 - k_{11}$
	$K(b_2) = k_2 - k_{22}$
	$\sum K = K(a_1)_1 + K(a_1)_2 + K(b_1) + K(b_2)$
Force field	$k_1 = (K(b_1) + A)/(1 + B)$
	$k_{11} = k_1 - K(b_1)$
	$k_2 = \left(\sum K - 2k_1\right) \Big/ 2$
	$k_{22} = k_2 - K(b_2)$
	$k_{12} = A - B[k_1 + k_2]/2$

Tetracarbonyls with C_{2v} symmetry (see Table 16), such as *cis*-$M(CO)_4(L)_2$ (M = Cr, Mo, W) and $M(CO)_4L$ (M = Fe, Ru, Os; L in an equatorial position in a trigonal bipyramid) are common.[33,36,37] There are four ν(CO) absorptions ($2a_1 + b_1 + b_2$) and five force constants (k_1, k_2, k_{11}, k_{22}, k_{12}), which means that the force field is underdetermined with one degree of freedom. One of the a_1 modes is at higher frequency and of lower intensity than the other three modes and the lower frequency a_1 mode is always higher in frequency than the b_2 mode. The ordering of the low-frequency a_1 and the b_1 mode is not easily predicted. Indeed, the IR spectrum of $Mn(CO)_4NO$, which is of this class, was initially confusing since the b_1 and low-frequency a_1 are accidentally degenerate.[38]

Using equation (18) to determine the force fields of octahedral *cis*-$M(CO)_4(L)_2$ complexes can be done in two ways. Either the b_1 or the b_2 modes can be used to obtain a set of force constants and the others can then be calculated. For equatorially substituted $M(CO)_4(L)$ complexes based on a trigonal bipyramid, the only variation is in changing the values of A and B in equation (18). While the force fields that this method produces are not exact, they are usually good enough to predict the a_1 modes with reasonable accuracy and enable the $^{13}C^{16}O$ satellite bands to be assigned. At natural abundance, 2.2% of the molecules will be substituted in an axial position and 2.2% in an equatorial position. All together, there are six possible absorptions because of the naturally occurring $^{13}C^{16}O$ in addition to the four modes of the all-$^{12}C^{16}O$ molecule.

Of even lower symmetry are the C_s, octahedral *cis*-$M(CO)_4(L_1)(L_2)$ complexes. The power of the EFFF in fitting isotopic spectra is, perhaps, best illustrated with a complex of this type: Poliakoff's matrix-isolated fragment *cis*-$Cr(CO)_4CS$.[39] The spectrum of a C_s tetracarbonyl complex shows three reasonably strong bands (all a' symmetry) and a very strong band (a'' symmetry), although overlap may reduce this number. The force field is badly underdetermined, with three degrees of freedom. Even so, using equation (18) gives surprisingly accurate results.

5.6 Pentacarbonyls

Pentacarbonyliron(0) is the best known example of a pentacarbonyl complex. Others in this category include $[Mn(CO)_5]^-$, $[Cr(CO)_5]^{2-}$, $Ru(CO)_5$, and $Os(CO)_5$. As they have D_{3h} symmetry (see Table 17), the energy factored force field requires five force constants but there are only four ν(CO) frequencies (only two of which appear in the infrared) so the force field is underdetermined. Two of the ν(CO) modes are fully symmetrical (a_1') and are IR-inactive. The asymmetric stretches are labeled a_2'' (due to the stretching of the axial CO groups) and e' (due to stretching of the equatorial CO groups). The e' mode is IR and Raman-active; the a_2'' mode is active in the IR only.

With the force field, we must use equation (18) or isotopic data to solve the force field. At natural abundance, isotopic labeling will occur in axial and equatorial positions, in 2.2% and 3.3% of the molecules, respectively. The axially substituted species belongs to the point group C_{3v}. The equatorially substituted species belongs to the point group C_{2v}. The a_2'' and one of the e' modes of the parent are relabeled b_1 and b_2, but are otherwise unchanged. The remaining modes belong to the representation a_1. Thus, there will be a total of six isotope bands in the IR spectrum of trigonal-bipyramidal $M(^{12}C^{16}O)_4(^{13}C^{16}O)$. Two will be readily apparent as satellites of the two IR absorptions, but the others will be much weaker. However, the observation of two isotope bands in the IR still leaves the problem underdetermined and isotopic enrichment by CO exchange is the only realistic answer to solving the force field and providing accurate force constants.

Complexes of the type $M(CO)_5L$ (e.g., $Mo(CO)_5PF_3$, $Cr(CO)_5CS$, $HMn(CO)_5$, $BrMn(CO)_5$) are among the most common and widely studied of carbonyl compounds.[40] There are, given both IR and Raman spectra, four ν(CO) absorptions ($2a_1 + b_2 + e$). At highest frequency is a generally sharp, often weak, feature that is (mainly) due to the in-phase (hence a_1 symmetry) motion of the four equatorial CO groups (see Table 18). To lower frequency is the b_2 mode which is, strictly, Raman-active only. However, this band very often appears as a weak feature in the IR spectrum, arising from asymmetric effects from either the ligand or the solvent.

Table 17 $M(CO)_5$ pentacarbonyls with D_{3h} symmetry

K(Γ)	$a_1': \begin{vmatrix} k_1 + k_{11} - K & \sqrt{6}k_{12} \\ \sqrt{6}k_{12} & k_2 + 2k_{22} - K \end{vmatrix} = 0$
	$K(a_2'') = k_1 - k_{11}$
	$K(e') = k_2 - k_{22}$
	$\sum K = K(a_1')_1 + K(a_1')_2 + K(a_2'') + 2K(e')$
Force field	$k_1 = (K(b_1) + A)/(1 + B)$
	$k_{11} = k_1 - K(b_1)$
	$k_2 = \left(\sum K - 2k_1\right) \Big/ 3$
	$k_{22} = k_2 - K(b_2)$
	$k_{12} = A - B[k_1 + k_2]/2$

Table 18 $M(CO)_5$ pentacarbonyls with C_{4v} symmetry

K(Γ)	a_1: $\begin{vmatrix} k_1 + 2k_{11(cis)} + k_{11(trans)} - K & 2k_{12} \\ 2k_{12} & k_2 - K \end{vmatrix} = 0$
	$K(b_2) = k_1 - 2k_{11(cis)} + k_{11(trans)}$
	$K(e) = k_1 - k_{11(trans)}$
	$\sum K = K(a_1)_1 + K(a_1)_2 + K(b_2) + 2K(e)$
Force field	$k_1 = (K(e) + A)/(1 + B)$
	$k_{11(trans)} = k_1 - K(e)$
	$k_2 = \sum K - 4k_1$
	$k_{11(cis)} = (k_1 - K(b_2) + k_{11(trans)})/2$
	$k_{12} = A - B[k_1 + k_2]/2$

Ligand asymmetry cannot be the whole story, as $Mn(CO)_5Br$ has a weak IR absorption corresponding to the b_2 mode. The remaining bands, as seen in the IR spectrum, are a very strong e mode (weak in the Raman) and a fairly strong a_1 mode that is mainly due to the stretching of the CO group trans to the ligand L. The order of the e and low-frequency a_1 modes is largely determined by the ligand. For strong π-acceptors (e.g., CS, PF_3), the a_1 mode is at higher frequency than the e mode. The situation is reversed for weaker π-acceptors (e.g., PPh_3, PMe_3). The number of force constants exceeds the ν(CO) absorptions by one and, so, the EFFF is underdetermined.

For more accurate force constants, we must use isotopic data. At natural abundance, 1.1% of the molecules will have a $^{13}C^{16}O$ group in an axial position and 4.4% will be isotopically substituted in an equatorial position. The axially substituted molecule retains the symmetry of the parent and only the a_1 modes are affected by the isotopic CO group. The high frequency a_1 mode of the axially substituted molecule is (for $^{13}C^{16}O$ in natural abundance) almost certainly too weak to be detected. The lower frequency a_1 mode will be very weak. The equatorially substituted molecule is of symmetry C_s and responsible for the stronger satellite bands. The a'' mode of *cis*-$M(^{12}C^{16}O)_4(^{13}C^{16}O)L$ is identical to the e mode of the parent and gives no new information. However, if one or more of the a' modes can be located they can be used to remove the degree(s) of freedom in the force field. The observation of the b_2 mode in the IR spectrum has been taken to indicate ligand asymmetry reducing the nominal symmetry of $M(CO)_5L$ complexes to C_s or lower. Additional to this, the e mode is usually broader than the other absorptions, which suggests a lifting of the twofold degeneracy.

5.7 Hexacarbonyls

Octahedral $M(CO)_6$[1,6] is a straightforward case. There are three ν(CO) absorptions (a_{1g} (Raman) + e_g (Raman) + t_{1u} (IR)) and three force constants in the force field (k_1, $k_{11(cis)}$, and $k_{11(trans)}$) (see Table 19).

The ordering $K(a_{1g}) > K(e_g) > K(t_{1u})$ is unambiguous since the interaction constants are always positive.

Table 19 $M(CO)_6$ hexacarbonyls with O_h symmetry

K(Γ)	$K(a_{1g}) = k_1 + 4k_{11(cis)} + k_{11(trans)}$
	$K(e_g) = k_1 - 2k_{11(cis)} + k_{11(trans)}$
	$K(t_{1u}) = k_1 - k_{11(trans)}$
	$\sum K = K(a_{1g})_1 + 2K(e_u) + 3K(t_{1u})$
Force field	$k_1 = \sum K \Big/ 6$
	$k_{11(trans)} = k_1 - K(t_{1u})$
	$k_{11(cis)} = (K(a_{1g}) - k_1 - k_{11(trans)})/4$

The monosubstituted species $M(^{12}C^{16}O)_5(^{13}C^{16}O)$ occurs at natural abundance to the extent of nearly 7%. The species belongs to the point group C_{4v} and the b_2 and e modes correlate with the e_g and t_{1u} modes, respectively, of $M(^{12}C^{16}O)_6$. The remaining modes are of symmetry a_1. Thus, the monosubstituted species should, in principle, give rise to three isotope bands. In the IR spectrum, one of these will be a lower frequency satellite of the strong t_{1u} mode, while the other two will be at a higher energy and much weaker.

6 APPLICATIONS OF CO FORCE CONSTANTS

There have been several attempts to use energy factored force constants, calculated from transition metal ν(CO) spectra, as probes into the nature of metal–ligand bonding[41] or reactivity,[42] as indicators of bond order.[43] A comprehensive study of the success (or otherwise) of these various studies has been published.[44]

One of the most successful systems[20] uses ligand effect constants and the k_{CO} for the triatomic metal monocarbonyl M–C–O. Assuming that ligand effect constants are additive, this model uses the simple equation

$$k_{CO} = k_d + \sum e_L^{\theta} \tag{28}$$

The parameter k_d is the force constant for the isolated monocarbonyl M(CO). The subscript ‘d’ draws attention to the fact that this parameter is more concerned with the number of d-electrons than the specific metal at the center. This means that $Cr(CO)_6$, $HMn(CO)_5$, and $[V(CO)_5PBu_3]^-$ will share a common value for k_d (*viz.* $k_6 = 1387\,N\,m^{-1}$). The terms contained in the summation are the ligand effect constants, which are transferable between metal centers. The values of k_d used are given in Table 20. In Table 21 are ligand effect constants for a variety of ligands. For ligands in an octahedral setting, two ligand effects constants (${e_L}^{cis}$ and ${e_L}^{trans}$) are required. In tetrahedra only one (${e_L}^{td}$) is needed and it is very easily calculated. For trigonal-bipyramidal species, three (${e_L}^{ax,ax}$, ${e_L}^{ax,eq}$ and ${e_L}^{eq,eq}$) are needed although ${e_L}^{eq,eq}$ is not always necessary since a large number of ligands only occupy an axial position in these systems.

Table 20 k_d Parameters

Period	k_5	k_6	k_7	k_8	k_9	k_{10}
1st	1373	1387	1444	1498	1554	1610
2nd	– [a]	1389	– [a]	1506	– [a]	1636
3rd	1353	1381	1445	1498	– [a]	1613

[a]Not determined, but probably close to the other group members.

It is quite a simple task to calculate ligand effect constants from force constants and *vice versa*. For example, the force constants for a $M(CO)_5L$ complex are given (in terms of equation 27) by:

$$k_1 = k_d + 3e^{cis}_{CO} + e^{trans}_{CO} + e^{cis}_L$$
$$k_2 = k_d + 4e^{cis}_{CO} + e^{trans}_L$$
$$k_{11(cis)} = 180 - 0.0929k_1$$
$$k_{11(trans)} = 241 - 0.1134k_1$$
$$k_{12} = 180 - 0.0929(k_1 + k_2)/2 \quad (29)$$

Using these equations, we can calculate ligand effect constants for some new ligand or, alternatively, calculate ν(CO) frequencies for a $M(CO)_5L$ complex with a known ligand.

The method has enjoyed considerable success in predicting ν(CO) frequencies for assumed structures[45] and assigning spectra. Much of the utility of the method stems from the ability to generate a force field for a supposed structure and then test this against experimental findings. For example, the ν(CO) frequencies for the whole series of unsaturated $Mo(CO)_{5-x}(PF_3)_x$ complexes isolated in CH_4 matrices at 20 K were predicted with a mean accuracy of 3 cm^{-1}.

The link between the matrix-isolation technique and metal carbonyl chemistry has had a relatively long and certainly fruitful history. The pairing began in the early 1960s with a series of experiments by Sheline and coworkers[46] using a variety of glassy matrices held at 77 K by liquid nitrogen. In 1969, Turner and Rest[47] began the study of carbonyls in less reactive matrices (e.g., argon) at lower temperatures (commonly 20 K). Comprehensive reviews of the matrix-isolation studies involving carbonyls exist.[48] Suffice it to say here that this work has produced some extremely interesting results and without using an energy factoring approach to the ν(CO) modes it is difficult to see how the many structural determinations could have been carried out.

Table 21 Ligand effect constants

Ligand	e^{cis}_L	e^{trans}_L	e^{td}_L	$e^{ax,eq}_L$	$e^{eq,eq}_L$	$e^{ax,ax}_L$

Technological advances have allowed the development of time-resolved infrared (TRIR) techniques in recent years and they too have exploited the intense, sharp spectra of the transition metal carbonyls. Some TRIR work has now been carried out, which confirms earlier matrix work;[49] and a review was published[50] some time ago. TRIR involving metal carbonyl species is now a maturing technique, with a considerable number of publications logged over the past 10 years.

The understanding of metal carbonyl reactions at electrode surfaces is also being tackled via the IR spectra of the participating complexes,[51] as are the chemical changes occurring on zeolites.[52]

7 POLYNUCLEAR CARBONYL COMPLEXES

Although the IR spectra of mononuclear carbonyl complexes are well understood, difficulties arise when dealing with the spectra of dinuclear complexes (e.g., $Mn_2(CO)_{10}$ and its substitution products), trinuclear species (e.g., $Os_3(CO)_{12}$), and larger carbonyls. In principle, the methodology for calculating energy factored force constants from observed ν(CO) bands (using either all-^{12}CO or isotopically enriched spectra) is identical with that employed so successfully for mononuclear complexes. The problems spring from the very large numbers of force constants required in the F matrix. Consider the $Mn(CO)_5$ fragment. This has (given IR and Raman spectra) four ν(CO) modes $(2a_1 + b_2 + e)$ and five force constants. The problem has one degree of freedom but, with a little data from isotopes, is relatively easily solved. Dimanganese decacarbonyl has seven ν(CO) modes:[53] two a_1 modes (Raman only), two b_1 modes (IR only), and three doubly degenerate e modes $(e_1 + e_2 + e_3)$ of which only the e_3 mode is IR-active. In addition to the five force constants for the $Mn(CO)_5$ fragments, there are another four interaction constants linking CO groups on different metals. This makes available seven ν(CO) fundamentals with which to calculate nine force constants, that is, two degrees of freedom. These 'through-space' interaction constants are generally smaller than those linking CO groups on the same metal but are certainly significant. There are few studies dealing with the force fields of polynuclear carbonyl complexes.[54]

For larger numbers of metal atoms surrounded by CO groups, the situation becomes quite perplexing. Instead of gradually increasing in complexity as the number of metal atoms increases, the IR spectra become extremely sparse with very few ν(CO) bands. One interpretation is that there is an 'F matrix collapse', with all the small through-space interactions tending to zero and the F matrix becoming quasi-diagonal. Supporting this view is the observation that partial ^{13}CO enrichment creates very few new absorptions and not the forest that might be expected.

There is much work still to be done on the force fields of polynuclear species and, with that area of carbonyl chemistry forming a sizable percentage of all carbonyl research, the work is overdue.

8 INTENSITIES

Apart from a fleeting mention earlier, the numerical analysis of the relative intensities of ν(CO) bands has not been elaborated on in this article. The topic of ν(CO) intensities has been authoritatively reviewed by Burdett.[55] In general, the use of intensity data depends on the nature of the carbonyl complex. If all the CO groups are chemically equivalent and the force field is fully determined (e.g., *cis*-$Cr(CO)_2(PMe_3)_4$, $Ni(CO)_3PMe_3$), there are few problems and the geometry of the molecule can be calculated from the relative intensities of the ν(CO) bands. Indeed, for all such cases the geometry of the $M(CO)_n$ unit can be determined without reference to the force constants. The situation becomes far more complex when there are chemically inequivalent CO groups (e.g., $HMn(CO)_5$, $Fe(CO)_4PMe_3$). Regardless of the symmetry, there will be as many symmetric stretches as there are different types of CO group. Since these modes will mix through the off-diagonal terms in the F matrix, the intensities associated with these vibrations will be redistributed. This generates two problems. Firstly, to ascertain the degree of mixing, the force field must be accurately known. Secondly, the dipole change caused by the vibration of one group may well be different to that caused by a chemically different group in the same molecule. In the case of C_{4v} pentacarbonyl complexes, the problem has been thoroughly investigated and, on the whole, bond angles calculated from intensities are in good agreement, where they can be checked, with observed bond angles (from X-ray data). This general confidence in the method tends to suggest that the calculation of bond angles from intensity considerations for matrix-isolated species is likely to be valid.

However, there is a caveat to add at this point. The fluctuating dipoles responsible for the infrared intensities may not, in fact, lie along the lines described by the atoms. So, while we can calculate 'geometries' we may not, in truth, be describing angles between bonds but angles between dipoles. The contribution of other ligands into this complex problem has yet to be quantified and our present level of understanding only allows us to offer general conclusions about bond angles. The curious ν(CO) intensities of $Cr(CO)_5CS$, where all the C–M–C bond angles are virtually 90° is a case in point. From the intensity data, we would conclude that the angle between the axial CO group and the equatorial groups was 82°.

9 RECENT DEVELOPMENTS

Studies involving the close scrutiny of the CO-stretching region of the spectrum have continued to be published. Indeed,

studies using TRIR (noted earlier) and the newer technique of carbonyl chemistry in supercritical fluids are highly dependent on the ν(CO) region. Fewer publications have followed the first studies of metal carbonyl photochemistry in supercritical fluids (such as scXe and $scCO_2$) but the work that has been done (e.g., by Poliakoff[56] and coworkers) makes considerable use of the ν(CO) bands around 2000 cm^{-1}.

Carbonyl spectra continue to be used to analyze σ/π bonding effects[57] and to monitor the processes taking place where CO groups are involved. Throughout the 1990s and into the new century, the number of studies dealing with $Re(CO)_3$(N-N)X complexes assumed plague proportions and each carried with it a more or less detailed description of the ν(CO) bands.

The combination of matrix-isolation and infrared spectroscopy has, since 1969, been used to identify carbonyl fragments (e.g., $Cr(CO)_5$), radicals (e.g., $Mn(CO)_5$) or unstable species (e.g., $Pd(CO)_4$). This type of work continues[58] and the understanding of what is actually going on in the ν(CO) region is crucial to the success or otherwise of the study. Recent work in this field includes the reactions of zirconium and hafnium atoms with CO, manganese carbonyl nitrosyl complexes in solid argon, reactions of iron atoms with nitric oxide and carbon monoxide in excess argon and reactions of laser-ablated ruthenium atoms with CO and H_2 mixtures. It would not be overstating the value of the ν(CO) spectra to say that, without this information the characterization of these matrix-isolated molecules would be impossible. The same is certainly true of species observed in TRIR studies where, in addition to structural information, we can also determine kinetic behavior.

There is no doubt that there remains much to be done and seen between 2100 to 1850 cm^{-1}.

abt = 1-iminobenzene-2-thiolate (2−); acac = pentane-2,5-dionate (2−); bdt = benzene-1,2-dithiolate (2−); cat = catecholate (2−); benzene-1,2-diolate (2−); cyclam = 1,4,8,11-tetraazacyclotetradecane; depe = bis(diethylphosphino)ethane; dme = 1,2-dimethoxyethane; dppe = bis(diphenylphosphino)ethane; diphos = chelating bis(dialkyl)- or (diaryl)- phosphine; dme = 1,2-dimethoxyethane; en = 1,2-diaminoethane; mnt = maleonitriledithiolate (2−); *cis*-1,2-dicyanoethene-1,2-dithiolate (2−); OTf = trifluoromethanesulfonate (1−) (triflate (1−)); pz = pyrazine; py = pyridine; tdt = toluene-3,4-dithiolate (2−); tht = tetrahydrothiophene; tos = tosyl.

1 INTRODUCTION

Unlike its congener element molybdenum, tungsten does not play a significant industrial catalytic role. The element is encountered in a number of enzymes,[1,2] and following from earlier developments in the understanding and modeling of nitrogen fixation, the coordination chemistry of tungsten with simple nitrogen-based ligands was extensively developed.

During the last decade of the twentieth century, the inorganic and coordination chemistry of tungsten has expanded. Among the major developments in this period have been (1) the introduction of a versatile range of polydentate ligands, including the tripodal tris(amido, triamidoamine, and tris(pyrazolyl)borato species, which have enabled the stabilization of novel species and chemistry; (2) continuing development of the chemistry of a range of complexes containing oxo and imido ligands; (3) increased activity and substantial sophistication in the chemical modeling of tungsto-enzymes structure, function and spectroscopy (*see* ***Tungsten Proteins***) and (4) the development and rationalization of major areas of cluster chemistry (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***), including the assembly of polyoxoanions (*see* ***Polyoxometalates***) and rational construction of chalcogenide-containing clusters.

Tungsten coordination has recently been comprehensively reviewed in *Comprehensive Coordination Chemistry*, particularly in the areas of mononuclear complexes,[3] dinuclear species containing single and multiple W–W bonds,[4] polyoxometallate synthesis, structure, and reactivity,[5,6] and chalcogen-containing cluster complexes.[7]

2 HALIDE AND CYANIDE COMPLEXES

Addition of one equivalent of anhydrous Et_4NF in thf to $[W(CO)_5(thf)]$ afforded $[Et_4N]_3[W_2(CO)_6(\mu\text{-}F)_3]$. Reaction of this species, whose structure was confirmed crystallographically, with CO afforded the unstable $[W(CO)_5F]^-$, which containing labile CO ligands. In the absence of CO, this anion reverted to the dinuclear species or to $[W(CO)_6]$ on prolonged exposure to CO. Reaction of $[W(CO)_6]$ with $LiI{\cdot}OEt_2$ afforded $[W(CO)_5I]^-$.

Reaction of $[W(CO)_6]$ with SbF_5 in the superacid mixture HF/SbF_5 afforded $[W^{II}(CO)_6(FSbF_5)][Sb_2F_{11}]$, without loss of CO.

The tungsten(III) fluoride, $K_3[WF_6]$ was obtained, as a mixture with $K_2[WF_7]$, when $K_3[WF_8]$ was reduced by tungsten metal. Treatment of WCl_4 with one equivalent of a reducing agent, usually Na/Hg or $NaBHEt_3$ in toluene in the presence of PMe_2Ph, afforded $[(PMe_2Ph)_2Cl_2W(\mu\text{-}Cl)_2WCl_2(PMe_2Ph)_2]$. By slight alteration of the stoichiometry, $[(PMe_2Ph)_2ClW(\mu\text{-}Cl)_3WCl_2(PMe_2Ph)]$ was obtained, and the analogous bromide was prepared from WBr_5. Monomeric $[WCl_3(PMe_2Ph)_3]$ was synthesized in the comproportionation reaction between $[WCl_4(PMe_2Ph)_2]$ and *trans*-$[WCl_2(PMe_2Ph)_4]$. The stable mer-isomer was obtained as the major product, but low yields of the fac-isomer were isolated.

The dinuclear mixed-valence W^{II}/W^{III} species $[(Me_2S)Cl_2W(\mu\text{-}Cl)(\mu\text{-}SPh)_2WCl_2(SMe_2)]$ was obtained in the reaction between $[WCl_4(SMe_2)_2]$ with exactly one equivalent of Me_3SiSPh. Treatment of this air-sensitive species with $[Ph_4As]Cl$ afforded $[Cl_3W(\mu\text{-}Cl)(\mu\text{-}SPh)_2WCl_2]^{2-}$, and analogous species $[Cl_3W(\mu\text{-}Cl)(\mu\text{-}SePh)_2WCl_3]^{2-}$ and

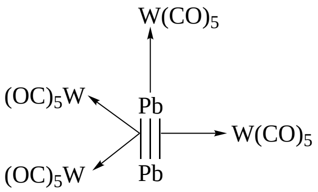
the W^{IV}/W^{IV} species $[Cl_3W(\mu\text{-Se})(\mu\text{-SePh})_2WCl_3]^{2-}$ were also isolated.

The seven-coordinate W^V fluoride K_2WF_7 was prepared by reaction of KWF_6 with LiF at high temperatures and under vacuum.

3 CYANIDE AND OTHER GROUP IV DONOR ATOM COMPLEXES

Reaction of $[W(CO)_5(CN)]^-$ with $[Cu(NCMe)_4]^+$ and PPh_3 afforded $[(OC)_5W(CN)Cu(PPh_3)_3]$ and the analogous isocyanide-bridged species $[(OC)_5W(NC)Cu(PPh_3)_3]$ was obtained by addition of $[Cu(PPh_3)_3CN)]$ to $[W(CO)_5(thf)]$ at low temperature. The latter slowly rearranged to the former.

Treatment of $[W_2(CO)_{10}]^{2-}$ with $Pb(NO_3)_2$ afforded $[\{W(CO)_5\}_4Pb_2]^{2-}$ (**1**), where the Pb–Pb distance was short (2.82 Å).



(**1**)

Polymeric $[W^{IV}(CN)_8(SnMe_3)_4]_n$ was obtained by reaction of $K_4[W(CN)_8]$ with four equivalents of Me_3SnCl, whereas the hexanuclear $[\{Mn(bipy)_2\}_2(\mu\text{-NC})_2\{W^{IV}(CN)_4\}_2(\mu\text{-CN})_2\{Mn(bipy)_2\}_2]$ was obtained by reaction of $[Mn(bipy)_2Cl_2]\cdot 2H_2O\cdot EtOH$ with $[W(CN)_8]^{4-}$ in aqueous media.

The W^V octacyanide $[W(CN)_8]^{3-}$ formed adducts or clusters with other metals, an example being $[Pt(en)_2]_3[W(CN)_8]_2$, in which there was electronic coupling between the metal centers in solution and in the solid state. Magnetically interesting materials were obtained in reactions between $[W(CN)_8]^{3-}$ and Mn^{2+}, namely $[Mn^{II}{}_6(H_2O)_9\{W^V(CN)_8\}_4 \cdot 13H_2O)]_n$ and $[Mn_9(W(CN)_8\}_6\cdot 24EtOH]\cdot 2EtOH$, the latter being high spin ($S = 39/2$).

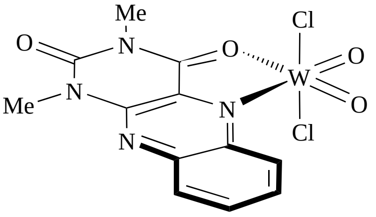
4 COMPLEXES WITH O-DONOR ATOMS

4.1 Tungstates and Oxo–tungsten Complexes

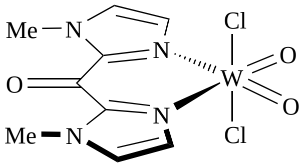
$[W^{IV}O(dppe)_2F]^+$ was prepared by reaction of *trans*-$[W(PPh_3)_2Cl_4]$ with BF_4^- and reacted with $[Et_4N]OH$ giving *trans*-$[WO_2(dppe)_2]$. On treatment of *trans*-$[WO_2(dppe)_2]$ with halide ions, NCS^- and MeI, the complexes *trans*-$[W^{IV}O(dppe)_2X]$ (X = halide, NCS, NCS, OMe) were formed.

Tungstate ion $[WO_4]^{2-}$ reacted readily with the Lewis acid $B(C_6F_5)_3$, giving tetrahedral $[WO\{OB(C_6F_5)_3\}_3]^-$.

Treatment of $WOCl_4$ with hexamethyldisiloxane in oxygenated solvents effected extraction of the chloride ion giving solvated species such as $[WO_2Cl_2(MeOCH_2CH_2OMe)]$, via elimination of Me_3SiCl. Polymeric $[\{WO_2Cl_2\}_n]$ reacted with 1,3-dimethylalloxazine (L^1) and bis(1-methylimidazol-2-yl)ketone (L_2) afforded the monomeric six-coordinated species $[WO_2Cl_2L^1]$ (**2**), and $[WO_2Cl_2L^2]$ (**3**).



(**2**)

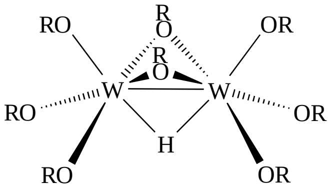


(**3**)

4.2 Alkoxide, Aryloxide, and Catecholate Complexes

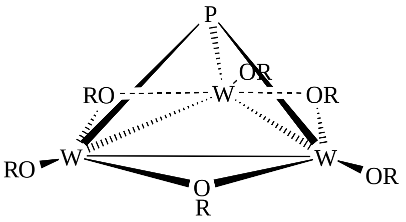
4.2.1 *Alkoxide Complexes*

Reaction of $[W_2(NMe_2)_6]$ with an excess of cyclopentanol in hexane afforded first the dimethylamine adduct $[W^{III}{}_2(O\text{-}c\text{-}C_5H_9)_6(NHMe_2)_2]$ but over a prolonged period in contact with cyclopentanol and $NHMe_2$, the green diamagnetic mixed-valence $W^{III}W^V$species $[W_2(\mu\text{-H})(\mu\text{-O-}c\text{-}C_5H_9)_2(O\text{-}c\text{-}C_5H_9)_5(NHMe_2)]$ (**4**) (R = c-C_5H_9) was formed. The W–W distance (2.44 Å) is consistent with a double bond.



(**4**)

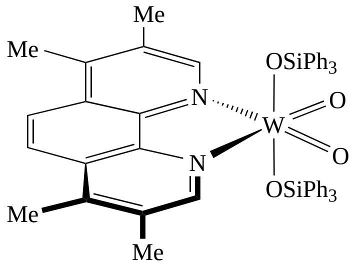
Reaction of $[W_2(OCH_2Bu^t)_6(NHMe_2)_2]$ with P_4 in hydrocarbon solvents afforded the phosphido-capped W_3^{IV}



(**5**)

alkoxide $[W_3(\mu^3\text{-P})(\mu\text{-OCH}_2\text{Bu}^t)_3(\text{OCH}_2\text{Bu}^t)_3]$ (**5**), together with the previously known $[W(\eta^3\text{-P}_3)(\text{OCH}_2\text{Bu}^t)(\text{NHMe}_2)]$.

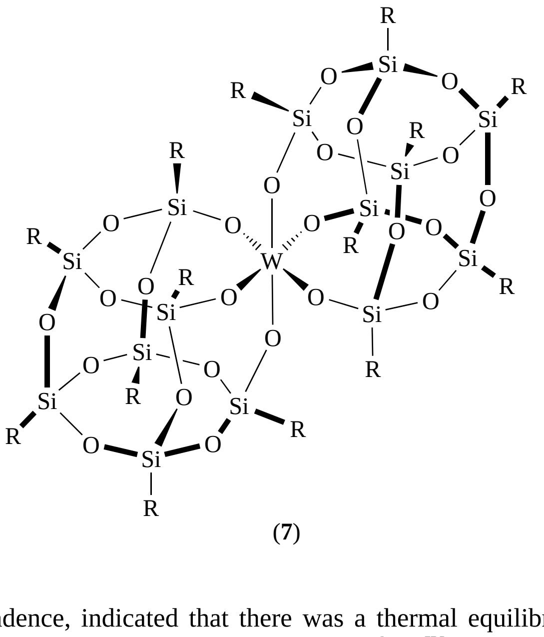
Treatment of $[W(\text{PMe}_2\text{Ph})_2\text{Cl}_4]$ with two equivalents of $\text{TlOCH}_2\text{CF}_3$ afforded $[W^{IV}\text{Cl}_2(\text{OCH}_2\text{CF}_3)_2(\text{PMe}_2\text{Ph})_2]$. Reaction of $[\text{WO}_{2-n}\text{S}_n]^{2-}$ with SiClPh_3 and Me_4phen (3,4,7,8-tetramethyl-1,10-phenanthroline) gave $[\text{WO}_{2-n}\text{S}_n(\text{OSiPh}_3)_2(\text{Me}_4\text{phen})]$ (**6**).



(**6**)

Reaction of $[W_2(\text{OCH}_2\text{Bu}^t)_8]$ with pyridine-*N*-oxide, elemental sulfur, selenium, and $\text{Bu}^t{}_3\text{PTe}$ afforded $[W^V{}_2(\mu\text{-E})(\mu\text{-OCH}_2\text{Bu}^t)_2(\text{OCH}_2\text{Bu}^t)_6]$ (E = O, S, Se, or Te).

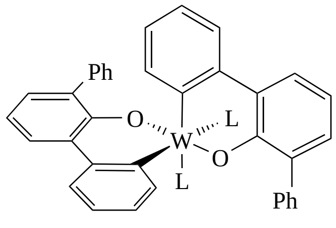
Anodic oxidation of metallic tungsten in methanol afforded a mixture of $[W(\text{OMe})_6]$ and $[\text{WO(OMe)}_4]$, and reaction of $[W(\text{NMe}_2)_6]$ with pinacol afforded the tris-pinacolate (2−) $[W(\text{OCMe}_2\text{CMe}_2\text{O})_3]$. Treatment of WCl_6 with one or two equivalents of the silsesquinoxane $\text{R}_7\text{Si}_7\text{O}_9(\text{OH})_3$ afforded the bis(silsesquinoxanato) complexes (**7**).



(**7**)

4.2.2 Aryloxide Complexes

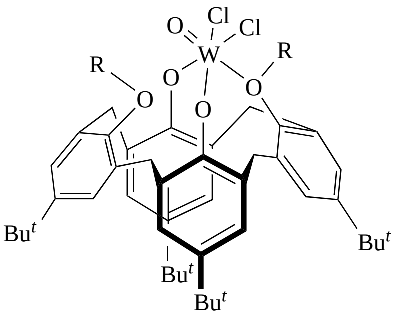
Reaction of $[\text{WCl}_4(\text{SEt}_2)_2]$ with $(\text{OC}_6\text{H}_3\text{R}_2)^-$ (R = Me, Pr^i) afforded the nearly square-planar species $[W^{IV}(\text{OC}_6\text{H}_3\text{R}_2)_4]$. Reaction of substituted pyridines (L), dipyridyls, and phenanthrolines (L_2) with *trans*-$[W(\text{OC}_6\text{H}_3\text{Ph-C}_6\text{H}_4\text{-}O,C)(\text{PMePh}_2)_2]$, itself generated by sodium amalgam reduction of $[W(\text{OC}_6\text{H}_3\text{-2,6-Ph}_2)_2\text{Cl}_4]$ in the presence of PMePh_2, gave $[W(\text{OC}_6\text{H}_3\text{Ph-C}_6\text{H}_4\text{-}O,C)\text{L}_2]$ (**7**), in which the diphenylphenoxide ligands are cyclometallated, the complex having mutually trans O atoms and cis pyridine ligands. The complexes (**8**) exhibited sharp contact-shifted ^{1}H NMR spectra, the amount of contact shifting being strongly dependent on the nature of the N-donor ligand L. Assignment of the signals in the ^{1}H NMR spectra, as well as their temperature dependence, indicated that there was a thermal equilibrium between a single ground state for the d^2 W^{IV} center and a triplet excited state, which underwent through-bond coupling to the ligand protons. The relative singlet-triplet energy gap for several ligand systems was calculated from the spectral data.



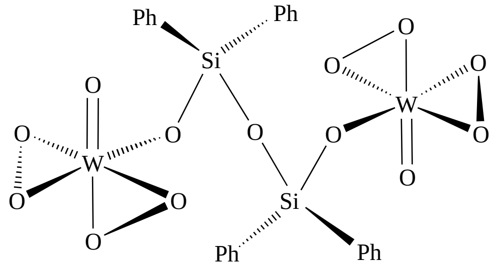
(**8**)

Reduction of $[\text{WCl}_2(\text{OAr})_4]$ (Ar = $\text{C}_6\text{H}_3\text{Cl}_2$-2,6) by sodium amalgam afforded $[W^V\text{Cl(OAr)}_4(\text{OEt}_2)]$, in which the ether is trans to Cl. Reaction of $[\text{WCl}_4(\text{OAr})_2]$ (Ar = $\text{C}_6\text{H}_3\text{Ph}_2$-2,6) with an excess of LiBH_4 or an equivalent of sodium amalgam in the presence of PMe_2Ph afforded $[\text{WCl}_3(\text{OAr})_2(\text{PMe}_2\text{Ph})]$, and $\text{WCl}_2(\text{OAr})_2(\text{thf})]$ was isolated following reduction by $\text{Mg}(\text{C}_4\text{H}_6)_2$ in thf.

Reaction of WOCl_4 with phenols (ArOH) afforded $[W^{VI}\text{OCl}_2(\text{OAr})_2]$. With aromatic diols, species such as $[\text{WO(OArOCl}_2(\text{thf})_2]$ or $[\text{WOCl}_3(\text{OArOH})\cdot\text{OEt}_2]$ were formed, depending on solvents used. Reaction of WOCl_4 with 1,3-dialkyl-*p*-Bu^tcalix[4]arene (R_2calH_2; R = Me, Et) afforded $[\text{WOCl}_2(\text{R}_2\text{cal})]$ (**9**), whereas use of the unalkylated calixarene (R = H) gave $[\text{WO(cal)}]\cdot n(\text{solvent})$ and [WO(cal)L] (L = H_2O, MeCO_2H). Reaction of $[W(\text{OCH}_2\text{CH}_2\text{O})_2(\text{OAr})_2]$ with HCl afforded *trans*-$[\text{WCl}_2(\text{OCH}_2\text{CH}_2\text{O})(\text{OAr})_2]$ (Ar = $\text{C}_6\text{H}_2\text{Me}_2$-2,6, $\text{C}_6\text{H}_2\text{Pr}^i{}_2$-2,6 and $\text{C}_6\text{H}_2\text{Me}_2$-2,6. The first structurally characterized complex containing W^{VI}–I bonds, $[\text{WI}_2(\text{OBu}^t)_4]$, was also reported.



(**9**)



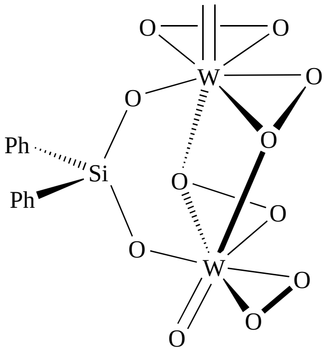
(**11**)

4.2.3 *Catecholate Complexes*

Treatment of $[W(CO)_5(thf)]$ with two equivalents of $[Et_4N][OC_6H_4OH]$ afforded the orange catecholato (2−) species $[Et_4N]_2[W(CO)_4(O_2C_6H_4)]\cdot HOC_6H_4OH$, in which the catechol hydrogen-bonded to adjacent O atoms of the catecholato (2−) ligands, thereby forming a chain-like structure in the solid state. Treatment of this species with an excess of NaOMe afforded $[Et_4N]_2[W(CO)_4(O_2C_6H_4)]$, and similar complexes containing $[O_2C_6H_2Bu^t{}_2]^{2-}$ (di-*t*-butylcatecholate) were also isolated. The tetracarbonyl species reversibly decarbonylated, affording $[W(CO)_3(O_2C_6H_2R_2]_2$–(R = H or But), and crystallographic studies showed the geometry of these five-coordinate species as intermediate between trigonal bipyramidal and square planar. A related amido-phenolato species $[W(CO)_3\{O(NH)C_6H_4\}]^{2-}$ was also reported.

4.2.4 *Peroxide Complexes*

Reaction of $WO_3\cdot H_2O$ with hydrogen peroxide (30%) followed by addition of $SiPh_2(OH)_2$ or $[\{Ph_2Si(OH)\}_2O]$ afforded dimeric species $[Ph_2SiO_2\{W_2O_2(\mu\text{-}O_2)_2(O_2)_2\}]_2$ –(**10**), and $[\{Ph_2SiOW(O)(O_2)_2\}_2\mu\text{-}O]_2$–(**11**).

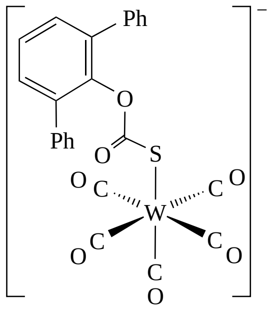


(**10**)

4.2.5 *Carboxylato, Carbonato, and Related Complexes*

Glycinato derivatives $[W(CO)_4\{\kappa^2\text{-}O_2CCH_2NRR'\text{-}N,O)]^-$ (RR′ = H_2, HMe, Me_2) were prepared by reaction of $[W(CO)_5(thf)]$ with the corresponding glycine derivatives. Reaction of $[W(CO)_5(NCMe)]$ with one equivalent of oxalate ion afforded $[W(CO)_4(\kappa^2\text{-}O_2CO_2)]^{2-}$. With two equivalents of oxalate, $[W_2(CO)_{10}(\mu\text{-}\kappa^1\text{-}O_2C_2O_2)]^-$ was formed initially, and following loss of CO, $[W_2(CO)_8(\mu\text{-}\kappa^2\text{-}O_2C_2O_2)]^{2-}$ was generated.

Reaction of bicarbonate ion with $[W(CO)_5(acetone)]$ or of $[W(CO)_5(OH)]^-$ with CO_2 afforded $[W(CO)_5\{\kappa^1\text{-}OCO(OH)\}]^-$. Insertion of COS into the W–O bond in $[W(CO)_5(OC_6H_3Ph_2\text{-}2,6)]^-$ afforded $[W(CO)_5\{SC(O)OC_6H_3Ph_2\}]^-$ (**12**).



(**12**)

Reaction of *trans*-$[W(CO)(N_2)(dppe)_2]$ with an excess of methanol of secondary amine under CO_2 afforded $[W^{II}H(\kappa^1\text{-}OCO_2Me)(CO)(dppe)_2]$ or the carbamato species $[W^{II}H(\kappa^2\text{-}O_2CNR_2(CO)(\kappa^1\text{-}dppe)(\kappa^2\text{-}dppe)]$. Treatment of the latter with $AlEt_3$ in thf under CO_2 afforded *trans*-$[W(CO)(\kappa^2\text{-}OCO\text{-}C,O)(dppe)_2]$.

Reaction of WCl_6 or $WOCl_4$ with salicylic acid (H_2sal) followed by crystallization of the product from thf afforded $[W^{VI}OCl(Hsal\cdot thf)(sal)]$. However, treatment of $WOCl_4$ with three equivalents of salicylic acid gave $[\{WO(Hsal)(sal)\}_2O]$.

4.2.6 *Schiff Base Complexes*

The dinuclear species $[W_2(CO)_8(salen)]^{2-}$ was obtained by reaction of two equivalents of $[W(CO)_5(thf)]$ with $(salen)^{2-}$.

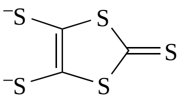
Reaction of $[W(CN)_3O_2]^{4-}$ with salicylaldehyde and 1,2-diaminoethane (precursors of the Schiff base salenH_2) afforded $[W^{IV}O(CN)(salen)]^{2-}$.

5 COMPLEXES WITH SULFUR, SELENIUM, AND TELLURIUM DONOR ATOMS

5.1 Dithiolene Complexes

Reaction of $[W(CO)_5(thf)]$ with $[HXYC_6H_4]^-$ (X = Y = S, X = O, Y = S, X = NH, Y = S) initially afforded $[W(CO)_4(HXYC_6H_4]^-$, but further treatment with OMe^- gave the dithiolate species $[W(CO)_4(XYC_6H_4)]^{2-}$. These tetracarbonyl complexes gradually converted to tricarbonyl species on bubbling argon into acetonitrile solutions at 40 °C. Trigonal bipyramidal structures were determined for $[PPN][W(CO)_3\{S(NH)C_6H_4\}]$ and $[PPN][W(CO)_3\{SOC_6H_4\}]$, but $[PPN]_2[W(CO)_4(S_2C_6H_4)]$ was octahedral.

Reaction of $[W(CO)_3L_2I_2]$ (L = PEt_3, PPh_3, L_2 = dppe) with mnt^{2-} or bdt^{2-} afforded $[W^{II}(CO)_2L_2(mnt)]$ and $[W^{II}(CO)_2L_2(bdt)]$. The related complexes $[W^{II}(CO)_2L_2(S_2C_2S_2CS)]$ ($S_2C_2S_2CS$ = (**13**)) were prepared similarly.



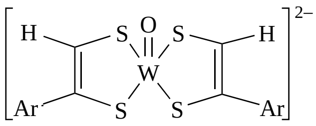
(**13**)

Reduction of $[W(S_2C_2Me_2)_3]$ by Et_4NBH_4 afforded $[W(S_2C_2Me_2)_3]^{2-}$ while $[WSe_9]^{2-}$ or $[WSe(Se_4)_2]^{2-}$ reacted with dimethylacetylenedicarboxylate, giving the tris(diselenolene) complex $[W(Se_2C_2R_2)_3]^{2-}$ (R = CO_2Me). Reaction of tetrathiapentalenedione, $C_2S_4(CO)_2$, with $[WS_4]^-$ afforded $[W\{S_2C_2S_2CO\}_3]^{2-}$. These ‘noninnocent’ species formally contain W(IV).

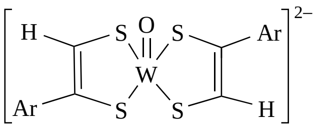
Treatment of $[W(CO)_2(S_2C_2R_2)_2]$ (R = Me, Ph) with OH^-, S^{2-}, or Se^{2-} afforded $[W^{IV}E(S_2C_2R_2)_2]^{2-}$ (E = O, S, Se).

Bis(dithiolene) tungsten(IV) complexes have been synthesized for comparison with the active sites in tungsto-enzymes. $[WO(bdt)_2]^{2-}$ was prepared by borohydride reduction of $[WO(bdt)_2]^-$, and the analogous $[WO(mnt)_2]^{2-}$ was prepared by reduction of $[W^{VI}O(\kappa^2\text{-}S_2)(mnt)_2]^{2-}$. Reaction of $[WO_2(CN)_4]^{4-}$ with $[SC(H){=}C(Ar)S]^{2-}$ (Ar = Ph, 2-, 3- or 4-pyridyl, quinoxalinyl) has afforded mixtures of cis (**14a**) and trans (**14b**) isomers of $[WO\{SC(H)C(Ar)S\}_2]^{2-}$, established by ^1H NMR spectroscopy, but only cis-isomers were crystallized and characterized crystallographically.

Reaction of $[WO(bdt)_2]^{2-}$ with one equivalent of $SiBu^tR_2Cl$ (R = Me, Ph) afforded the ‘desoxo’ complexes $[W(OSiR_2Bu^t)(bdt)_2]^-$. Addition of OR'^- ($R' = Pr^i$ or



(**14a**)



(**14b**)

Ph) to $[W(CO)_2(S_2C_2Me_2)_2]$ afforded $[W(OR'(S_2C_2Me_2)_2]^-$ and reaction of these species with Me_3NO afforded $[WOOR'(S_2C_2Me_2)_2]^-$. With EAr^-, $[W(CO)(EAr)(S_2C_2Me_2)_2]^-$ (E = S, Se; Ar = 2-adamantyl, Ph, C_6H_2-2,4,6-Pr^i_3) was formed. Similar reactions with alkoxides and phenolates afforded $[WO(ER)(S_2C_2Me_2)_2]^{3-}$ (E = O, R = Pr^i, 2-adamantyl, *p*-C_6H_4X, where X = CN, Br, Me, OMe, NH_2; E = S, Se, R = 2-adamantyl). Treatment of $[W(CO)_2(S_2C_2Me_2)_2]$ with O_2CPh^- gave $[W(O_2CPh)(S_2C_2Me_2)_2]^-$. The structure of $[WO(OPh)(S_2C_2Me_2)_2]^-$ and the catalytic center of one DMSO reductase isoenzyme have similar overall stereochemistry and comparable bond lengths. The W^{IV} complex $[W(OPh)(S_2C_2Me_2)_2]^-$ reacted quantitatively with various substrates XO to afford $[W^{VI}O(OPh)(S_2C_2Me_2)_2]^-$ and X in second order reactions with associative transition states.

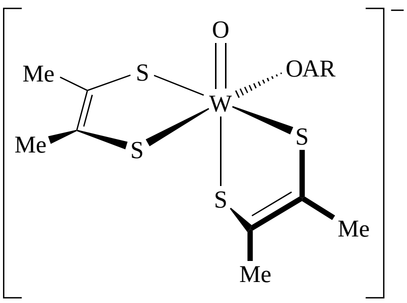
Sodium naphthalenide reduction of $[W^VO(bdt)_2]^-$ afforded a mixture of $[W(bdt)_3]^{2-}$ and $[W^{IV}O(bdt)_2]^{2-}$ which, with Me_3NO, under O-atom transfer afforded $[W^{VI}(O)_2(bdt)_2]^{2-}$. Reaction of this dioxo species with Me_3SiCl afforded $[W^{VI}OCl(bdt)_2]^-$. Reaction of the oxo-chloro complex with $P(OEt)_3$) in the absence and presence of Bu^tNC afforded $[W^{IV}\{(P(OEt)_3\}_2(bdt)_2]$ and $[W^{IV}CNBu^t)_2(bdt)_2]$, both reduction processes, but with OBu^{t-} and SPh^- $[W^{VI}(O)(OBu^t)(bdt)_2]^-$ and $[W^{VI}(O)(SPh)(bdt)_2]^-$ were formed. Reaction of $[W^{IV}O(bdt)_2]^{2-}$ with Me_3SiCl afforded $[W^{IV}(OSiMe_3)(bdt)_2]^-$.

Treatment of $[W(CO)_3(NCMe)_3]$ with $[Ni(S_2C_2R_2)_2]$ gave the dithiolene complexes $[W(CO)_2(S_2C_2R_2)_2]$ (R = Me, Ph). Reaction of $[W(CO)_2(S_2C_2Me_2)_2]^{2-}$ with $[W(CO)_2(S_2C_2Me_2)_2]$ afforded the paramagnetic $[W(CO)_2(S_2C_2Me_2)_2]^-$. The dicarbonyl species $[W(CO)_2(S_2C_2Me_2)_2]^z$ and the related tris(dithiolene) complexes $[W(S_2C_2Me_2)_3]^z$ exist as a three-membered electron transfer chain, $z = 0, -1$, and -2, which were interconnected by reversible redox reactions. Members of both series have similar distorted trigonal prismatic structures. As the most oxidized species ($z = 0$) were reduced, the M–S, S–C, and C–O distances increased, and the M–C, chelate ring C–C, and ν_{CO} values decreased. Whereas the most oxidized species $[W(CO)_2(S_2C_2Me_2)_2]$ and $[W(S_2C_2Me_2)_3]$ formally contain W^{IV} and W^{VI}, respectively, the trends in bond lengths and vibrational frequencies, coupled to density functional calculations, established that the redox orbital in these ‘noninnocent’ complexes was predominantly sulfur ligand based, that is, that the electron transfer behavior is largely ligand based.

Crystallographic studies of $[WO(bdt)_2]^-$ and $[WO(S_2C_2Me_2)_2]^-$ established that they had square pyramidal structures. Reaction of $[W^{IV}(OPh)(S_2C_2Me_2)_2]^-$ with two

equivalents of benzenethiol or benzene selenol afforded $[W^{V}(EPh)_2(S_2C_2Me_2)_2]^-$ (E = S or Se), but when one equivalent of Ph_3CSH was employed, dinuclear $[W_2(\mu\text{-}S_2(S_2C_2Me_2)_4]^{2-}$ was formed. This complex could also be generated by reaction of $[W(CO)_2(S_2C_2Me_2)_2]$ with $S_2{}^{2-}$ or the oxidation of $[W^{IV}S(S_2C_2Me_2)_2]^{2-}$ by iodine. The corresponding dinuclear species $[W_2(\mu\text{-}S_2(S_2C_2Ph_2)_4]^{2-}$ was obtained by tropylium cation oxidation of $[WS(S_2C_2Ph_2)_2]^{2-}$.

Recent crystallographic studies of the active sites in tungsto-enzymes has suggested the possibility of desoxo-tungsten(IV) and mono-oxo-tungsten (VI) bis(dithiolato) centers to which serine molecules might be additionally coordinated. Attempts to mimic the coordination environment around the tungsten atom led to the generation of $[W^{VI}O(OSiBu^tPh_2)(bdt)_2]^-$ and $[WO(OPh)(S_2C_2Me_2)_2]^-$ (**15**) by treatment of $[W(OR)(dithiolate)_2]^-$ precursors with an excess of Me_3NO, as described above.



(**15**)

Treatment of $WOCl_4$ with Li_2bdt or of $[WO(bdt)_2(OSiBu^tPh_2)]^-$ with $SiMe_3Cl$ afforded $[W^{VI}O(bdt)_2Cl]^-$. Reaction of $[W(OR)(S_2C_2Me_2)_2]^-$ (R = Ph or $SiBu^tPh_2$), which formally contains W(IV), with dibenzyltrisulfide or $(Me_3Si)_2S$ afforded the sulfido complexes $[W^{VI}S(bdt)(OR)]^-$, an oxidative addition formally generating W(VI) species.

Addition of trimethylamine *N*-oxide to $[W^{IV}O(bdt)_2]^-$ and to $[WO(S_2C_2Me_2)_2]^-$ afforded the W(VI) complexes $[WO_2(bdt)_2]^{2-}$ and $[WO_2(S_2C_2Me_2)_2]^{2-}$, in which the oxo groups were mutually cis. Because of trans influences, the W–S bonds trans to the oxo groups in $[WO_2(bdt)_2]^{2-}$ (as the Et_4N^+ salt) were longer (2.60 Å) than those which were cis (2.43 Å). Reaction of aqueous $WO_4{}^{2-}$ with mnt^{2-} in the presence of an excess of $HSO_3{}^-$ (*pH* 5.5) followed by addition of acetic acid afforded the structurally similar $[WO_2(mnt)_2]^{2-}$.

5.2 Thiolato Complexes

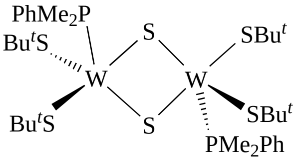
Addition of RSH (R = Bu^t, Ph) to $[W(CO)_3(phen)(NCEt)]$ afforded $[W(CO)_3(phen)(Bu^tSH)]$ or $[W(CO)_3H(phen)(SPh)]$. $[W(CO)_5(SPh)]^-$, obtained by reaction of $[W(CO)_5(thf)]$ with $(SPh)^-$, converted slowly to $[W(\mu\text{-}S)_2(CO)_8]^{2-}$ on gentle heating.

Addition of PhSSPh to $[W(CO)_3(PPr^i{}_3)_2]$ afforded the paramagnetic W^I complex $[W(CO)_3(PPr^i{}_3)_2(SPh)]$.

Reaction of $[W^{IV}H(tipt)_3(PMe_2Ph)_2]$ with CNMe in thf afforded *cis*-$[W^{II}(CNMe)_4(tipt)_2]$ (tipt = $SC_6H_2Pr^i{}_3$-2.4.6). Similarly, reaction of $[WH(tipt)_3(PMe_2Ph)_2]$ with CO led to loss of thiol and formation of $[W(CO)_2(PMe_2Ph)_2](tipt)_2]$. The dicarbonyl was isolated as two isomers (green 90%; red 10%), and variable-temperature ^1H NMR spectroscopy indicated that they were fluxional and interconverted in solution. The structure of the green isomer of the analogous $[W(CO)_2(PMe_2Ph)_2(SC_6H_2Me_3\text{-}2,4,6)_2]$ revealed that it had a twisted trigonal prismatic geometry. The selenolate $[W(CO)_2(PMe_2Ph)_2(SeC_6H_3Pr^i{}_2)_2]$ was obtained similarly and had a slightly distorted trigonal prismatic geometry.

Reaction of $[W(CO)_3(PEt_3)_2I_2]$ with SPh^- or $[S(CH_2)_nS]^{2-}$ (n = 2, 3) afforded the octahedral species $[W^{II}(CO)_2(PEt_3)_2(SPh)_2]$ and $[W^{II}(CO)_2(PEt_3)_2\{S(CH_2)_nS)]$. The W(0) complex$[W(CO)_3(phen)(NCEt)]$ underwent oxidative addition with dialkyl and diaryl disulfides forming $[W^{II}CO)_2(phen)(SR)_2]$ (R = Ph, CH_2Ph, Me, Bu^t). $[W(CO)_2(phen)(SPh)_2]$ reacted with $P(OMe)_3$ giving $[W(CO)\{P(OMe)_3\}(phen)(SPh)_2]$ and the X-ray structures of $[W(CO)_2(phen)(SPh)_2]$ and $[W(CO)\{P(OMe)_3\}(phen)(SPh)_2]$ showed that they were both octahedral, with the phenylthiolato ligands in trans positions. Both molecules reacted with SO_2 giving $[W(CO)(phen)(SPh)_2)(\kappa^2\text{-}SO_2)]$. The coordinated S–O bond was long (1.58 Å) and could be cleaved to give $[WO_2(phen)(SPh)_2]$ (cis dioxo groups, trans thiolato groups), with loss of CO and sulfur.

The tetrathiolate $[W^{IV}(SBu^t)_4]$ was obtained by reaction of $[WCl_4(SEt_2)_2]$ with SBu^{t-}. Reaction of *cis*-$W(N_2)_2(PMe_2Ph)_4]$ with Bu^tSH in thf afforded the dinuclear species $[\{W(SBu^t)_2(PMe_2Ph)\}_2(\mu\text{-}S)_2]$ (**16**). Reaction of $[W(CO)_3I_2(NCMe)]$ with the potential NS_3-podand ligand $N(CH_2CH_2SH)_3$ afforded, in the presence of NEt_3, the dinuclear species $[\{W^{IV}(SCH_2CH_2)_3N\}_2\{\mu\text{-}SCH_2CH_2N(CH_2CH_2SH)_2\}_2]$.

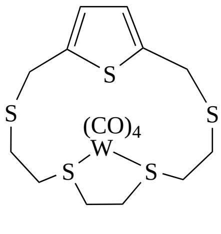


(**16**)

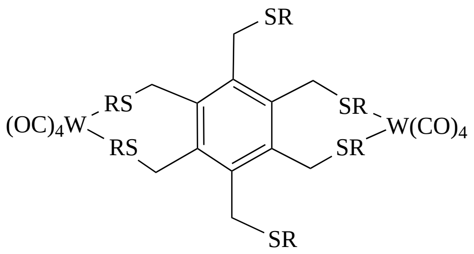
The square-planar ethanedithiolato complexes $[W^VO(SCH_2CH_2S)_2]^-$ were obtained by a ligand exchange reaction involving $[WO(SPh)_4]^-$. The X-ray crystallographic examination of $[W^VO(SC_6H\text{-}2,3,5,6\text{-}Me_4)_4]^-$ revealed that it too was nearly square planar.

5.3 Thioether Complexes

The cyclic polythioether complex $[W(CO)_4L]$ (L = 2,5,8,11-tetrathia[12](2,5)thiophenophane was prepared by UV irradiation of $[W(CO)_6]$ in the presence of the ligand in thf. Variable-temperature ^{1}H NMR studies showed that this species was fluxional, and the derived molecular structure indicated κ^2-L-S^5S^8 coordination (**17**). The thioether-bridged complexes $[\{W(CO)_4\}_2L]$ (**18**), where L is the hexakis(alkylsulfanylmethyl)benzene, $C_6(CH_2SR)_6$ (R = C_5H_{11}, Pr^n) were obtained by reaction of $[W(CO)_4(NCMe)_2]$ with the appropriate thioether. Reaction of $[W(CO)_4(tmpa)]$ (tmpa = N,N,N',N'-tetramethyl-1,3-propanediamine) with 1,5-diselenacyclooctane ([8]aneSe_2) gave the cis-disubstituted produce $[W(CO)_4\{[8]aneSe_2\}]$.



(**17**)



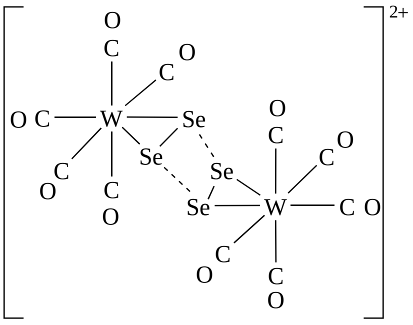
(**18**)

5.4 Sulfides, Selenides and, Tellurides

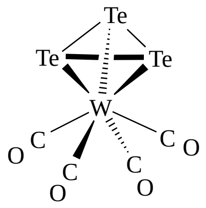
Reaction of $Se_4(AsF_6)_2$ or $Se_8(AsF_6)_2$ with $[W(CO)_6]$ in liquid SO_2 afforded the diamagnetic $[W_2(CO)_{10}Se_4][AsF_6]_2$ (**19**), which contained a μ-Se_4^+ moiety. The short Se···Se bond lengths (2.29 Å) are close to those found in gaseous Se_2 (2.19 Å), while the longer Se–Se bonds suggested that the complex should be formulated as containing two $\{W(CO)_5(\kappa^2\text{-}Se_2)\}^+$ groups.

Treatment of $[W(CO)_6]$ with $Te_4(SbF_6)_2$ in SO_2/AsF_3 afforded $[W(CO)_4(\eta^3\text{-}Te_3)][SbF_6]_2$ (**20**). The molecular structure of this species confirmed the 'piano-stool' geometry, and the triangular Te_3^{2+} group. Reaction of $[W(CO)_6]$ with K_2Te_4 afforded $[W(CO)_4(\kappa^2\text{-}Te_4)]$, which contained a five-membered WTe_4 chelate ring.

Reaction of $[W(CO)_5(thf)]$ with $[Fe(CO)_3I_2(TePh_2)]$ and with $Bu^t{}_3P{=}Te$ caused replacement of the thf and



(**19**)

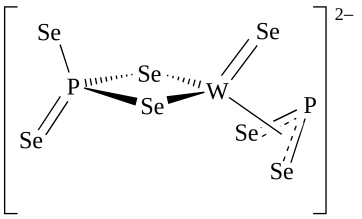


(**20**)

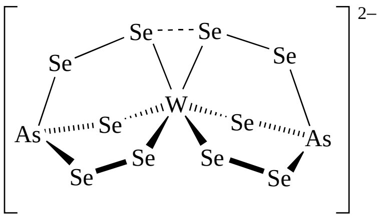
formation of the tellurium adducts $[W(CO)_5(TePh_2)]$ and $[W(CO)_5(Te{=}PBu^t{}_3)]$, respectively.

The monomeric tetraselenide ion $[W^{IV}(E)(Se_4)_2]^{2-}$ (E = O, S, Se) was prepared by reaction of $[WSe_4]^{2-}$ with Se_8, SeS_2, or $Se_4(NC_5H_{10})_2$ in dmf, respectively. Tungsten hexachloride, WCl_4, or $WOCl_4$ reacted with polytelluride ions Te_3^{2-}, Te_4^{2-}, and Te_5^{2-} in dmf giving $W^{IV}O(\kappa^2\text{-}Te_4)_2]^{2-}$.

Reaction of $[WSe_4]^{2-}$ with phosphorus selenide glass, 'P_2Se_4', afforded $[W^{IV}Se(PSe_2)(PSe_4)]^{2-}$ (**21**), which contained PSe_4^{3-} and the trihapto hetero-allylic PSe_2^{2-} group. Treatment of $[W(CO)_6]$ or $W(CO)_2(As_2Se_3)_2]^{2-}$ with As_4Se_4 and K_2Se_3 afforded $[W(AsSe_5)_2]^{2-}$ (**22**). $[W(CO)_2(As_3Se_3)_2]^{2-}$ (**23**) was generated by reaction of $[W(CO)_6]$ with $As_4Se_6^{2-}$, and its reaction with red selenium converted it into $[W(AsSe_5)_2]^{2-}$.

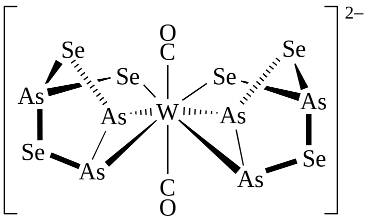


(**21**)



(**22**)

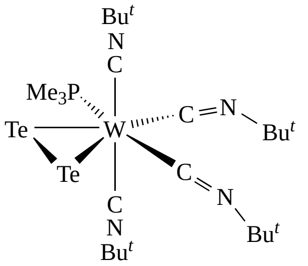
Treatment of $[W(PMe_3)_6]$, better formulated as $[W(\kappa^2\text{-}CH_2PMe_2)_2H_2(PMe_3)_4]$, with H_2E (E = S or Se) or elemental tellurium afforded *trans*-$[W(E)_2(PMe_3)_4]$ (E = S, Se or Te). These reactions proceeded through the intermediate $[W(E)(H_2)(PMe_3)_4]$, the species containing E = Se being characterized crystallographically. The species



(**23**)

$[W(PMe_3)_4(H)_2(SH)_2]$ could also be detected. Reaction of the dihydride $[WH_2(PMe_3)_4]$ with elemental tellurium afforded $[WH_2(PMe_3)_4(\kappa^2\text{-}Te_2)_2]$, from which $[W(Te)_2(PMe_3)_4]$ could be obtained by oxidative cleavage of the Te–Te bonds.

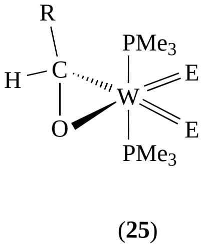
Reaction of *trans*-$W(E)_2(PMe_3)_4]$ (E = S or Se) with isonitriles, CNR (R = alkyl, aryl), afforded all-*trans*-$[W(E)_2(CNR)_2(PMe_2)_2]$ whereas reaction of $[W(Te)_2(PMe_3)_4]$ with $CNBu^t$ afforded $[W(CNBu^t)_4(PMe_3)(\kappa^2\text{-}Te_2)]$ (**24**).



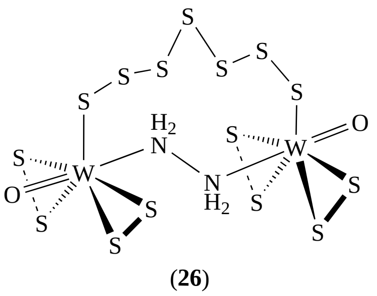
(**24**)

Treatment of $[WO_4]^{2-}$ with NH_4SCN in aqueous HCl gave oxotungsten(V) species, and reaction of this solution with polysulfide ion afforded $[(S_4)(O)W(\mu\text{-}S)_2W(O)(S_2)]^{2-}$ and the symmetrical species $[\{WO(S_4)\}_2)\mu\text{-}S)_2]^{2-}$.

Relatively few tungsten(VI) selenide or telluride species are known. Treatment of *trans*-$[W^{IV}E_2(PMe_3)_4]$ (E = S, Se, Te) with aldehydes afforded the metalla-oxirane derivative $[W^{VI}E_2(PMe_3)_2(\kappa^2\text{-}OCHR)]$ (**25**). Reaction of species containing $\{WO\}^{3+}$ with $(NH_4)_2S_x$ in the presence of 2,2′-dipyridyl (bipy) afforded the mononuclear species $[WO(\kappa^2\text{-}S_2)_2(bipy)]$ and reaction of $[WO_2S_2]^{2-}$ with elemental sulfur and hydrazinium hydrochloride afforded $[\{WO(\kappa^2\text{-}S_2)_2\}_2(\mu_2\text{-}S_7)(\mu_2\text{-}NH_2NH_2)]$ (**26**).



(**25**)



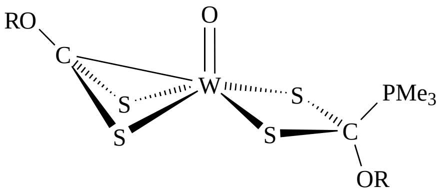
(**26**)

5.5 Dithioacid, Dithiocarbamate, Dithiophosphate, and Related Complexes

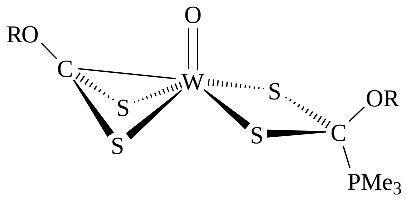
Elimination of HCl from $[W(CO)_2(H)Cl(PMe_3)_2]$ upon treatment with CS_2 and PMe_3 afforded $[W(CO)_2(PMe_3)_2](\kappa^3\text{-}S,S',C\text{-}S_2CPMe_3]$. Treatment of this complex with HBF_4 generated a dithioformato species $[W(CO)_2(PMe_3)_2\{\kappa^2\text{-}S_2C(H)PMe_3\}]^+$ and addition of MeI gave the analogous $[W(CO)_2(PMe_3)_2\{\kappa^2\text{-}S_2C(SMe)PMe_3\}]^+$

The tungsten carbyne complex $[W(\equiv CPh)(CO)_2(py)_2Cl]$ reacted with $(S_2CNEt_2)^-$ giving $[W^{II}(CO)(\eta^2\text{-}SCHPh)(\kappa^2 = C,S\text{-}SCNEt)_2]$, which was regarded as containing a neutral dihapto thiobenzaldehyde group. The complex could equally well be regarded as a metallacyclic W^{IV} complex binding $(SCHPh)^{2-}$.

Reaction of $[WOCl_2(PMe_3)_2]$ with potassium *O*-alkyl xanthates, KS_2COR (R = Me, Et, Pr^i) in thf afforded two isomers of $[W^{IV}O\{S_2C(PMe_3)(OR)\text{-}S,S'\}(S_2COR\text{-}S,S'C]$ (**27a**) and (**27b**). These two isomers were identified in solution, and the structure of (**27a**) was confirmed for a molybdenum analog (R = Pr^i). It was suggested that the zwitterionic ligand $^-S_2C^-(^+PMe_3)OR$ was generated by nucleophilic attack of trimethylphosphine on the C atom of the CS_2 moiety.



(**27a**)



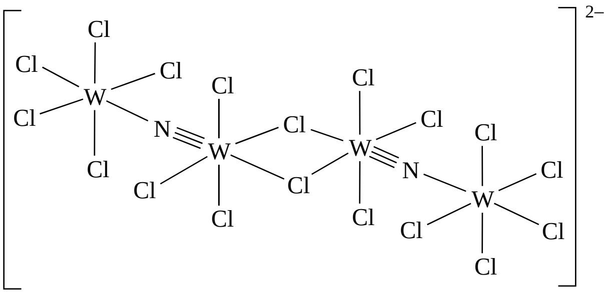
(**27b**)

Reductive desulfurization of $[WS(S_2)(S_2CNEt_2)_2]$ using $SiMe_3I$ afforded $W^V(\mu\text{-}S_2)_2(S_2CNEt_2)_4]I(I_3)$. Reaction of $[W(S_2CNR_2)_4]^+$ with LiTCNQ gave $[W(S_2CNEt_2)_4][TCNQ]$.

6 COMPLEXES WITH N-DONOR ATOMS

6.1 Nitrido Complexes

Reaction of WCl_6 with $Me_3SiNPMePh$ afforded the mixed-valence $W^V{}_2W^{VI}{}_2$ species $[PClMePh_2]_2[W_4N_2Cl_{18}]$ (**28**). This species contains two W^{VI} components $[WNCl_4]^-$ and



(**28**)

two neutral WCl_5 fragments. Two distinct W–N bonds were detected in the crystal structure, one a triple bond (1.69 Å) and the other a single bond (2.06 Å), with an almost linear W–N–W bond angle (178°).

Reaction of $[W^{III}_2(OBu^t)_6]$ with acetonitrile or benzonitrile afforded alkylidyne and nitrido complexes: $[\{W^{VI}(N)(OBu^t)_3\}_n]$ was polymeric, the terminal nitrido group interacting with neighboring W atoms via a weak donor bond. While $[W_2(OCH_2CH_2CF_3)_6]$ did not react with acetonitrile, with benzonitrile the trinuclear triangular species $[\{W(N)(OCH_2CH_2CF_3)\}_3]$, having μ-nitrido bridges, was formed. The W–N bond lengths alternate from 1.72 Å to 2.14 Å.

6.2 Imido Complexes

Reaction of the zwitterionic $[W(CO)_5\{NPhNPhC(OMe)Ph\}]$ with PCl_5, Br_2, or I_2 gave the imido complex $[\{W^{IV}(NPh)_2(CO)_2X(\mu\text{-}X\}_2]$. This dinuclear species reacted with donor ligands (L = pyridine, PR_3, or NCMe) giving $[WNPh)_2(CO)_2(LX_2]$.

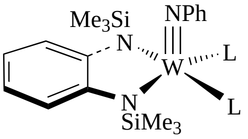
The dinuclear complex containing a bridging diimido ligand $[\{W^{IV}(CO)(PMePh_2)_2Cl_2\}_2(\mu\text{-}NHC_6H_4NH\text{-}p)]$ was obtained by the reaction of $[WCl_2(PMePh_2)_4]$ with the diisocyanate 1,4-$C_6H_4(NCO)_2$. A range of analogous complexes $[\{W(CO)(\{PMePh_2)_2Cl_2)_2(\mu\text{-}N\text{–}X\text{–}N)]$, where N–X–N = p-N-o-MeC_6H_3N, p-N(o-$MeOC_6H_3C_6H_3$ OMe-o)N, 1,5-$NC_{10}H_6N$, or m-NC_6H_4N, were prepared similarly and several complexes were investigated crystallographically. In all of these species, the $PMePh_2$ groups are mutually trans and the chloride ions cis. Electrochemical studies established that all complexes underwent two oxidation processes at low temperatures, indicating weak electronic communication between the metal centers. Only the species containing p-NC_6H_4N and p-N-o-MeC_6H_3N exhibited well-defined reduction behavior, undergoing two one-electron reduction processes, the remainder of the complexes exhibiting irreversible reduction behavior.

The silylimido complex $[W(NSiMe_3)Cl_2(PMe_3)_3]$ was prepared by reaction of $WCl_2(PMe_3)_4]$ with Me_3SiN_3.

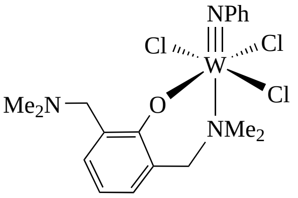
Treatment of $[WCl_4(SEt_2)_2]$ with the tetradentate triamidoamine ligand $N(CH_2CH_2NHC_6F_5)_3$ afforded $[W^{IV}\{[N(C_6F_5)CH_2CH_2]_3N\}Cl]$, which had a distorted trigonal bipyramidal structure.

Reaction of $[W(NPh)(\eta^4\text{-}C_6H_5Pr^n)\{(o\text{-}C_6H_4(NSiMe_3)_2\}]$ with pyridine, 4-picoline, or quinoline (L) or reduction of $[W(NPh)\{o\text{-}C_6H_4(NSiMe_3)_2\}Cl_2]$ with sodium in the presence of L afforded $[W^{IV}(NPh)\{o\text{-}C_6H_4(NSiMe_3)_2\}L_2]$ (**29**). This complex reacted with CO or PMe_3 (L′) in toluene to form the 6-coordinate *trans*-$[W(NPh)\{o\text{-}C_6H_4(NSiMe_3)_2\}L_2L']$.

Addition of $LiOC_6H_2(CH_2NMe_2)_2$-2,6-Me-4 to $[W(NPh)Cl_4((OEt_2)]$ resulted in displacement of the ether and formation of $[W^{VI}(NPh)Cl_3\{OC_6H_2(CH_2NMe_2)_2Me\}]$ (**30**), in which one of the two NMe_2 groups is coordinated trans to the phenylimido ligand. Oxidation of $[W(NPR_3)Cl_5]$ (R = Me or Ph), or addition of R_3PO to $[\{W(NCl)Cl_4\}_2]$, afforded $[W(NCl)Cl_4(OPR_3)]$.



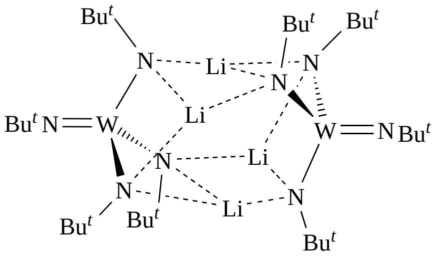
(**29**)



(**30**)

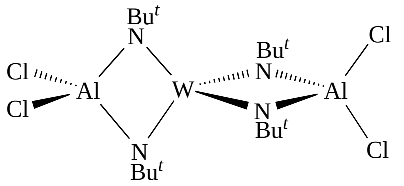
Treatment of $[W(NAr)Cl_4(thf)]$ (Ar = 2,6-$Pr^i{}_2C_6H_3$) with two equivalents of $Me_3SiNHAr$ in thf gave $[W(NAr)_2Cl_2(thf)_2]$ and this dichloride reacted with LiNHAr giving tetrahedral $[W(NAr)_3Cl]^-$.

Deprotonation of $[W(NBu^t)_2(NHBu^t)_2]$ by LiMe afforded dimeric $Li_2[W(NBu^t)_4]$, whose crystal-structure determination revealed that it should be formulated as $[Li_4W_2(NBu^t)_8]$ (**31**). The bridging NBu^t groups are coordinated as amido rather than imido ligands, and the terminal NBu^t group exhibits a reasonably short W=N bond (1.72 Å). This species reacted with the Lewis acids $AlCl_3$, $GaCl_3$, and $AlMe_3$ giving $[\{W(\mu\text{-}NBu^t)_2M'X_2\}_2]$ (M′ = Al or Ga, X = Cl or Me, e.g. (**32**)).



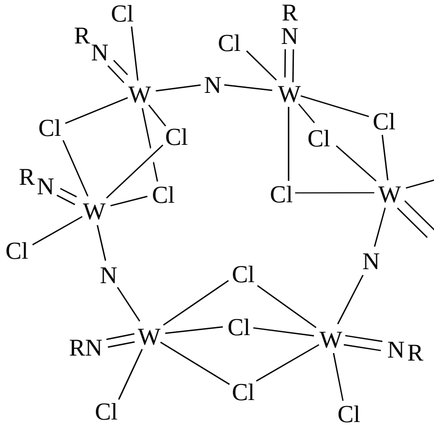
(**31**)

Protonation of $Li_2[W(NBu^t)_4]$ in ether gave initially $[W(NBu^t)_2(NHBu^t)_2]$, but further acid (CF_3SO_3H, CF_3CO_2H)



(**32**)

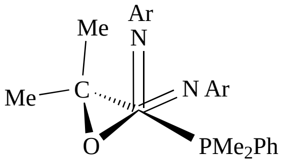
gave octahedral species such as $[W(NBu^t)_2(NH_2Bu^t)_2X_2]$ ($X = OSO_2CF_3$, $OC(O)CF_3$). With HBF_4, two species, $[W(NBu^t)_2(NHBu^t)(NH_2Bu^t)][BF_4]$ and $[W(NBu^t)_2(NHBu^t)(NH_2Bu^t)(F_2BF_2)]$, were isolated, whereas with HCl, only $[\{W(NBu^t)_2(NH_2Bu^t)Cl\}_2(\mu\text{-}Cl)_2]$ was formed. Treatment of $[W(NR)Cl_4L]$ (R = Et, L = nothing; R = C_6H_4Me-4, L = OEt_2) with $N(SiMe_3)_3$ in a 2:1 ratio afforded the hexanuclear species $[\{W_2(\mu_2\text{-}N)(NR)_2Cl_5\}_3]$ (**33**). Within each $(RN)W(\mu\text{-}N)W(NR)$ group, the two imido groups have nearly orthogonal orientations that maximize W–N π-bonding.



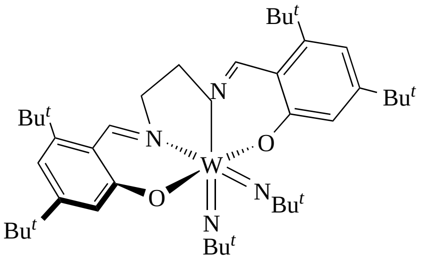
(**33**)

Reaction of $[W^{II}Cl_2L_4]$ (L = PMe_3 or $PMePh_2$) with one equivalent of Me_3SiN_3 gave the bis(silylimido) complex $[W^{VI}(NSiMe_3)_2Cl_2L_3]$. When two equivalents of Me_3SiN_3 were used, oxidative replacement afforded the five-coordinate mono(silylimido) complex $[W(NSiMe_3)Cl_2(PMePh_2)_2]$, which has a trigonal bipyramidal geometry, with cis equatorial imido ligands and short W–N bonds (1.70 Å).

Treatment of $[W(NAr)_2(PMe_2Ph)_2]$ (Ar = 2,6-$Pr^i{}_2C_6H_3$) with acetone in pentane afforded $[W(NAr)_2(PMe_2Ph)(\kappa^2\text{-}OCMe_2)]$. The long C–O bond (1.39 Å) in, and spectroscopic properties of, this complex were thought to be consistent with an oxo-metallopropane W^{VI} arrangement (**34**). Tetradentate Schiff bases derived by condensation of 1-hydroxy-2-benzaldehydes with alkane diamines reacted with $[W(NBu^t)_2(NHBu^t)_2]$ giving six-coordinate species such as (**35**), which contained *cis*-butylimido groups. Reaction of $[W(NBu^t)_2(NHBu^t)_2]$ with $\{HOSiPh_2\}_2O$ afforded an imido metallosiloxane $[W(NBu^t)(NH_2Bu^t)(OSiPh_2OSiPh_2O)_2]$, in which the two N atoms were trans to each other, and the two Bu^t groups were distinguishable by ^1H NMR spectroscopy.

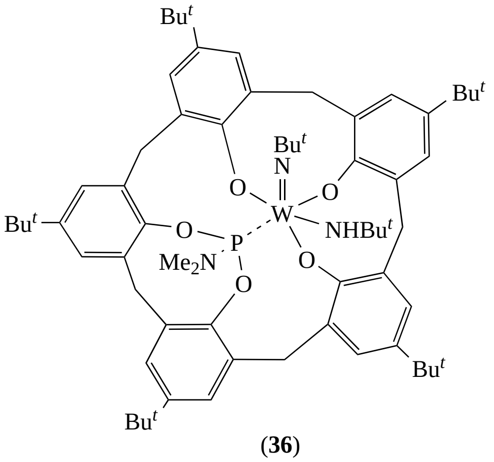


(**34**)



(**35**)

Treatment of $[W(NBu^t)_2(NHBu^t)_2]$ with a Me_2NP-modified calix[5]arene afforded (**36**), in which the W···P bond was relatively weak. The amido ligand was displaced by triflic acid, the W–P bond in the resulting triflate species becoming stronger.



(**36**)

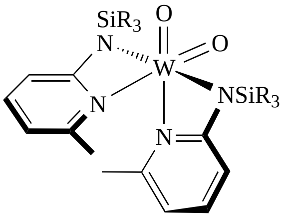
6.3 Amido Complexes

Treatment of $W(CO)_5(thf)]$ with $o\text{-}[OC_6H_4NH_2]^-$ and $o\text{-}C_6H_4(NH_2)_2$ in the presence of deprotonating agents afforded $[W(CO)_3\{o\text{-}O(NH)C_6H_4\}]^-$ and $[W(CO)_3\{o\text{-}(NH_2)C_6H_4\}]^-$, which had trigonal bipyramidal structures. Reaction of 2-aminopyridine (2-ampH) with $[W(CO)_5(thf)]$ gave

$[W(CO)_5(2\text{-ampH})]$, which was deprotonated by NAH giving dinuclear $[\{W(CO)_4(\mu\text{-2-amp})\}_2]$ and mononuclear $[W(CO)_5(\kappa^1\text{-2-amp})]^-$, the latter stabilized by a $\{Na^+\text{-crown ether}\}$ counter-cation.

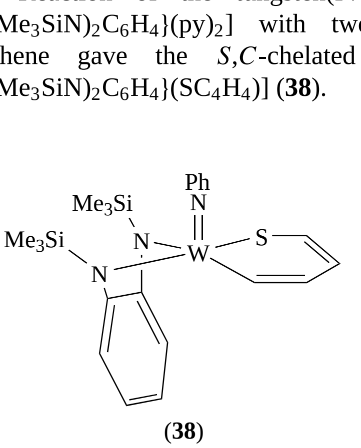
Reaction of $[W(NSiMe_3)Cl_2(PMe_3)_3]$ with $PCl_2RR'_2$ ($R = R' = Me$ or $R = Me$, $R' = Ph$) afforded the diamagnetic phospho-aminato species $[W^{IV}N{=}PR_3)Cl_2(PMe_3)_3]Cl$. Treatment of $WSCl_4$ with $NR_2(SiMe_3)$ afforded *fac*-$[WCl_3(NR_2)_3]$ R = Me, Et, or pyrrolidine). Reaction of $[W(NSiMe_3)Cl_2(PMe_3)_3]$ with Cl_2 at $-196\,°C$, followed by warming to room temperature, caused elimination of Me_3SiCl and Me_3PCl_2, the speed of the warm-up procedure determining the product. By these procedures, the phosphoraminato complexes $[W(N{=}PMe_3)Cl_5]$ and $[W(N{=}PMe_3)Cl_4(PMe_3)]$ were formed. Stoichiometric reaction of WCl_6 with one or two equivalents of $Cl_3P{=}NSiMe_3$ afforded $[W(NPCl_3)Cl_5]$ and $[\{W(N{=}PCl_3)Cl_4\}_2]$. Reaction of $[W(N{=}PCl_3)Cl_5]$ with $GaCl_3$ gave $[W(N{=}PCl_3)WCl_4][GaCl_4]$, in which a chlorine atom of the $[GaCl_4]^-$ ion is weakly coordinated to the tungsten trans to in aminato group, making W six-coordinate.

Reaction of lithium salts of pyridino-amido ligands $LiN(SiMe_3)(2\text{-}C_5H_3N\text{-6-Me})$ and $LiN(SiBu^tMe_2)(2\text{-}C_5H_3N\text{-6-Me})$ with $[WO_2Cl_2(dme)]$ (dme = 1,2-dimethoxyethane) gave *cis*-$W^{VI}O_2\{N(SiR_3)C_5H_3MeN\}_2]$ (**37**).

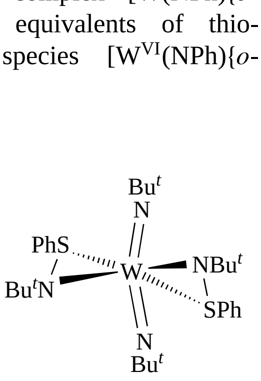


(**37**)

Reaction of the tungsten(IV) complex $[W(NPh)\{o\text{-}(Me_3SiN)_2C_6H_4\}(py)_2]$ with two equivalents of thiophene gave the *S*,*C*-chelated species $[W^{VI}(NPh)\{o\text{-}(Me_3SiN)_2C_6H_4\}(SC_4H_4)]$ (**38**).



(**38**)



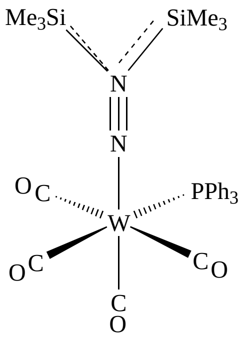
(**39**)

Treatment of $Li_2[W(NBu^t)_4]$ with PhSCl gave the sulfenamido complex $[W(NBu^t)_2(\kappa^2\text{-PhSNBu}^t)_2]$ (**39**), which has a distorted bicapped tetrahedral geometry.

Treatment of $[W(NPh)Cl_4]$ with one equivalent of methanol afforded $[W(NPh)Cl_3OMe)]$, which reacted further with $LiNMe_2$ to give $[W(NPh)(NMe_2)_4]$.

6.4 Hydrazido Complexes

Reaction of lithium trimethylsilyldiazomethanide with $[W(CO)_5(PPh_3)]$ in the presence of Me_3SiCl afforded $[W(CO)_4(PPh_3)\{\kappa^1\text{-NNC(SiMe}_3)_2\}]$ (**40**). The W–N bond is long (2.16 Å) and the N=N (1.17 Å) and N–C (1.343 Å) distances are intermediate between double and triple, and single and double bonds, respectively. Treatment of $[W(CO)_5({=}NNMe_2)]$ with dppe afforded $[W(CO)_3(dppe)({=}NNMe_2)]$, in which the W=N–N group is bent.



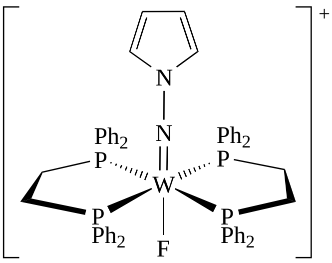
(**40**)

The arylation of $[WCl_4(dme)]$ with mesityl magnesium bromide under nitrogen afforded the dinuclear W^{III} species $[\{W_2(mes)_3Cl\}_2(\mu\text{-}N_2)]$ (mes = 2,4,6-$Me_3C_6H_2$), a species which could be regarded as containing the bridging N_2^{4-} group. Further addition of magnesium under nitrogen and under thf or mixtures of thf and dioxane afforded tri and tetranuclear species, $[Cl(mes)_3W(N{=}N)W(mes)_3(N{=}N)W(mes)_3Cl]^-$ and $[Cl(mes)_3W(N{=}N)W(mes)_3(N{=}N)W(mes)_3(N{=}N)W(mes)_3Cl]^{2-}$.

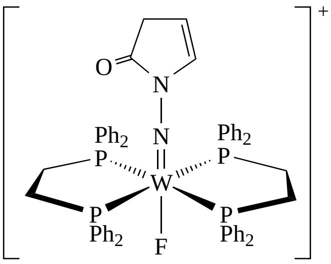
Reaction of WCl_6 with $Ph_2NNH_2{\cdot}HCl$ afforded $[W^{VI}(NNPh_2)Cl_4]$, which on Na/Hg reduction in the presence of PMe_2Ph, afforded $[W^{IV}(NNPh_2)(PMe_2Ph)_2Cl_2]$. This complex reacted with HCl or water to generate ammonia and diphenylamine.

Reaction of $[W(NNH_2)(dppe)_2F]^+$ (dppe = bis(diphenylphosphine)ethane) with 2,5-dimethoxotetrahydrofuran under acid-catalyzed conditions afforded the pyrrolylimido complex (**41**). However, when the same reaction was carried out with the corresponding 2,5-dihydrofuran, the kinetic product formed initially (**42**), slowly isomerizing to the thermodynamically more stable (**43**).

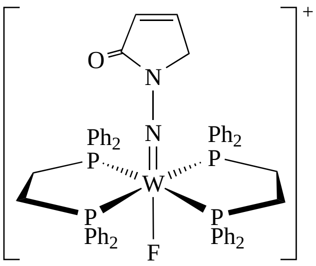
In related reactions, *cis,mer*-$[W(NHNH_2)(PMe_2Ph_2)_3X_2]$ (X = Cl or Br) with phthalaldehyde afforded (**44**).



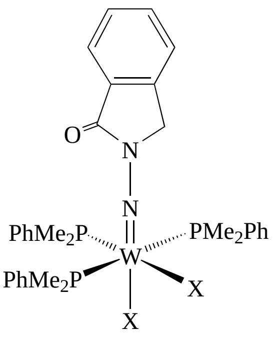
(**41**)



(**42**)



(**43**)



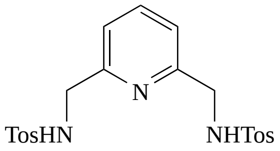
(**44**)

Treatment of $[W(N_2)_2(PMe_2Ph)_4]$ with HCl under CO afforded $[W^{IV}(NNH_2)(CO)(PMe_2Ph_2)Cl_2]$, which reacted with 2,4,6-trimethylpyrylium tetrafluoroborate in the presence of HCl giving the (1-pyridino)imino complex $[W^{IV}(NNC_5H_2Me_3)(CO)(PMe_2Ph)_2]^+$.

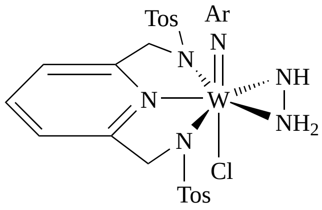
Reaction of *cis*-$[W(N_2)_2(dppe)_2]$ with triflic acid afforded *trans*-$[W^{IV}(NNH_2)(dppe)_2(OTf)]^+$, which could also be generated by reaction with two equivalents of *trans*-$[Ru(\eta^2\text{-}H_2)(dppe)_2Cl][OTf]$ under hydrogen.

Treatment of $[WCl_4(PR_3)_2]$ with two equivalents of $Me_3SiNHNMe_2$ gave the bis(hydrazido(2−) complex $[W^{VI}(NNMe_2)_2(PR_3)_2Cl]^+$. Reaction of $[W(NNPh_2)Cl_4]$ with Me_3SiCH_2MgCl and C_6F_5OH in thf afforded $[W(NNPh_2)(CH_2SiMe_3)_3(OC_6F_5)]$ whereas with $PhCH_2MgCl$, $[W(NNPh_2)Cl_2(OC_6F_5)_2(thf)]$ was formed.

Reaction of $[W(NAr)Cl_4]$ (Ar = 2,6-$Pr^i{}_2C_6H_3$) with AgOTf followed by the tridentate pyridyl ligand L (**45**) afforded $[W^{VI}(NAr)L(OTf)Cl]$, which reacted with two equivalents of hydrazine giving the hydrazido(1−) complex $[W(NAr)(\kappa^2\text{-}NHNH_2)LCl]$ (**46**).



(**45**)



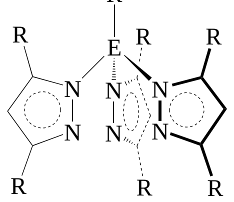
(**46**)

Ligand exchange reactions involving $[W(NNPh_2)(OBu^t)_4]$ with calixarenes afforded $[W(NNPh_2)(cal)]$. The W–N–bond angle was nearly linear, and the W–N was short (1.74–1.75 Å) whereas the N–N distance was long (1.32–1.33 Å), consistent with a W=N-NPh_2 bonding arrangement.

6.5 Tris(pyrazolyl)borato and Related Triaza Ligand Complexes

6.5.1 Nitrosyl Complexes

Treatment of $[W(NO)Tp^*Cl_2]$ [for Tp* and related ligands see (**47**)] with 1,3:5,6-di-*O*-isopropylidene-D-glucofuranase, HG_f, afforded diastereoisomers of $[W(NO)Tp^*Cl(OG_f)]$, a crystallographic study of the thermodynamically stable isomer establishing *S* absolute configuration at the metal atom.



(**47**)

Tp^{*-}, E = B, R′ = H, R = Me

A series of complexes $[Fe(C_5H_5)\{C_5H_4QNHW(NO)Tp^*Cl\}]$, where Q = nothing, C_6H_4, $CH{=}CHC_6H_4$, or

$N{=}NC_6H_4$, were prepared by reaction of the appropriate amino or anilino ferrocene with [W(NO)Tp*Cl_2]. Some of these complexes exhibited nonlinear optical properties, in particular, second order harmonic generation, although the response was significantly lower than that of their molybdenum counterparts.

6.5.2 *Carbonyl Complexes*

Treatment of [W$(CO)_3$Tp*] with bromine or iodine in acetonitrile afforded [$W^{II}(CO)_3$Tp*X] (X = Br, I). Under certain circumstance, addition of Br_2 also caused bromination of the Tp* ligand at the 4-position on the pyrazole rings. These complexes were monodecarbonylated by heating in acetonitrile, the products being, for example, [W$(CO)_2${HB(3,4-Me_2-4-Br$C_3N_2)_3$}] and [W(CO)(η^2-NCMe){HB(3,4-Me_2-4-Br$C_3N_2)_3$}], the precise product being determined by the heating time. The structures of the sideways-bonded acetonitrile adduct (C–N 1.10 Å) and that of the seven-coordinate [W$(CO)_3${HB(3-$Pr^i$$C_3H_2)_3$}I] were determined crystallographically.

The dinuclear species [{$W^{II}(CO)_2$Tp*}$_2$(μ-S)] was obtained by refluxing [W$(CO)_2$Tp*Br] or [W$(CO)_3$Tp*H] with propylene sulfide in 1,2-dichloroethane. The W–S–W chain is nearly linear, suggesting multiple bond character within the group, consistent with relatively short W–S bonds (2,17–2.18 Å).

Treatment of [$W^{II}(CO)_2$Tp*I], obtained by prolonged refluxing of [W$(CO)_3$Tp*I] in thf, with alkyl and aryl thiolates afforded [W$(CO)_2$Tp*(SR)] (R = Me, Et, Pr^i, CH_2Ph or p-$C_6H_4NO_2$). However, reaction of [W$(CO)_3$Tp*Br] with NaSPr^i in acetonitrile afforded [{W$(CO)_2$Tp*}$_2${μ-NC(Me)C(Me)N-N,N'}], which contains a bridging *anti*-butane-2,3-diimino-(2−) -$N{:}N'$ ligand formed by the coupling of two acetonitrile molecules.

Reaction of [W^{II}(CO)(η^2-NCMe)Tp*Br] with $(S_2PR'_2)^-$ (R′ = (−)-mentholate) afforded [W(CO)(η^2-NCMe)Tp*(κ^1-$S_2PR'_2$)], the structure of the (R)-isomer being determined crystallographically. Oxidative decarbonylation of [W$(CO)_3$Tp*]$^-$ by tetraethylthiuramdisulfide, Et_2NC(S)SSC(S)NEt_2, afforded the seven-coordinate W^{II} species [W$(CO)_2$Tp*(κ^1-$S_2CNEt_2)_2$], which had distorted pentagonal bipyramidal structure with a CO group and one N-donor atom of the Tp* occupying the axial positions.

The seven-coordinate phosphine complexes [$W^{II}(CO)_3$Tp*L]$^+$ were prepared by oxidation of the radical species [W$(CO)_3$Tp*] by ferrocenium cation, followed by addition of L (PMe_3, PEt_3, PPh_3, PMe_2Ph). These species exhibited capped octahedral geometries.

Reaction of [W$(CO)_2$Tp*I] with ammonia in dichloromethane at low temperatures afforded the amido species [$W^{II}(CO)_2$Tp*(NH_2)] which, on treatment with LDA or LiBu^t followed by MeI, could be converted to [W$(CO)_2$Tp*(NMe_2)]. Hydride ion abstraction from [W$(CO)_2$Tp*(NH_2)] using CPh_3^+ afforded the 'nitrene' species [W$(CO)_2$Tp*(NR)]$^+$ (R = H, CPh_3). Treatment of [W$(CO)_2$Tp*(NH)]$^+$ with base (KH, LDA, or NEt_3) afforded the nitrido W^{IV} species [W$(CO)_2$Tp*(≡N)] and reaction of this with MeOTf and MeCOCl afforded [W$(CO)_2$Tp*(NMe)]$^+$ and [WTp*Cl{NC(O)Me)], respectively. Heating [W$(CO)_3$Tp*H] with tosyl azide in thf gave the amido species [$W^{II}(CO)_2$Tp*(NHtos)].

Irradiation of [W$(CO)_3$Tp*H] in the presence of benzonitrile caused insertion of the nitrile into the W–H bond, giving [$W^{II}(CO)_2$Tp*(N=CHPh)], and related complexes [W$(CO)_2$Tp*(NCHR)] (R = Me, Et) were prepared similarly. Protonation of [W$(CO)_2$Tp*(NCHR)] by HBF_4 at low temperature afforded the cationic imido complexes [$W^{IV}(CO)_2$Tp*(=NCH_2R)]$^+$ (R = Me, Et, CH_2Ph), but when Ph_3CBF_4 was used instead of HBF_4, [$W^{IV}CO)_2$Tp*{=NCH(R)CPh_3}]$^+$ was formed.

Oxidative decarbonylation of [W$(CO)_3$Tp*]$^-$ by tetraethylthiuram disulfide afforded a mixture of [{W($S_2CNEt_2)_2$}$_2$(μ-S)] and [W^{IV}(S)Tp*(S_2CNEt_2)]. [W$(S)_2$Tp*(OPh)] reacted with MeO_2CC≡CCO_2Me giving the dithiolato species [W^{IV}Tp*(OPh){$S_2C_2(CO_2Me)_2$}].

Air oxidation of [W$(CO)_3$Tp*I] in refluxing toluene afforded W^{IV}(O)(CO)Tp*I]. Reaction of [W(CO)Tp*I(κ^2-C,N-NCMe)] with pyridine-N-oxide afforded the acylimino complex [W^{IV}(CO)Tp*{=NC(O)Me}I], whereas reaction with propylene sulfide afforded [W^{IV}(S)(CO)Tp*I]. Reaction of [W(CO)Tp*I{NC(O)Me}] with SPh^- and with {S_2PPh_2)$^-$ afforded [W^{IV}(CO)Tp*{NC(O)Me}(SPh)] and [W^{IV}(CO)Tp*{NC(O)Me}(κ^1-S_2PPh_2)]. Propylene sulfide reacted with this last complex, affording the sulfido derivative [W^{IV}(S)(CO)Tp*(κ^1-S_2PPh_2)], and the analogous oxo species [W^{IV}(O)(CO)Tp*(κ^1-S_2PPh_2)] was prepared by reaction of [W$(CO)_2$Tp*(κ^1-S_2PPh_2)].

Treatment of the amido W^{II} complex [W$(CO)_2$Tp*(NHtos)] (tos = tosyl) with AgOTf or I_2 afforded the 'nitrene' (or imido complex) [W$(CO)_2$Tp*(Ntos)]$^+$, and iodine or trityl cation oxidation of [W$(CO)_2$Tp*(NHR)] (R = Bu^t, Ph) similarly afforded [W$(CO)_2$(NR)Tp*]$^+$. The W–N–C bond angles and W–N distances were 172° (R = Bu^t and Ph), and 1.72 Å (R = Bu^t and 1.76 Å (R = Ph), respectively. A related carbene complex [W$(CO)_2${=C(Ph)Me}Tp*] was also reported, in which there was an agostic interaction between a methyl hydrogen atom of the carbene and the metal. Reaction of [W$(CO)_2$Tp*(Ntos)]$^+$ with PMe_3 afforded the phosphinimine Me_3P=Ntos, [W$(CO)_2$Tp*$(PMe_3)_2$]$^+$, and [W$(CO)_2$Tp*(PMe_3(Ntos)]$^+$. [W$(CO)_2$Tp*(PMe_3(Ntos)]I_3 slowly decomposes to form [W(CO)Tp*(Ntos)I].

Reaction of WCl_6 with $Me_3SiCH{=}CH_2$ in ether and thf afforded [$WCl_3(thf)_2$], which reacted with Tp*$^-$ giving low yields of [W^V(O)Tp*Cl_2]. This complex reacted with mono and difunctional phenolates, affording [W^V(O)Tp*Cl(OAr)] (Ar = Ph, 2,5-$Cl_2C_6H_3$, C_6Cl_5, C_6H_4R-p where R = OMe, OH, C_6H_4OH, $N_2C_6H_4$OH) and the dinuclear [{W^V(O)Tp*Cl}$_2$(OC_6H_4O)], [{W^V(O)Tp*Cl}$_2$($OC_6H_4QC_6$

$H_4O)]$, and $[\{W^V(O)Tp^*Cl\}_2(OC_6H_2Cl_2O)]$. The tungsten atom in each of these species has pseudo-octahedral geometry. The mononuclear species could be electrochemically oxidized and reduced in reversible one-electron steps to W^{VI} and W^{IV} species, but none of these was isolated. The dinuclear complexes exhibited more complex redox behavior, oxidation occurring in discrete one-electron steps, generating mono and dications. Reduction occurred, at least for the species containing OC_6H_4O, in two clearly separate one-electron processes, but for the other species reduction appeared to occur in two nearly or actually coincident one-electron steps. From simple molecular orbital calculations, supported by detailed spectroelectrochemical and EPR spectral measurements, it was clear that for most of the complexes, the first one-electron oxidation resulted in the formation first of mixed-valence species (W^VW^{VI}) and the second process resulted in formation of the $W^{VI}W^{VI}$ dication. Reduction resulted in generation of $W^{IV}W^V$ and $W^{IV}W^{IV}$ species, the interaction between the two oxidized species being significantly greater than that between the reduced species. The antiferromagnetic magnetic exchange interactions in the dinuclear species, apparent in the EPR spectra and quantified by the determination of J by solid-state susceptibility measurements, depended on the length and planarity of the bridging ligand and hence was strongest for $[\{W(O)Tp^*Cl\}_2(OC_6H_4O)]$ and weakest for $[\{W(O)Tp^*Cl\}_2OC_6H_4C_6H_4O]$. The EPR spectra of the mono-oxidized dinuclear species indicated that these monocations were valence-trapped, at least on the EPR timescale. These dinuclear tungsten complexes exhibited weaker electronic and magnetic interactions than their molybdenum analogs probably because of poorer W–OAr $d_\pi - p_\pi$ orbital overlap.

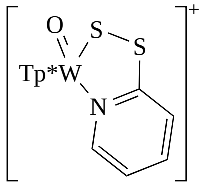
Oxidative hydrolysis of $[W(CO)_3Tp^*]^-$ afforded the mixed-valence species $[Tp^*(O)_2W(\mu\text{-}O)W(CO)(O)Tp^*]$, which is believed to contain W^{VI} and W^{IV} centers.

6.5.3 Other Complexes

Reaction of $[W(CO)_3Tp^*I]$ with DMSO in the presence of water afforded $[W^{VI}Tp^*(O)_2(OH)]$, which, on treatment with OH^-, afforded the octahedral species $[WTp^*(O)_3]^-$. Oxidation of $[WTp^*(O)_2(\mu\text{-}O)W(O)(CO)Tp^*]$ by Bu^tOOH gave the dinuclear $[\{WTp^*(O)_2\}_2(\mu\text{-}O)]$.

Treatment of $[W(CO)_3Tp^*]^-$ with one equivalent of elemental sulfur in dmf afforded the mononuclear species $[WTp^*(S)_3]^-$, analogous to $[WTp^*(O)_3]^-$. A similar reaction using $[W(CO)_3Tp]^-$ afforded the trisulfide and $[\{WTp^*(O)(S_2)_2\}_2(\mu\text{-}S)]^{2-}$. Reaction of $[WTp^*(O)_2Cl]$ with B_2S_3 or P_4S_{10} afforded $[WTp^*(O)(S)Cl]$ and $[WTp^*(S)_2Cl]$, which reacted with OPh^-, SPh^-, $SePh^-$, or (−)-mentholate (X) giving $[WTp^*(O)(S)X]$ and $[WTp^*(S)_2X]$, the crystal structures of $[W(S)_2Tp^*(OPh)]$ and (R,S)-[W(O)(S)Tp*{(−)-mentholate}] confirming their octahedral geometries.

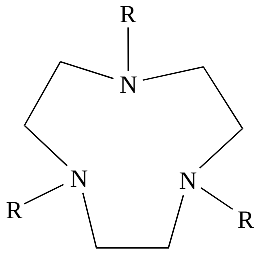
Reaction of $[WTp^*(S)_2X]$ (X = monoanion) with alkynes afforded dithiolato complexes $[W^{VI}Tp^*(S_2C_2R_2)X]$ (R = CO_2Me or Ph; X = SePh or 2-quinoxalinyl). Treatment of $[W(CO)Tp^*(S)(S_2PR_2)]$ (R = OEt or Ph) with pyridine-N-oxide in toluene afforded $[W^{VI}Tp^*(O)(S)(\kappa^1\text{-}S_2PR_2)]$, and when $[WTp^*(O)(S)Cl]$ reacted with $[Spy]^-$red $[W^{VI}Tp^*(O)(S)(Spy)]$ was formed. In this last species, the pyridine thiolato ligand was monodentate and S-bonded. Reaction of $[W^{VI}Tp^*(O)(S)(Spy)]$ with NO^+ afforded green paramagnetic $[W^VTp^*(O)(S_2py)]^+$ (**48**).



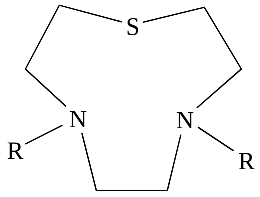
(**48**)

6.6 Complexes of Cyclic Triaza and Related Ligands

Photolysis of $[W(CO)_6]$ in the presence of $Bu^t{}_3tacn$ (**49**, R = Bu^t), afforded $[W(CO)_3(Bu^t{}_3tacn)]$, which has a piano-stool conformation similar to that of $WO_3(Bu^t{}_3tacn)]$. Reaction of $[W(CO)_3(tdcn)]$ (tdcn = (**50**)) with NO^+ (prepared directly from $NaNO_2$/HCl) gave $[W(CO)_2(NO)(tdcn)]^+$, which, on prolonged exposure to NO^+, was converted to $[W(NO)_2(tdcn)Cl]^+$.



(**49**)



(**50**)

Oxidation of $[W(CO)_3(R_3tacn)]$ (R = benzyl (**49**, R = CH_2Ph) by ferrocenium cation afforded the air- and light-sensitive $[W^I(CO)_3(R_3tacn)]^+$. Oxidation of $[W(CO)_3(R_3\ tacn)]$ (R = H (**49**, R = H), itself obtained by reaction of $[W(CO)_6]$ with R_3tacn) by iodine afforded $[W^{II}CO)_3(R_3tacn)I]^+$.

Oxidation of $[W(CO)_3(Bu^t{}_3tacn)]$ [$Bu^t{}_3$tacn = (**49**, R = Bu^t)] by hydrogen peroxide afforded $[W^{VI}(Bu^t{}_3tacn)(O)_3]$, which also has octahedral symmetry.

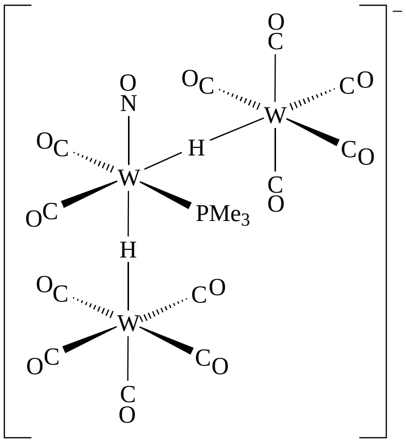
6.7 Nitrosyl Complexes

Reaction of NO with $[W(CO)_2(phen)(SPh)_2]$ gave $[W(CO)_2(NO)(phen)(SPh)]$, formally containing W^0, together

with PhSNO. The NO group is trans to the thiophenolate ligand. Similar treatment of *cis*-$W(CO)_2$(phen)(tdt)] (tdt = toluene-3,4-dithiolate), the dinitrosyl *cis*-$[W(NO)_2$(phen)(tdt)] was formed. $[W(CO)_3H$(phen)(SPh)], the latter reacting with NO to give $[W(CO)_2(NO)$(phen)(SPh)], N_2O and HNO_2 (the last two by decomposition of eliminated HNO).

The hydrido complex *trans,trans*-$[WH(CO)_2(NO)(PR_3)_2$ (R = Me, Et, Ph, OPr^i) reacted with $BH_3{\cdot}L$ (L = thf, SMe_2) to give *trans*-$[W(\kappa^2\text{-}BH_4)(CO)(NO)(PR_3)_2]$, which has octahedral geometry (R = Me confirmed crystallographically). $[WH(CO)_2(NO)(PMe_3)_2]$ reduced β-diketones to β-hydroxyketones with concomitant formation of *trans*-[W(diketonate)(CO)(NO)$(PMe_3)_2$].

Treatment of $[W_2H(CO)_9(NO)]$ with tertiary phosphines or pyridine afforded mono and disubstituted complexes, two isomers existing for each compound, although only one was isolated successfully by column chromatography. The species $[(OC)_5W(\mu\text{-}H)W(CO)_3L(NO)]$ [L = $P(p\text{-}C_6H_4F)_3$] and $[(OC)_5W(\mu\text{-}H)W(CO)_2L_2(NO)]$ (L = py or $P(p\text{-}C_6H_4F)_3$; L_2 = bipy) were characterized crystallographically. Treatment of $[W_2H(CO)_7(thf)_2(NO)]$ with the sterically bulky $PBu^t{}_3$ caused monosubstitution, giving $[W_2H(CO)_8(PBu^t{}_3)(NO)]$, and also abstraction of the hydride with formation of $[HPBu^t{}_3]^+$ as well as $[W_2(\mu\text{-}H)(CO)_{10}]^-$ and $[W_3(\mu\text{-}H)_2(CO)_{13})(NO)]^-$. The trinuclear tungsten nitrosyl dihydride was also formed by reaction of $[W_2H(CO)_9(NO)]$ with $[W(CO)_5H]^-$, and reacted with PMe_3 giving $[W_3(\mu\text{-}H)_2(CO)_{12}(PMe_3)(NO)]^-$ (**51**).



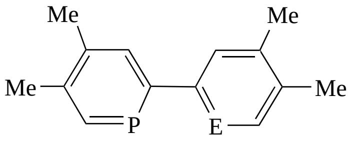
(**51**)

$[W(NO)(SBu^t)_3(py)]$ was prepared by reaction of $[W(NO)(OBu^t)_3(py)]$ with an excess of Bu^tSH in toluene. The structure of this molecule was trigonal bipyramidal, in which the py and NO ligands were in axial positions. The W–N–O bond was linear.

7 COMPLEXES WITH P-, As-, Sb-, AND Bi-DONOR ATOMS

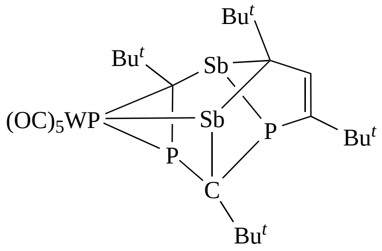
When *trans*-$[W(N_2)_2(dppe)_2]$ was irradiated in the presence of 1,4-diisocyanobenzzene and 4-isocyanobenzonitrile, *cis*-$[W(CNC_6H_4NC)_2(dppe)_2]$ and *cis*-$[W(CNC_6H_4CN)_2(dppe)_2]$ were formed. The isocyanide ligands exhibited bent W–C–NAr bonds.

Reduction of WCl_6 by an excess of Mg powder in the presence of 4,4′,5,5′-tetramethyl-2,2′-diphosphinine, tmbp (**52**) (E = P), a fully phosphinated analog of 2,2′-dipyridyl, afforded the trigonal $[W(tmbp)_3]$. A regular octahedral complex would have a twist angle $\theta = 60°$ and in this complex the twist angle θ is $15 \pm 0.6°$ indicating that the ligand may be partially reduced, a situation reminiscent of the behavior of tris(dithiolene) complexes. UV irradiation of $[W(CO)_6]$ with (**52**) (E = N), another analog of 2,2′-dipyridyl, afforded $[W(CO)_4(\kappa^2\text{-}C_{12}H_{12}NP\text{-}N,P)]$.



(**52**)

Reaction of $[W(CO)_5(thf)]$ with the phosphorus-antimony cage $P_4Sb_2C_4Bu^t{}_4$ afforded the dinuclear $[\{W(CO)_5\}\{\kappa^1\text{-}P_4Sb_2C_4Bu^t{}_4\text{-}P,Sb\}]$ (**53**).

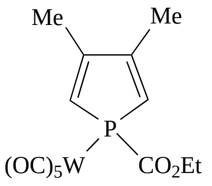


(**53**)

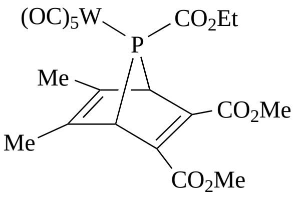
Reaction of $[W(CO)_5Br]^-$ and *fac*-$W(CO)_3(NCMe)_3]$ with $Me_2SbCH_2SbMe_2$ afforded $[W(CO)_5(\kappa^1\text{-}Me_2SbCH_2SbMe_2)]$ and *fac*-$[W(CO)_3(\kappa^1\text{-}Me_2SbCH_2SbMe_2)_3]$ whereas $W(CO)_5$(thf)], $[W(CO)_6]$, and $[W(CO)_4(Me_2NCH_2CH_2CH_2NMe_2)]$ reacted with $Ph_2SbCH_2SbPh_2$ affording $[(OC)_5W(\mu\text{-}Ph_2SbCH_2SbPh_2)W(CO)_5]$ and *cis*-$[W(CO)_4(\kappa^1\text{-}Ph_2SbCH_2SbPh_2)_2]$, respectively.

Treatment of the cyclic $[As(PBu^t)_3]^-$ with water afforded $[Bu^tP(PHBu^t)_2$, which subsequently reacted with $[W(CO)_5(thf)]$ giving $[W(CO)_4\{\kappa^2\text{-}(Bu^tP)_2PBu^t\text{-}P,P'\}]$. Reaction of $[W_2(CO)_{10}]^{2-}$ with PCl_3 afforded a mixture of $[W(CO)_5(PCl_3)]$, $[\{W(CO)_5\}_2(\mu\text{-}PCl)]$, and $[W(CO)_5\{\mu,\eta^2{:}\kappa^1{:}\kappa^1\text{-}P_2Cl_2[W(CO)_5]\}]$.

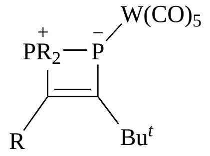
The phosphole complex (**54**) reacted with $MeO_2CC{\equiv}CCO_2Me$ giving phosphanornadiene complexes (**55**). This reacted in turn with PEt_3 giving a phosphoranylidenephosphine complex $[W(CO)_5\{EtO_2CPPEt_3\}]$, in which the P–P bond length (2.16 Å) was closer to a single bond than to a double bond, consistent with zwitterionic character in the diphosphorus ligand, viz. $\{EtO_2CP^{-}{-}^{+}PEt_3\}$. A similar zwitterionic situation appears to have occurred in the diphosphate derivative (**56**) (R = $SiMe_3$), which reacted with F^- affording (**56**) (R = H).



(**54**)



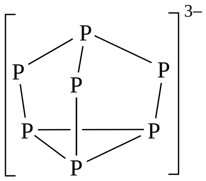
(**55**)



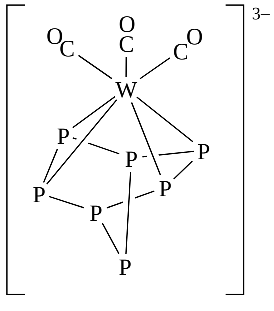
(**56**)

Reaction of *trans*-$W(N_2)_2(dppe)_2]$ with aromatic isocyanides afforded *cis*- and *trans*-$[W(CNAr)_2(dppe)_2]$ (Ar = *p*-RC_6H_4 where R = CF_3, NO_2, CN, NC, F, and Me).

Treatment of $[W(CO)_3(\eta^6\text{-}C_6H_3Me_3)]$ with K_3P_7 (**57**) and 2,2,2-crypt in 1,2-diaminoethane afforded $[W(CO)_3(P_7)]^{3-}$ (**58**), which could be alkylated and protonated giving $[W(CO)_3(P_7Et)]^{2-}$ (**59**) and $[W(CO)_4(P_7H)]^{2-}$ (**60**). Under CO at atmospheric pressure, (**58**) was converted to $[W(CO)_4(\kappa^2\text{-}P_7)]^{3-}$.

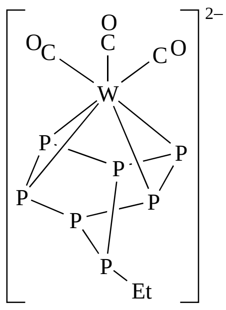


(**57**)

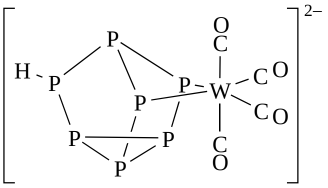


(**58**)

Reaction of $[W(CO)_5]^{2-}$ with $(Me_3Si)_2CHBiCl_2$ afforded $[\{W(CO)_5\}_2(\mu_3\text{-}\kappa^2\text{-}Bi_2)]$ (**61**) and $[W_2(CO)_8(\mu\text{-}\kappa^2\text{-}Bi_2)(\mu\text{-}BiMe)W(CO)_5]$ (**62**). The species (**62**) contains a Bi_2 group bridging two W atoms and if the Bi–Bi bond order is regarded as one, then the formal oxidation state of the transition metal is II. However, the Bi–Bi bond is quite short (2.80 Å) and

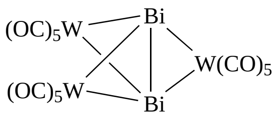


(**59**)

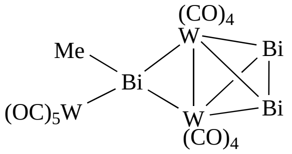


(**60**)

corresponds approximately to a bond order of 2, and so the formal oxidation state of the tungsten atoms is between I and II.



(**61**)

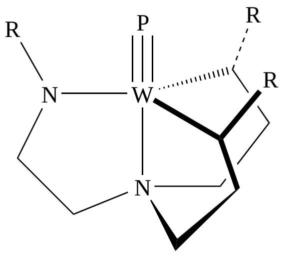


(**62**)

Reaction of $[W(CO)_5]^{2-}$ with $Br_2BN(SiMe_3)_2$ afforded the terminal borylene complex $[\{(Me_3Si)_2NB{=}\}W(CO)_5]$, which is octahedral, with a linear W–B–N group and short B–N bonds (1.34 Å).

Reaction of $[WCl_2(PMe_3)_4]$ with ArP=C=O (Ar = 2,4,6-$Bu^t{}_3C_6H_2$) afforded the W^{IV} complex $[W({=}PAr)(CO)(PMe_3)Cl_2]$, in which the W–P–C group was essentially linear (168°).

Treatment of $[WCl\{(Me_3SiNCH_2CH_2)_3N\}]$ with LiPHPh afforded the phosphido tungsten (VI) species $[W({\equiv}P)\{(Me_3SiNCH_2CH_2)_3N\}]$ (**63**, R = $SiMe_3$), and the corresponding arsenido complex, $[W({\equiv}As)\{(Me_3SiNCH_2CH_2)_3N\}]$ (very low yield), together with $[WPh\{(Me_3SiNCH_2CH_2)_3N\}]$, was obtained using LiAsHPh. The arsenide was obtained in more substantial yields in the reaction between $[WPh\{(Me_3SiNCH_2CH_2)_3N\}]$ and a small excess of AsH_2Ph.

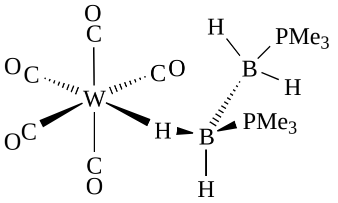


(**63**)

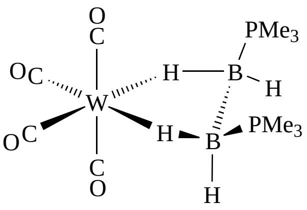
8 HYDRIDO AND BOROHYDRIDO COMPLEXES

Photolysis of $[W(CO)_6]$ in the presence of $B_2H_4(PMe_3)_2$ afforded $[W(CO)_5\{\kappa^1\text{-}HB_2H_3(PMe_3)_2\}]$ (**64**) and $[W(CO)_4$

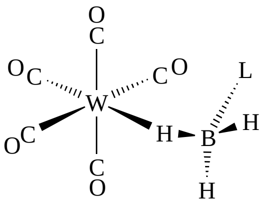
{(κ^2-$H_2B_2H_2(PMe_3)_2$}] (**65**). Analogous reactions involving $BH_3(PR_3)$ (R = Me, Ph) or $BH_3(NMe_3)$ afforded [$W(CO)_5$(κ^1-HBH_2L)] (L = PR_3 or NMe_3) (**66**).



(**64**)

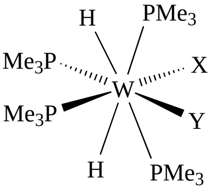


(**65**)



(**66**)

The species previously formulated as [$W(PMe_3)_4H_2(H_2O)$]F was reformulated as [$W^{IV}(PMe_3)_4H_2F_2(H_2O)$] or [$W(PMe_3)_4H_2F_2(FHF)$]. Treatment of [$W(PMe_3)_4$($\kappa^2$-$CH_2PMe_2$)H] with aqueous HCl afforded [$W^{IV}(PMe_3)_4H_2Cl_2$] and anion exchange with bromide and iodide gave [$W(PMe_3)_4H_2X_2$] (X = Br or I). The structure of these species is represented as (**67**) (X = Y = F, Cl, Br, I; X = F, Y = F···H–F).



(**67**)

Controlled potential electrolysis of [WH_2(κ^2-O_2CMe)$(dppe)_2]^+$ containing one equivalent of $MeCO_2H$ afforded [$W^{IV}H_3$(κ^1-OCOMe)$(dppe)_2$] in high yields.

9 METAL–METAL BONDED COMPLEXES AND CLUSTER COMPOUNDS

9.1 Dinuclear Complexes

Several reviews of ditungsten compounds having multiple bonds have described this area.[4,8] In very general terms, the formal bond order for ditungsten compounds ranges from four to less than unity. The range of bond lengths varies from ca. 2.30 Å, formally representing a quadruple bond, to ca. 2.83 Å, formally representing a single bond, although variations occur depending on the nature of the terminal and bridging ligands. Quadruply bonded species are normally encountered in $W^{II}W^{II}$ complexes, triply bonded species in $W^{III}W^{III}$ compounds, and doubly bonded species in $W^{IV}W^{IV}$ complexes. Dinuclear complexes containing the W^VW^V core usually have W–W single bonds. A significant number of multiply bonded ditungsten complexes carry the η^5-C_5H_5 or related ligands but these are not discussed here.

Probably the most dominant species amongst the dinuclear species are those containing W^{III}, lower oxidation state species being highly susceptible to oxidation.

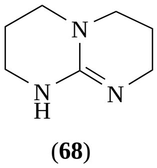
9.1.1 Complexes Containing $W^{II}W^{II}$

The dominant structural feature of complexes containing W_2^{4+} is the presence of a quadruple bond. However, the ditungsten core is extremely sensitive to oxidative addition and consequently the chemistry of $W^{II}W^{II}$ species is less well developed than that of molybdenum. However, [$(Me_3P)_2(MeCC)_2WWCl_2(PMe_3)_2$] ($d_{W\text{–}W}$ 2.27 Å) was obtained by reaction of [$W_2Cl_4(PMe_3)_4$] with LiC≡CMe. A range of complexes containing carboxylates, amines, N-based chelating ligands, tertiary phosphines, and halides has also been described. Addition of $PhICl_2$ to [$W_2Cl_4(PMe_3)_4$] afforded the mixed-valent $W^{III}W^{II}$ species [$W_2Cl_5(PMe_3)_3$] ($d_{W\text{–}W}$ 2.43 Å).

9.1.2 Complexes Containing $W^{III}W^{III}$

The simplest dinuclear tungsten (III) species are of the type [W_2X_6] have an ethane-like structure and have W–W bonds in the range 2.26–2.29 Å. A smaller but significant group also contain the {W_2X_6} core but carry two or three additional neutral ligands and in some species, although the ditungsten core can be defined as carrying a +6 charge, the two W atoms may have different formal oxidation states. In general, in these latter species, the W–W bond distances are slightly larger than in [W_2X_6], within the range 2.31–2.50 Å, depending on the coligands.

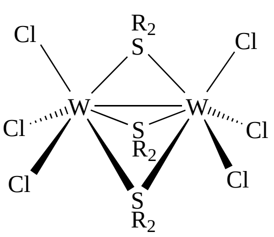
Reduction of WCl_4 by one equivalent of $NaBHEt_3$ in the presence of Lihpp (hppH = (**68**)) afforded [$W_2(hpp)_4Cl_2$] (W–W 2.25 Å).



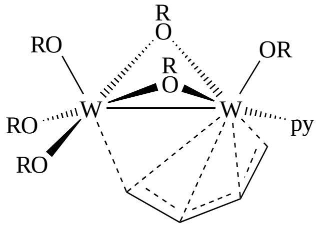
(**68**)

However, reduction of WCl_4 using sodium amalgam in the presence of an excess of tertiary phosphine L afforded $[W_2(\mu\text{-Cl})_2Cl_4L_4]$ [L = PMe_2Ph (d_{W-W} 2.70 Å); L = PEt_3 (d_{W-W} 2.74 Å), PMe_3 (d_{W-W} 2.71 Å)]. These complexes have edge-sharing dioctahedral geometries, but their face-sharing analogs $[W_2(\mu\text{-X})_3X_3L_3]$ were obtained by restricting the amount of L used in the reaction. Species characterized crystallographically included $[W_2(\mu\text{-Cl})_3Cl_3(PMe_2Ph)_3]$ (d_{W-W} 2.44 Å), $[W_2(\mu\text{-Cl})_3Cl_3(PEt_3)_3]$ (d_{W-W} 2.47 Å), and $[W_2(\mu\text{-Br})_3Br_3(PMe_2Ph)_3]$ (obtained from WBr_5) (d_{W-W} 2.48 Å). Addition of water to $[W_2(\mu\text{-Cl})_3Cl_3(PEt_3)_3]$ afforded $[W_2(\mu\text{-Cl})_3Cl_4(PEt_3)_3]^-$ (d_{W-W} 2.44 Å).

When WCl_4 was reduced by sodium amalgam in the presence of thioethers such as SEt_2, 1,4-dithiane, 1,4-dithioxane, or pentamethylene sulfide, the sulfur rather than Cl ligand frequently acted as the bridging ligand, viz. $[W_2(\mu\text{-SR}_2)_3Cl_6]$ (**69**) (L = SEt_2, d_{W-W} 2.50 Å, L = 1,4-dithiane, d_{W-W} 2.48 Å, L = 1,4-dithioxane, d_{W-W} 2.50 Å, L = pentamethylene sulfide, d_{W-W} 2.51 Å). However, reaction with SMe_2 invariably afforded $[W_2(\mu\text{-Cl})(\mu\text{-SMe}_2)_2Cl_6]^-$ and the precise nature of these bridged species (i.e. exclusively bridging SR_2 or mixtures of halide and SR_2) was dependent on reaction conditions. The bridging sulfur centers in the anionic species were susceptible to attack by anions X^- (X = SR, SeR, Cl, Br or H), resulting in loss of an alkyl group, as in conversion of $[W_2(\mu\text{-SEt}_2)_3Cl_6]$ to $[W_2(\mu\text{-Cl})(\mu\text{-SEt})(\mu\text{-SEt}_2)Cl_6]^-$ (d_{W-W} 2.44 Å) by treatment of the former with $[SC_6H_4Me]^-$. Further, cyclic species, such as those containing μ-tetrahydrothiophene, underwent ring opening on addition of Cl^- giving $[W_2(\mu\text{-SC}_4H_8)_2(\mu\text{-SCH}_2CH_2CH_2CH_2Cl\}Cl_6]^-$ (d_{W-W} 2.49 Å).



(**69**)



(**70**)

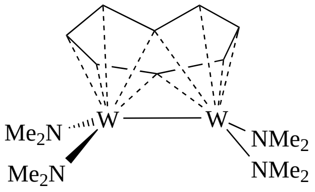
9.1.3 Complexes Containing $W^{IV}W^{IV}$

Reaction of $[W_2(OR)_6(py)_2$ (R = CH_2Bu^t) with 1,3-butadiene and with isoprene afforded blue–black $[W_2(\mu\text{-}\kappa^1\text{:}\eta^4\text{-C}_4H_6)(\mu\text{-OR})_2(OR)_4(py)]$ (**70**) (d_{W-W} 2.49 Å) and $[W(\mu\text{-}\kappa^1\text{:}\eta^4\text{-C}_5H_8)(\mu\text{-OR})_2(OR)_4(py)]$ (d_{W-W} 2.46 Å). The metal–metal separations were indicative of double bonds.

In the reaction between $[W_2(OR'')_6]$ (R″ = $SiMe_2Bu^t$) and NO in hydrocarbon solvents containing pyridine, $[W(NO)(OR'')_3(py)_2]$, $[WO(OR'')_4(py)]$, and $[W_2O_4(OR'')_4(py)_2]$ were formed. An intermediate $[W_2(\mu\text{-O})(\mu\text{-OR}'')(OR'')_5(py)_2]$ was apparently formed along with N_2O after the coupling of two nitrosyl ligands during this reaction. This subsequently decomposed with loss of W–W bonding and the generation of the tungsten oxo complexes, which were also thought to arise from reactions involving N_2O. Both $[W^{VI}{}_2O_4(OR'')_4(py)_2]$ (d_{W-W} 3.04 Å) and $[W_2(\mu\text{-O})(\mu\text{-OR}'')(OR'')_6(py)_2]$ (d_{W-W} 2.49 Å) were characterized crystallographically.

The species $[W_2(OBu^t)_7]^-$, which existed in an equilibrium with $[W_2(OBu^t)_6]$ and $[OBu^t]^-$, decomposed forming red $[W_2(\mu\text{-O})(\mu\text{-H})(OR)_6]^-$ with concurrent loss of $Me_2C{=}CH_2$. The structure of the oxo-hydride was confirmed crystallographically, the metal–metal distance (d_{W-W} 2.44 Å), being consistent with a double bond in a $W_2{}^{8+}$ core. $[W_2(OR')_6(NHMe_2)_2]$ (R = *cyclo*-C_5H_9) also decomposed over four days in the presence of cyclopentanol, affording a bridging hydride species $[W_2(\mu\text{-H})(\mu\text{-OR}')(OR')_5(NHMe_2)]$ (d_{W-W} 2.44 Å). This molecule was fluxional in solution, and the dimethylamine could be replaced by PMe_3.

Treatment of $[W_2Cl_2(NMe_2)_4]$ with $Li_2C_8H_8$ afforded $[W^{IV}{}_2(\mu\text{-}\eta^5,\eta^5\text{-C}_8H_8)(NMe_2)_4]$ (**71**) (d_{W-W} 2.43 Å), in which the hydrocarbon ligand, regarded formally as $C_8H_8{}^{4-}$, functioned as a four electron bridging group.

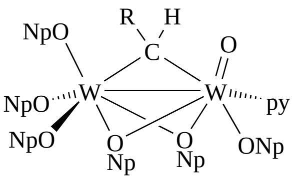


(**71**)

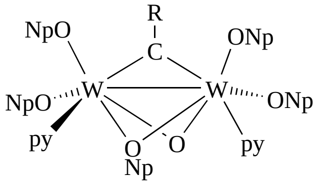
9.1.4 Complexes Containing W^VW^V

Treatment of *cis*-$[WF_2(OMe)_4]$ in thf with lithium powder, followed by an excess of NaOMe, afforded $[W_2(OMe)_{10}]$, which has an edge-sharing dioctahedral structure (d_{W-W} 2.79 Å). Aldehydes RCHO (R = cyclopropyl, tolyl, anisyl) reacted with $[W^{III}{}_2(ONp)_6(py)_2]$ (Np = CH_2Bu^t) giving alkylidene complexes $[W_2(\mu\text{-ONp})_2(ONp)_4(\mu\text{-CHR})(O)(py)]$ (**72**) (R = cyclopropyl or tolyl, d_{W-W} 2.66 Å). These complexes reacted with an excess of pyridine giving $[W_2(\mu\text{-CR})(\mu\text{-O})(ONp)_5(py)_2]$, (**73**) (R = cyclopropyl or anisyl, d_{W-W} 2.45 Å). Reaction of $[W^{III}{}_2(OR)_6(py)_2]$ with cyclohexenone afforded $[W_2(\mu\text{-O})((\mu\text{-OC}_{12}H_{16})(OR)_6]$ (d_{W-W} 2.82 Å) and other dinuclear species containing W^V centers were obtained from reaction with acrolein (d_{W-W} 2.65 Å), methyl vinyl ketone (d_{W-W} 2.79 Å), and crotonaldehyde (d_{W-W} 2.62 Å).

Reaction of cooled solutions of $[W^{IV}{}_2(\mu\text{-H})(\mu\text{-OR}')_2(OR')_5(NHMe_2)]$ (R′ = *cyclo*-C_5H_9) with four equivalents of ethane afforded the diamagnetic $[W_2(\mu\text{-OR}')_3(OR')_4Et(\eta^2\text{-C}_2H_4)]$ (**74**) (d_{W-W} 2.67 Å). $[W_4(\mu\text{-H})_2(\mu\text{-OPr}^i)_6(OPr^i)_8]$ reacted similarly but no crystalline product was obtained.

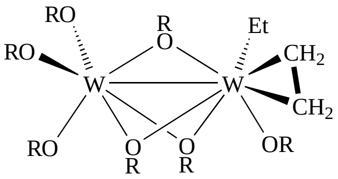


(72)

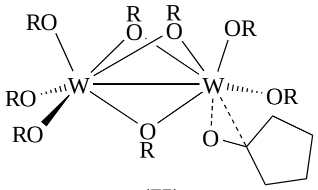


(73)

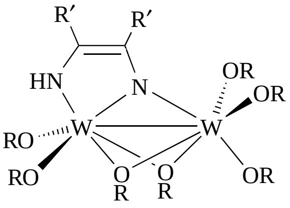
When two equivalents of cyclopentanone in hexane were added to the same hydrido precursor, diamagnetic $[W_2(\mu\text{-OR}')_3(OR')_5(\eta^2\text{-OC}_5H_8)]$ (**75**) (d_{W-W} 2.67 Å) was formed. Treatment of $[W_4H_2(OPr^i)_{14}]$ with benzophenone in pentane afforded the analogous $[W_2(H)(\mu\text{-OPr}^i)_3(OPr^i)_4(\eta^2\text{-OCPh}_2)]$ (d_{W-W} 2.65 Å), in which one terminal alkoxide group was replaced by hydride. Reaction of the tetranuclear dihydride with nitriles led to coupling of the nitrile molecules and formation of a dinuclear species $[W_2(\mu\text{-OPr}^i)_2(OPr^i)_5\{NC(Ph)C(Ph)NH\}]$ (**76**) ($R' = Ph$, d_{W-W} 2.59 Å).



(74)

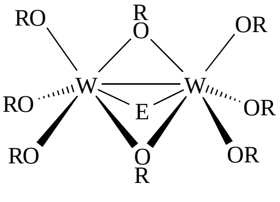


(75)



(76)

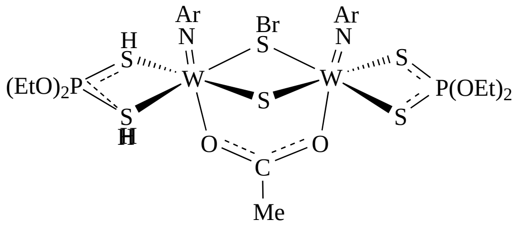
Addition of *t*-butanol to hydrocarbon solutions of $[W_2(\kappa^1\text{-SC}_4H_3)_2(NMe_2)_4]$ afforded $[W_2(\mu\text{-SC}_4H_4(\kappa^1\text{-SC}_4H_3)(OBu^t)_5]$ (d_{W-W} 2.63 Å). Treatment of $[W_2(OR)_8]$ ($R = CH_2Bu^t$) with pyridine-*N*-oxide and elemental sulfur, elemental selenium, and tellurium afforded $[W_2(\mu\text{-E})(\mu\text{-OR})_2(OR)_6]$ (**77**) (E = O, Se or Te), in which the metal–metal bond was in the range 2.55–2.66 Å.



(77)

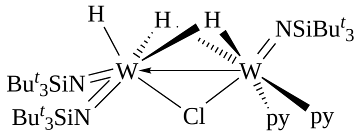
Treatment of $[W_2S_4Br_4]^{2-}$ with PPh_3 afforded $[W_2(\mu\text{-S})_2S_2Br_2(PPh_3)_2]$, which contains the *syn*-$\{(S)W)\mu\text{-})_2W(S)\}^{2+}$ fragment (d_{W-W} 2.81 Å). When $[WSe_4]^{2-}$ was stirred in an $MeCN/CH_2Cl_2$ solution with PPh_3, $[W_2Se_6]^{2-}$ (d_{W-W} 2.85 Å) was formed. Further reaction of this species with $P(c\text{-}C_6H_{11})_3$ in the presence of copper (I) chloride afforded the cluster species $[Cu\{P(C_6H_{11})_3\}_2(\mu\text{-Se}_2WSe_2)Cu\{P(C_6H_{11}\}_3\}]$ and the cubane-like $[W_2(\mu_3\text{-Se})_4(\kappa^2\text{-Se}_2CH_2)_2Cu\{P(C_6H_{11})_3\}_2]$.

The diamagnetic $[W_2(\mu\text{-CNEt}_2)(\mu\text{-S})(\mu\text{-S}_2CNEt_2)(\mu\text{-S}_2SnCHSiMe_3)(S_2CNEt_2)_2]$ (d_{W-W} 2.61 Å) was formed by refluxing the mononuclear $[W(CO)_2(S_2CNEt_2)(SnCHSiMe_3)]$ in benzene. Addition of *N*-bromophthalimide to a chloroform solution of $[\{W_2(Ntol)\{S_2P(OEt)_2\}S\}_4]$ containing $[Et_4N][OAc]$ afforded the sulfur-bridged species $[W_2(Ntol)_2\{S_2P(OEt)_2)_2\}(\mu\text{-OAc})(\mu\text{-S})(\mu\text{-SBr})]$ (**78**) (d_{W-W} 2.83 Å).



(78)

Pyridine reacted at 60 °C with $[W_2Cl_2(NHSiBu^t{}_3)_4]$ to give $[WHCl(NSiBu^t)_2(py)]$, $[WCl_2(NBu^t{}_3)_2(py)]$, and $[W_2(\mu\text{-H})_2(\mu\text{-Cl})HCl_2(NHSiBu^t{}_3)_3(py)_2]$ (**79**) (d_{W-W} 2.79 Å).



(79)

9.2 Polyoxoanions

Polyoxometallate ions containing tungsten form an enormous range of compounds, which have been reviewed extensively.[5,6] They may be subdivided into (1) isopolyanions containing W as the dominant and frequently the only metal component, and (2) heteropolyanions where other metals and/or nonmetal atoms may be present in the core structure.

9.2.1 Isopolyanions

NMR studies have demonstrated that above pH 6 the major polytungstate species are $[W_7O_{24}]^{6-}$ (known

also as paratungstate-A) and $[H_2W_{12}O_{42}]^{10-}$ (known as paratungstate-B). These species have been isolated as several different types of salt, and have been characterized crystallographically and by their ^{183}W chemical shifts. Below pH 5.5, equilibria are slowly established and most polytungstate species, excepting the Keggin ion α-$[(H_2)W_{12}O_{40}]^{6-}$ (known as metatungstate and in which the protons are in the center of the cage) are normally metastable. Acidification of solutions containing paratungstates ultimately afforded α-$[H_2W_{12}O_{40}]^{6-}$, but intermediates appear to include the partially characterized $[H_7W_{11}O_{40}]^{7-}$, which may be a lacunary species derived from $[H_2W_{12}O_{42}]^{10-}$, $[W_{10}O_{32}]^{4-}$ (sometimes known as tungstate-Y), and small amounts of β-$[(H_2)W_{12}O_{40}]^{6-}$ (known previously as tungstate-X), α- and β-$[(H)W_{12}O_{40}]^{7-}$, in which the protons are in the center of the cage. Other isopolytungstates have been reported, including $[(H_4)W_{12}O_{40}]^{4-}$, in which the protons are thought to be in the center of the cage, $[H_3W_6O_{22}]^{5-}$, and $[HW_5O_{19}]^{7-}$.

In nonaqueous media, $[W_6O_{19}]^{2-}$ and $[W_{10}O_{32}]^{4-}$ are stable and have been characterized spectroscopically (particularly by ^{183}W nmr), and $[H_6W_{18}O_{60}]^{6-}$ exhibited reversible voltammetric behavior in acetonitrile.

Mixed metal isopolyanions incorporating vanadium, $[V_xW_{6-x}O_{19}]^{(2+x)-}$ ($x = 1$–3), the Keggin ions $[(V)V_x W_{12-x}O_{40}]^{(3+x)-}$ ($x = 1$–4), and $[H_2W_{11}VO_{40}]^{7-}$ have been described. ^{51}V NMR spectral investigations of vanadate-tungstate mixtures revealed that $[WV_9O_{28}]^{5-}$ existed at pH 5 and an isomer of $[V_3W_3O_{19}]^{5-}$ at pH 6.5. From ^{183}W and ^{95}Mo NMR spectral studies, it was established that all possible mixtures of $[(Mo,W)_7O_{24}]^{6-}$ existed but that only one molybdenum center could be substituted into $[H_2W_{12}O_{42}]^{10-}$ and α-$[H_2W_{12}O_{40}]^{6-}$.

9.2.2 *Heteropolyanions*

The Keggin-structure anion α-$[XW_{12}O_{40}]^{n-}$, particularly the tungstophosphates and tungstosilicates, are the most frequently investigated because of the potential and real catalytic applications. The central heteroatoms, X, in the Keggin and isomeric anions $[XW_{12}O_{40}]^{n-}$ include, in the α-form $(H)_2$, Be, B, Al, Ga, Si, Ge, P^V, As^V, V, Cr^{3+}, Fe^{3+}, $Co^{2+,3+}$, $Co^{1+,2+}$, and Zn, and in the β form $(H)_2$, Al, Ga, Si, Ge, and P^V. Unlike the situation in heteropolymolybdate chemistry, no capped heteropolytungstates have yet been reported.

Four of the possible six possible skeletal isomers having the Wells–Dawson structure, as exemplified by $[E_2W_{18}O_{62}]^{6-}$ ($E = P$ or As), have been structurally identified. The so-called 'Preyssler' anion was structurally identified as $[\{Na(H_2O)\}P_5W_{30}O_{110}]^{14-}$, it being shown that the $Na(H_2O)^+$ group was tightly bound in the center of the cluster. However, under forcing conditions, the aqua-sodium cation could be replaced by Ca^{2+}, trivalent lanthanide cations and some tetravalent actinide cations, all of which have similar ionic radii (ca. 1/Å). All of these anions exhibited reversible tungsten-based reduction behavior.

Lacunary version of the Keggin- and Dawson-type structures have been isolated and crystallographically characterized. In these species, up to three 'octahedral W' units may be extracted, generating species such as $[EW_{11}O_{39}]^{n-}$, $[EW_{10}O_{36}]^{n-}$, $[EW_9O_{34}]^{n-}$, $[E_2W_{17}O_{61}]^n$, and $[E_2W_{15}O_{56}]^{12-}$. In an exceptional case, α-$[P_2W_{12}O_{48}]^{14-}$, which has six W units extracted from the Wells–Dawson core, has been characterized. All of these lacunary anions have structures, in which no WO_6 octahedral has more than two (cis) terminal oxygen atoms. As such, these species are particularly useful synthetic precursors for the incorporation of other metal ions, thereby reconstituting the idealized Keggin or Wells–Dawson structure. Species having one mixing W unit, such as $[EW_{11}O_{39}]^{n-}$ or $[E_2W_{17}O_{61}]^{n-}$, have generated a very large number of species, in which the inserted atom is a metal cation carrying a variety of terminal ligands, or in some case, no addition ligands. Such cluster complexes could be regarded as coordination compounds with the polyoxometallate group functioning as a tetra or pentadentate ligand. In such species, the polyoxometallate ligand appears to act as a π-acceptor species. Corresponding heteropolytungstates with two missing W units may be reconverted to Keggin structures, as in the conversion of $[SiW_{10}O_{36}]^{8-}$ to $[SiW_{10}M_2O_{40}]^{n-}$ where M = Mo, Mn^{III}, Fe^{III}, $Ti(\eta\text{-}C_5H_5)_2$, and a similar situation occurred with the trivacant lacunary anions, $[EW_9O_{34}]^{n-}$ and $[P_2W_{15}O_{56}]^{12-}$. The magnetic properties of a number of metal complexes containing $M^{II}O_6$ octahedra, such as $[PW_9O_{34}Ni_4(OH)_3(H_2O)_6]^{4-}$ and $[Co_7(H_2O)_2(OH)_2\{PW_9O_{34}\}_2(W_7O_{26})]^{16-}$, have been measured.

A large number and variety of polytungstate complexes incorporate pairs of trivacant lacunary anions, which effectively sandwich three of four metal atoms. Typical examples include $[\{EW_9O_{34}\}_2(RQ)_3]^{n-}$ ($E = P$ or Si; $Q = Si$ or Sn), $[\{EW_9O_{34}\}_2(UO_2)_2]^n$–($E = P$ or Si),$[\{PW_9O_{34}\}_2Fe^{III}{}_4(H_2O)_2]^{n-}$, $[\{P_2W_{15}O_{56}\}_2Fe^{III}{}_4(H_2O)_2]^{12-}$, and $[\{BiW_9O_{33}\}_2Cu_3]^{n-}$.

Polyoxo(thio)metallates have been prepared by incorporating thio-metal groups into lacunary anions, giving, for example, $[PW_{11}O_{39}(MX)]^{4-}$ (M = Nb, Ta; X = S, Se)$[SiW_{10}O_{38}M_2S_2]^{6-}$(M = Mo or W), $[\{PW_{11}O_{39}\}_2\{Mo_2S_2(OH)_2O_2]^{10-}$, $[\{PW_9O_{234}\}_2\{Mo_2S_2(OH)_2O_2\}_3]^{10-}$, and $[\{SiW_{11}O_{39}\}_2\{Mo_3S_4(H_2O)_3(OH)\}_2]^{10-}$.

9.2.3 *Very Large Polyoxotungsten Anions*

Composite anions have been constructed from assemblies of relatively simple, usually lacunary, polytungstate anions. Examples include $[Ln_2(H_2O)_2\{SbW_9O_{33}\}(W_5O_{18})_2]^{15-}$ (molar mass 5056; Ln = Y, Sm, Er), $[Ce_4(OH)_2(H_2O)_9\{P_2W_{16}O_{59}\}_2]^{4-}$ (molar mass 8652), $[Ln(Ln_2(OH)(H_2O)_{11}(WO_4)_4\{AsW_9O_{33}\}_4]^{20-}$ (molar mass 10 529; Ln = Ce, Nd,

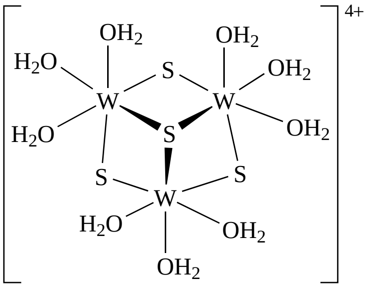
Sm, Gd), and $[Ln_{16}(H_2O)_{36}(WO_4)_4(W_2O_6)_8\{AsW_9O_{33}\}_{12}(W_5O_{18})_4]^{76-}$ (molar mass 39 383).

9.3 Cluster Compounds Containing Chalcogenide Atoms

There are three main cluster types encountered in this group of important compounds: the incomplete cuboid $\{W_3(\mu_3\text{-}E)(\mu\text{-}E)_3\}^{4+}$, the sulfur-rich incomplete cuboid $\{W_3(\mu_3\text{-}E)(\mu,\mu'\text{-}E)_3\}^{4+}$, and the cuboid $\{W_4(\mu_3\text{-}E_4\}^{5+}$.[7] These species are described as 'cuboidal' since this illustrates the best approximation in what are usually somewhat distorted structures.

9.3.1 Trinuclear Clusters, $[W_3E_4]^{4+}$

The parent species $[W_3S_4(H_2O)_9]^{4+}$ is well established and characterized (**80**) but an efficient synthesis was devised by heating $[W_3S_4(S_4)_3(NH_3)_3]^{2-}$ with concentrated HCl, or by treatment of polymer $[\{W_3S_7Br_4\}_n]$ with H_3PO_2 in hot concentrated HCl. The core cluster $[W_3S_4(H_2O)_9]^{4+}$ was structurally characterized in two salts, establishing the W–W bond length as 2.72 Å, identical to that in the analogous molybdenum cluster $[Mo_3S_4(H_2O)_9]^{4+}$. All three mixed O/S clusters were prepared by comproportionation of $[[NH_4]_2[WS_4]$ with $K_3[W_2Cl_9]$ in aqueous media. $[W(CO)_6]$ reacted with Na_2S in acetic anhydride, affording the $\{W_3O_3S\}^{4+}$ core as the sole isolable product, and it was extracted by NCS^-, giving $[W_3O_3S(NCS)_9]^{5-}$ (W–W 2.61 Å).



(**80**)

While no fully chlorinated species $[W_3E_4Cl_9]^{5-}$ (E = S or Se) have been detected, some Cl^- coordination can occur giving, for example, $[W_3E_4Cl(H_2O)_8]^{3+}$, $[W_3S_4Cl_2(H_2O)_7]^{2+}$, and $[W_3S_4Cl_3(H_2O)_6]^+$. Apparently no complexes containing F^-, Br^- or, I^- have been described. In $[W_3S_4(O_2CH)_9]^{5-}$ it was established crystallographically that the formato ligand was monodentate, whereas in $[W_3S_4(O_2C_2O_2)_3(H_2O)_3]^{2-}$ the oxalato ligand was bidentate. The pentanedionato species $[W_3E_4(acac)(py)_3]^+$ (E = S or Se) were obtained by reaction of $[W_3E_4(H_2O)_9]^{4+}$ in dilute HCl with Hacac, followed by addition of pyridine and a precipitating anion (usually PF_{6-}). ^1H NMR spectral studies established the stereochemical rigidity of these species in solution, and cyclic voltammetric studies established that the clusters underwent two quasi-reversible reductions corresponding to the generation of species containing $W^{IV}{}_2W^{III}$ and $W^{IV}W^{III}{}_2$. The species $[W_3S_4(acac)(NH_3)_3]^+$ has also been reported. Nitrilotriacetic acid (H_3nta) reacted with mixed O/S clusters, affording species including $[W_3O_3S(Hnta)_3]^{2-}$, $[WO_2S_2(Hnta)_3[^{2-}$, and $[WOS_3(Hnta)_3]^{2-}$, and mixed metal clusters $[Mo_2WS_4(Hnta)_3]^{2-}$ and $[MoW_2S_4(Hnta)_3]^{2-}$ have also been characterized. These clusters undergo three consecutive one-electron reductions corresponding to the stepwise reduction of each metal center. Polyaminoplycarboxylic acids also formed complexes containing the $\{W_4S_{4-n}O_n\}^{4+}$ cores. These included $[\{W_3S_4\}_2(egta)_3]^{4-}$ (H_4egta = ethyleneglycol-bis(2-aminoethyl)tetraacetic acid), $[\{W_3O_3S\}_2(egta)_3]^{4-}$, $[W_3S_4(ttha)]^{2-}$ (H_6ttha = triethylenetetraminehexaacetic acid), $[\{W_3S_4\}_2(ttha)_2]^{4-}$, and $[\{W_3S_4\}_2(ttha)_3]^{10-}$. The crystal-structure determination of a salt of $[\{W_3S_4\}_2(ttha)_2{}^{4-}$ revealed that the ttha ligands were decadentate, being alternately hexadentate with respect to one $\{W_3S_4\}$ cluster and tetradentate with respect to the other. Anionic clusters of similar complexity containing the $\{W_3O_3S\}^{4+}$ core included $[W_3O_3S(obeta)_3]^{4-}$ (H_4obeta = oxybis(ethylamine)tetraacetic acid), $[\{W_3O_3S\}_2(obeta)_3]^{4-}$, $[\{W_3O_3S\}_2(bdta)_3]^{4-}$ (H_4bdta = 1, 4-butylenediaminetetraacetic acid), and $[\{W_3O_3S\}_2(pdta)_3]^{4-}$ (H_4pdta = 1, 3-propylenediaminetetraacetic acid). In studies of the reactions of $[W_3E_4(H_2O)_9]^{4+}$ (E = S or Se) with NCS^-, it was concluded that the first product formed involved an S-bonded thiocyanate isomer, but this later isomerized to a more stable N-bonded form, $[W_3E_4(NCS)_9]^{5-}$. $[W_3S_4(NCS)_9]^{5-}$ was obtained either by heating polymeric $[\{W_3S_7Br_4\}_n]$ in a melt of KNCS or by reaction of NCS^- with $[W_3S_7Br_6]^{2-}$ in refluxing acetonitrile. Reaction of $[\{W_3Se_7Br_4\}_n]$ with KNCS afforded a mixture of all possible $[W_3S_nSe_{4-n}(NCS)_9]^{5-}$, but these were eventually converted into $[W_3S_4(NCS)_9]^{5-}$.

Polymeric $[\{W_3S_7Br_4\}_n]$ reacted slowly with $(NH_4)_2S_x$ at room temperature giving black needles of $[NH_4]_2[W_3S_4(S_4)_3(NH_3)_3]\cdot H_2O$. The tetrasulfido ligand was bidentate and the W–S bond distances were rather long (2.5 Å), explaining why this species reacted with concentrated HCl easily giving $[W_3S_4(H_2O)_9]^{4+}$.

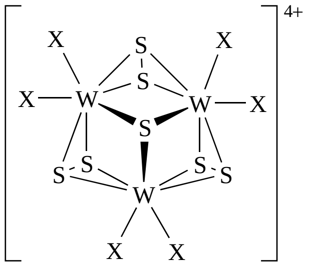
Treatment of $[\{W_3S_7Cl_4\}_n]$ with PPh_3 in thf afforded $[W_3S_4Cl_4(PPh_3)_3(H_2O)_2]\cdot 3$thf. However, reaction of PEt_3 with $[\{W_3S_7Br_4\}_n]$ in thf afforded $[W_3S_4Br_4(PEt_3)_3\{P(O)HEt_2\}(H_2O)]$, in which partial P–C bond fission and phosphine oxidation had occurred. With bidentate phosphines (dmpe, dppe), $[\{W_3S_7X_4\}_n]$ (X = Cl or Br) was converted to $[W_3S_4X_3(dmpe)_3]^+$ and $[W_3S_4X_3(dppe)_3]^+$. In the course of these reactions, mixed halide clusters $[W_3S_4Cl_2Br(dmpe)_3]^+$ and $[W_3S_4ClBr_2)dmpe)_3]^+$ could be detected. The mixed sulfido/selenido cluster $[W_3S_xSe_{4-x}(NCS)_9]^{5-}$ reacted with dppe giving $[W_3S_xSe_{4-x}(NCS)_3(dppe)_3]^+$, and $[W_3Se_4Br_3(dppe)_3]^+$ was obtained directly from $[\{W_3Se_7Br_4\}_n]$.

Reaction of $[W_3S_4Cl_3(dmpe)_3]^+$ with BH_4^- gave the pink air-stable trihydrido complex $[W_3S_4H_3(dmpe)_3]^+$.

Treatment of polymeric $[\{W_3Se_7Br_4\}_x]$ with hot aqueous KCN afforded $[W_3Se_4(CN)_9]^{5-}$, which could be electrochemically reduced in a one-electron step, affording $[W_3Se_4(CN)_9]^{6-}$, containing the $W^{IV}{}_2W^{III}$ core.

9.3.2 *Trinuclear Complexes, $[W_3E_7]^{4+}$*

The polymeric clusters $[\{W_3E_7X_4\}_x]$ (E = S or Se; X = Cl or Br) were prepared by heating the elements in a sealed tube at ca. 350 °C. The structure of $[\{W_3S_4Br_4\}_x]$ consists of $W_3(\mu_3\text{-}S)(\mu\text{-}S_2)_3{}^{4+}$ units bridge by four Br atoms forming an extended zigzag structure. The corresponding selenides are thought to have the same basic structure. The bridging S_2 groups are asymmetrically coordinated and since the metal atoms are formally in oxidation state IV, there are six electrons available to form three single metal–metal bonds in the triangle. Under certain conditions, the halide ion can cleave the bridges giving $[W_3E_7X_6]^{2-}$ (**81**) (X = Cl or Br) and the clusters can be aquated to form relatively stable ions $[W_3E_7(H_2O)_6]^{4+}$. The structural dimensions of the $\{W_3S_7\}^{4+}$ core are very similar to those of its molybdenum analog.



(**81**)

Treatment of $[\{W_3Se_7X_4\}_x]$ with PPh_4X (in melts) or Et_4NX (in vibration mills) afforded $[W_3Se_7X_6]^{2-}$. Treatment of the hexahalides with NaS_2CNR_2 afforded $[W_3Se_4(S_2CNR_2)_3]^+$, in which there are strong interactions between the axial Se atom and an S atom of the dithiocarbamate ligand. When $[W(CO)_6]$ was refluxed with selenium and tetraethylthiuram disulfide in 1,2-dichlorobenzene, red $[\{W_3Se_7(S_2CNEt_2)_3\}_2Se]$ was formed. Treatment of $[W_3Se_7Br_6]^{2-}$ with $[S_2P(OEt)_2]^-$ in acetonitrile afforded the dithiophosphato cluster $[W_3Se_7\{S_2P(OEt)_2\}_3]^-$ and the 1,10-phenanthroline (phen) cluster $[W_3Se_7(phen)_3]^{4+}$ was obtained by melting $[\{W_3Se_7X_4\}_x]$ with the bidentate heterocycle. Treatment of $[W_3S_7X_6]^{2-}$ (X = Cl or Br) with PPh_3Se afforded $[W_3S(SSe)_3X_6]^{2-}$ and reaction of this with KNCSe, in the presence of an excess of KNCS, gave $[W_3S(SSe)_3(NCS)_6]^{2-}$. The aqua cluster $[W_3Se_4(H_2O)_9]^{4+}$ reacted with P_4S_{10} in ethanolic HCl to give $[W_3Se(SSe)_3\{S_2P(OEt)_2\}^3]^+$.

9.3.3 *Tetranuclear cubic $\{W_4E_4\}^{5+}$ Clusters*

Brown–red $[W_4S_4(H_2O)_{12}]^{6+}$ was prepared by the reaction of $[W_3S_4(H_2O)_6]^{4+}$ with $[W(CO)_6]$ in aqueous HCl under hydrothermal conditions. This species is presumed to have a structure very similar to its molybdenum analog, viz. consisting of two interpenetrating W_4 and S_4 tetrahedra of different sizes, leading to a distorted pseudo-cubic geometry. The hexa-cation was electrochemically reduced to $[W_4S_4(H_2O)_{12}]^{5+}$, the potentials indicating its oxidative instability.

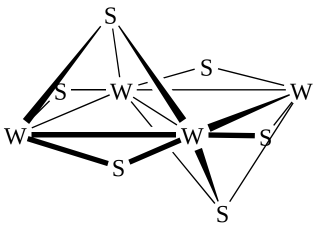
Mixed metal clusters were obtained by reaction of $[W_3S_4(H_2O)_9]^{4+}$, $[W_3Se_4(H_2O)_9]^{4+}$, $[MoW_2S_4(H_2O)_9]^{4+}$, and $[Mo_2WS_4(H_2O)_9]^{4+}$ with $[Mo_2Cl_8]^{4-}$, giving $[MoW_3S_4(H_2O)_{12}]^{5+}$, $[MoW_3Se_4(H_2O)_{12}]^{5+}$, $[Mo_2W_2S_4(H_2O)_{12}]^{5+}$, and $[Mo_3WS_4(H_2O)_{12}]^{5+}$. Oxidation of these pentacationic species by $[Fe(H_2O)_6]^{3+}$ initially afforded the hexacations but these decomposed by loss of one W atom, for example, in the process $[MoW_3S_4(H_2O)_{12}]^{5+} \rightarrow [MoW_3S_4(H_2O)_{12}]^{6+} \rightarrow [MoW_2S_4(H_2O)_9]^{4+}$. Electrochemical studies of these pentacationic mixed metal cubic clusters revealed two reversible redox processes corresponding to a one-electron reduction and a one-electron oxidation.

When WTe_2 was heated with KCN, $[W_4Te_4(CN)_{12}]^{6-}$ was formed, while in a KNCS melt, chalcogen exchange occurred, leading to $[W_4S_4(CN)_{12}]^{6-}$. These species have been structurally characterized and it was established that the symmetry of the cluster core was sensitive to the nature of the counter ion. The core clusters in the $NH_6{}^+$ salts had ideal T_d symmetry ($d_{W\text{–}W}$ 2.85 Å) in the $[KCs_5]^{6+}$ salt C_1 symmetry ($d_{W\text{–}W}$ 2.80–90 Å), and in the K^+ salt C_2 symmetry ($d_{W\text{–}W}$ 2.83–2.91 Å). $K_6[W_4Se_4(CN)_{12}]\cdot 6H_2O$ exhibited a cuboidal core with C_{2v} symmetry ($d_{W\text{–}W}$ 2.88 Å). The complexes were electrochemically active, showing two reversible or quasi-reversible reduction processes, one corresponding to the formation of 7(−) and 8(−) species. Despite the distortions observed in the solid state, the ^{77}Se, ^{125}Te and ^{183}W NMR studies on $[W_4E_4(CN)_{12}]^{6-}$ indicated the equivalence of metal and chalcogen atoms in solution.

In a solvento-thermal reaction involving $[W(CO)_6]$, K_2S_4, and 1,2-diaminoethane (en) at 300 °C, the slightly electron-deficient (54-valence electron) black–red cluster $[W_4S_4(en)_4(S)_4]S$ was formed. This species contains a W_4S_4 cuboidal skeleton ($d_{W\text{–}W}$ 2.80–2.88 Å) and S^{2-} as a counter-anion. While the W–S bonds involving the μ_3-bridges is 2.36–2.41 Å, the formal W=S bond lengths are 2.54 Å, rather longer than expected. This suggested that the species might be better formulated as the 58-electron $[W_4S_4(en)_4(SH)_4]S$, which was more consistent with the geometry of the cluster but no S–H vibrational bands were detected by IR spectroscopy. The species was paramagnetic, obeying the Curie–Weiss law, with μ = 2.67 BM at 400 K.

9.3.4 *Raft-like Clusters $[W_4(\mu_3-S)_2)(\mu\text{-}S)_4]^{2+}$*

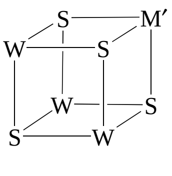
Treatment of *cis*-$W(N_2)_2(PMe_2Ph)_4]$ with two equivalents of $(Me_3Si)_2S$ in methanol afforded $[W_4(\mu_3\text{-}S)_2(\mu\text{-}S)_4(SH)_2(PMe_2Ph)_6]$. This 58-electron cluster has sufficient electrons (10) to form five W–W bonds, including one between the hinge atoms (see (**82**)) ($d_{W\text{–}W}$ 2.81−2.84 Å), and the presence of S–H groups was confirmed crystallographically. Reaction of this complex with $SnCl_2$ in thf effected Cl/SH group exchange, giving $[W_4(\mu_3\text{-}S)_2(\mu\text{-}S)_4Cl_2(PMe_2Ph)_6]$. Oxidation of this species by Ag^+ afforded $[W_4(\mu_3\text{-}S)_2(\mu\text{-}S)_4Cl_2(PMe_2Ph)_6]^{2+}$, a 56-electron cluster that retained its raft-like connectivity, although the core no longer retained C_{2h} symmetry but was distorted, with a pair of opposing W–W bonds elongated to 2.94 Å, another pair shortened to 2.74 Å, and only the W–W hinge remaining relatively unperturbed at 2.83 Å. Reduction of $[W_4(\mu_3\text{-}S)_2(\mu\text{-}S)_4Cl_2(PMe_2Ph)_6]$ by sodium amalgam afforded $[W_4(\mu\text{-}S)_6(PMe_2Ph)_4]$, which contains an adamantane-like core. There are 12 electrons in this W^{III} species ($d_{W\text{–}W}$ 2.63 Å), the basic coordination geometry around each metal atom (neglecting the formal W–W bond) being essentially tetrahedral.



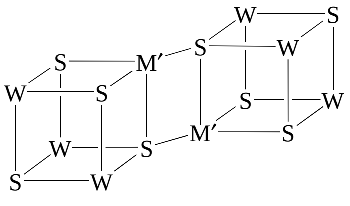
(**82**)

9.3.5 *Heterometallic Derivatives of $[W_3E_4(H_2O)_9]^{4+}$*

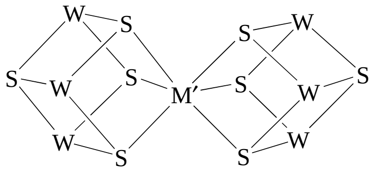
The incomplete cubes $[W_3E_4(H_2O)_9]^{4+}$ (E = S, Se) reacted with metal ions to generate cuboidal species. These are generally of three types, shown in (**83**), (**84**), and (**85**). The cluster (**83**) utilizes a heterometal atom with variable coordination preferences (usually octahedral or tetrahedral), constituting a cuboidal species. However when M′ prefers tetrahedral geometry, the edge-linked double cube (**84**) can be formed. The incomplete cube can also function as a pair of tridentate ‘ligands’, generating a corner-shared cube (**85**).



(**83**)



(**84**)



(**85**)

The conversion of (**83**) to (**84**) occurred when the anions accompanying the reaction were normally noncoordinating, such as ClO_4^- or *p*-$MeC_6H_4SO_3^-$, and regeneration of (**83**) would occur when ligands such as CO, PR_3, Cl^-, or NCS^- were added and attached to M′. In general, the W–W distances in these species were relatively short (2.5−2.8 Å) and while relatively short W–M′ bonds (ca. 2.7 Å) were characteristic when M′ was a transition metal in (**84**) and (**85**), long nonbonding interactions (>3.5 Å) were typical features of (**83**) and (**84**) when M′ was a metal from groups 12 or 13.

While the mixed metal clusters $[Mo_3WS_4(H_2O)_9]^{4+}$ and $[WMo_3S_4(H_2O)_9]^{4+}$ were described earlier, there are no reported examples of $[CrW_3S_4(H_2O)_9]^{4+}$. A similar situation exists with Mn and Re. No clusters containing Fe, Ru, Os, or Co have been reported but there is evidence that $[W_3S_4(H_2O)_9]^{4+}$ reacted with $RhCl_3$ in 4M HCl, although the product was not characterized. Reaction of metallic Ni with $W_3S_4(H_2O)_9]^{4+}$ afforded green $[W_3NiS_4(H_2O)_{10}]^{4+}$ [(**83**, M′ = Ni(H_2O)], and the mixed Mo/W clusters $[MoW_2NiS_4(H_2O)_{10}]^{4+}$ and $[Mo_2WNiS_4(H_2O)_{10}]^{4+}$ were also isolated. In these three species, the Ni^{II} center adopted tetrahedral geometry. Crystallization of the tungsten-rich clusters resulted in edge-linked double cubes $[\{W_3NiS_4(H_2O)_9\}_2]^{8+}$ ($d_{Ni\text{–}Ni}$ 2.56 Å) and $[\{MoW_2NiS_4(H_2O)_9\}_2]^{8+}$ ($d_{Ni\text{–}N}$i 2.55 Å), (**84**). $[W_3NiS_4(H_2O)_{10}]^{4+}$ reacted with CO giving $[W_3Ni(CO)S_4(H_2O)_9]^{4+}$. While no clusters containing Pd have been described, $[W_3S_4(H_2O)_9]^{4+}$ reacted with $[PtCl_4]^{2-}$ giving the edge-linked double cube $[\{W_3PtS_4(H_2O)_9\}_2]^{8+}$.

Reaction of $[W_3S_4(H_2O)_9]^{4+}$ with copper metal afforded the green air-sensitive $[W_3CuS_4(H_2O)_{10}]^{5+}$, but no evidence for $[W_3CuS_4(H_2O)_{10}]^{4+}$ could be found. $[W_3S_4X_3(dmpe)_3]^+$ (X = Cl or Br) reacted with Cu^I halides or with $[Cu(NCMe)_4]^+$ in the presence of X^- to give $[W_3(CuX)S_4X_3(dmpe)_3]^+$ ($d_{W\text{–}W}$ 2.78 Å; $d_{Cu\text{–}W}$ 2.88 Å). Dithiophosphato derivatives such as $[W_3(CuI)S_4(\mu\text{-}O_2CCCl_3)\{S_2P(OEt)_2\}_3(NCMe)]$ and $[W_3(CuI)S_4(\mu\text{-}O_2CMe)\{S_2P(OEt)_2\}_3(py)]$ were also prepared. Reaction of $[Mo_2WS_4(\mu\text{-}S_2PR_2)(S_2PR_2)_3]$ with CuI in the presence of pyridine afforded $[Mo_2W(CuI)(\mu\text{-}S_2PR_2)(S_2PR_3)_3(py)]$ (R = Et, Pr^n).

Treatment of $[W_3S_4(H_2O)_9]^{4+}$ with mercury afforded the purple corner-shared double cube $W_6Hg_2S_8(H_2O)_{18}]^{8+}$ (**85**). However, no reaction was observed between the trinuclear tungsten species and metallic Ga or $GaCl_3$ reduced by $NaBH_4$. However, when metallic In was added to $[W_3E_4(H_2O)_9]^{4+}$, $[W_3InE_4(H_2O)_{12}]^{5+}$ was formed (**83**; E = S, dark blue, E = Se, blue−green). When equimolar

amounts of $[W_3InS_4(H_2O)_{12}]^{5+}$ and $[Mo_3S_4(H_2O)_9]^{4+}$ were mixed, rapid and quantitative In^+ transfer took place, giving $[W_3S_4(H_2O)_9]^{4+}$ and $[Mo_3InS_4(H_2O)_{12}]^{5+}$. Treatment of $[W_3E_4(H_2O)_9]^{4+}$ (E = S or Se) with GeO or GeO_2/H_3PO_2, the single cubes $[W_3GeE_4(H_2O)_{12}]^{6+}$ (**83**), only were formed. However, the double cubes $[W_6GeE_8(H_2O)_{18}]^{8+}$, (**85**), were obtained by reduction of $[W_3GeE_4(H_2O)_{12}]^{6+}$ ($d_{W–W}$ 2.67 Å when E = S) by BH_4^- in the presence of a further equivalent of $[W_3E_4(H_2O)_9]^{4+}$. Solution studies of $[W_3GeS_4(H_2O)_{12}]^{6+}$ indicated that the Ge center was coordinated by three H_2O ligands, which could be replaced by Cl^- giving $[W_3(GeCl_3)S_4(H_2O)_{12}]^{3+}$. Reaction of metallic tin (as shot) with $[W_3S_4(H_2O)_9]^{4+}$ gave only the single cube $[W_3SnS_4(H_2O)_{12}]^{6+}$. However, BH_4^- reduction of $[W_3(SnCl_3)S_4(H_2O)_9]^{3+}$ in the presence of $[W_3S_4(H_2O)_9]^{4+}$ afforded the double cube $[\{W_6SnS_8(H_2O)_{18}]^{8+}$ (**85**, M′ = Sn). This method of reductive coupling was also employed to make $[Mo_3W_3SnS_8(H_2O)_{18}]^{8+}$ and $[Mo_3W_3SnS_4Se_4(H_2O)_{18}]^{8+}$, the latter being obtained in a reaction involving BH_4^- reduction of $[Mo_3(SnCl_3)S_4(H_2O)_9]^{3+}$ in the presence of $[W_3Se_4(H_2O)_9]^{4+}$. These double cubes could be oxidized by O_2 or $[Fe(H_2O)_6]^{3+}$ to $[W_3SnE_4(H_2O)_{12}]^{6+}$ and then, with an excess of oxidant, to $[W_3E_4(H_2O)_9]^{4+}$ and Sn^{IV}. Treatment of $[W_3Se_4(H_2O)_9]^{4+}$ with Pb shot afforded the air-sensitive wine-red $[W_6PbSe_8(H_2O)_{18}]^{8+}$ (**85**, M′ = Pb), but no reaction occurred with $[W_3S_4(H_2O)_9]^{4+}$. No single cubes of the type $[W_3PbE_4(H_2O)_{12}]^{6+}$ have been reported but treatment of $[W_3S_4(H_2O)_9]^{4+}$ with PbI_3^- in the presence of $[S_2P(OEt)_2]^-$ in pyridine-based media afforded $[W_3(PbI_3)S_4\{S_2P(OEt)_2\}_3(py)_3]$.

Gray arsenic did not react with $[W_3E_4(H_2O)_9]^{4+}$ (E = S or Se) but with $NaAsO_2$ in the presence of H_3PO_2, red $[W_6AsSe_8(H_2O)_{18}]^{8+}$ (**85**, M′ = As^0) was formed. No single cubes containing As were detected, but oxidation of the double cube afforded As^{III} and $[W_3Se_4(H_2O)_9]^{4+}$. Treatment of $[W_3Se_4(H_2O)_9]^{4+}$ with $SbCl_3$ or with Sb shot in the presence of HCl afforded yellow–brown $[W_3(SbCl_3)Se_4(H_2O)_9]^{4+}$ (**83**, M′ = $SbCl_3$). The dithiophosphate complex $[W_3(SbI_3)S_4(OAc)\{S_2P(OEt)_2\}_3](dmf)]$ was also prepared, and the $SbCl_3$ group in $[W_3(SbCl_3)Se_4(H_2O)_9]^{4+}$ could be readily exchanged with $SnCl_3^-$. Reaction of $[W_3Se_4(H_2O)_9]^{4+}$ with $SbCl_3$ and H_3PO_2 gave the green–blue double cube $[W_6SbSe_8(H_2O)_{18}]^{8+}$ (**85**, M′ = Sb^0). Like its arsenic analog, this species could be oxidized with degradation to Sb^{III} and the precursor cluster. Reduction of Bi^{III} citrate by H_3PO_2 in the presence of $[W_3Se_4(H_2O)_9]^{4+}$ afforded the green–blue $[W_6BiSe_8(H_2O)_{18}]^{8+}$ (**85**, M′ = Bi^0), which was oxidized to regenerate Bi^{III} and $[W_3Se_4(H_2O)_9]^{4+}$. The dithiophosphato cluster $[W_3(BiI_3)S_4(OAc)\{S_2P(OEt)_2\}_3(H_2O)]$ has also been characterized.

9.3.6 Octahedral Clusters, W_6E_8

Clusters of this type are found, with Mo, in the Chevrel phases Mo_6E_8 (E = S, Se or Te) and in the ternary phases $M'Mo_6E_8$, but no such solid-state analogs containing tungsten have been confirmed. However, reaction of $[\{W_6Cl_{12}\}_n]$ with NaSH and OBu^{n-} in pyridine afforded the dark red 20-electron cluster $[W_6S_8(py)_6]$ if the molar ratio of W:S was at least 1:12. This species was diamagnetic and insoluble, although single crystals could be obtained under special conditions. The cluster has an octahedral core of W atoms, each triangular face being bridged by S, the pyridine ligands binding terminally to the metal centers. If the W:S molar ratios were set at 1:8 and the reaction took longer, the insoluble red 22-electron cluster $[W_6S_6Cl_2(py)_6]$ was produced and if the molar ratio was maintained between 1:6 and 1:8, and using shorter reactions times, the red soluble 24-electron cluster $[\{W_6Cl_6S_2\}Cl_2(py)_6]\cdot 5py$ was generated. However, if pyridine was replaced by its 4-butyl analog, Bu^tpy, and if $[Bu_4N]_2[W_6Cl_{14}]$ was used in place of $[\{W_6Cl_{12}\}_n]$, the orange soluble $[W_6S_8(Bu^tpy)_6]$ was formed. The pyridine could be substituted by piperidine or PEt_3, and $[W_6S_8(PEt_3)_6]$ could also be generated by reductive dimerization of $[W_3S_4Cl_4(PEt_3)_n]$ (n = 3 or 4) using Mg in thf.

The clusters $[W_6S_8L_6]$ (L = PEt_3, Bu^tpy) could be oxidized by ferrocenium cation to give the green paramagnetic 19-electron species $[W_6S_8L_6]^+$ (L = PEt_3, μ = 1.71 BM; L = Bu^tpy, μ = 1.60 BM). The structures of the neutral and cationic $[W_6S_8(PEt_3)_6]^z$ (z = 0 or +1) showed that oxidation only marginally increased the W–W distances in the cluster (ca. 2.68 Å in both species). Treatment of $[W_6S_8(Bu^tpy)_6]$ with CN^-afforded $[W6S_8(CN)_6]^6{}_-$ but with $P(C_6H_{11})_3$, only partial substitution could occur, affording *cis*-$[W_6S_8(Bu^tpy)_2\{P(C_6H_{11})_3\}_4]$. $[W_6S_8\{P(C_6H_{11})_3\}_6]$ could be obtained from $[W_6S_8(NH_2Bu^n)_6]$. Prolonged heating of *cis*-$[W_6S_8(Bu^tpy)_2\{P(C_6H_{11})_3\}_4]$ in benzene afforded a mixture of redistribution products, *fac*- and *mer*-$[W_6S_8(Bu^tpy)_3\{P(C_6H_{11})_3\}_3]$, *cis*- and *trans*-$[W_6S_8(Bu^tpy)_2\{P(C_6H_{11})_3\}_4]$, and $[W_6S_8(Bu^tpy)\{P(C_6H_{11})_3\}_5]$.

Red $[W_6Se_8L_6]$ (L = piperidine or pyridine) were obtained by reaction of $[\{W_6Cl_{12}\}_n]$, Na_2Se and L over several days. However, reaction with PEt_3 (W:Se ratio 1:8) afforded the red–brown 20-electron species $[W_6Se_7Cl(PEt_3)_6]^+$ (counter-anion Cl^-). The Se and Cl atoms were randomly distributed over the eight possible positions ($d_{W–W}$ 2.70 Å). If K_2Se replaced Na_2Se, the W:Se ratio being 1:10, $[W_6Se_{6.4}Cl_{1.6}(PEt_3)_6]^+$ (as Cl^-) was formed, this cation being shown to be a mixture of diamagnetic 20-electron $[W_6Se_7Cl(PEt_3)_6]^+$ and paramagnetic 21-electron $[W_6Se_6Cl_2(PEt_3)_6]^+$ in the ratio 2:3.

Reaction of $[\{W_6Cl_{12}\}_n]$ with Na_2Te in refluxing piperidine or pyridine afforded the dark blue 20-electron $[W_6Te_8(pip)_6]\cdot 6pip$ (W–W 2.74 Å) and the 21-electron $[Na(py)_6][W_6Te_8(py)_6]\cdot py$ ($d_{W–W}$ 2.72–2.75 Å). Treatment of the piperidine cluster with pyridine afforded black $[W_6Te_8(py)_6]$ and of this with PEt_3 dark purple $[W_6Te_8(PEt_3)_6]$ ($d_{W–W}$ 2.77 Å).

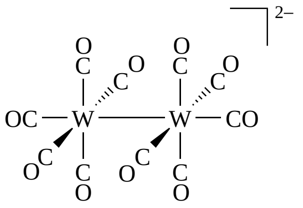
1 INTRODUCTION

This article surveys the organometallic chemistry of tungsten in a systematic manner according to the various types of complexes known to contain tungsten–carbon bonds. Within each category of complex, the material is generally presented in the following order: common methods of synthesis of these complexes, their characteristic physical properties, and their representative chemical properties. The latter are usually illustrated by examples taken from the literature published since 1992, the final year of coverage by the first edition of the Encyclopedia of Inorganic Chemistry. Other articles in the current encyclopedia also cover some aspects of this chemistry, most notably alkene and alkyne metathesis reactions mediated by organotungsten complexes (*see* ***Organic Synthesis Using Metal-mediated Metathesis Reactions***), the organometallic chemistry of di- and polynuclear tungsten complexes (*see* ***Dinuclear Organometallic Cluster Complexes***), and tungsten compounds containing main group element ligands (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***). Consequently, these topics are not specifically discussed in this article, which focuses primarily on the chemistry of mononuclear tungsten complexes containing organic ligands.

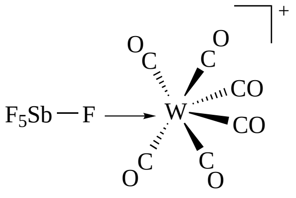
2 TUNGSTEN COMPLEXES CONTAINING CARBONYL, ISOCYANIDE, AND CYANIDE LIGANDS

2.1 Tungsten–Carbonyl Complexes

$W(CO)_6$ continues to be the most ubiquitous and readily available low-valent organometallic complex of tungsten (*see* ***Carbonyl Complexes of the Transition Metals***), and it serves as a convenient entry point into much of the organometallic chemistry described in this chapter. One or more of its CO ligands may be replaced with neutral donors to form carbonyl compounds (*see Carbonyl Compound*) of the type $W(CO)_{6-n}(L)_n$ (L = Lewis base). The homoleptic (*see Homoleptic Compound*) carbonyl anions $[W(CO)_5]^{2-}$ and $[W(CO)_4]^{4-}$ have been prepared by chemical reduction of suitable carbonyl compounds,[1] and the di- and tritungsten carbonyls, $[W_2(CO)_{10}]^{2-}$ (**1**) and $[W_3(CO)_{14}]^{2-}$, containing W–W bonds have also been described.[2,3] The photochemistry of (**1**), which results in the formation of the highly reducing 19e radical $[W(CO)_5(S)]^-$ upon irradiation in donor solvents, S (e.g. S = MeCN, THF), has been the topic of a recent review.[2] Treatment of $W(CO)_6$ with HF/SbF_5 in the presence of CO results in a remarkable 2e oxidation process and leads to the isolation of the cationic, seven-coordinate carbonyl complex $[W(CO)_6(\eta^1\text{-}FSbF_5)][Sb_2F_{11}]$, that is, $[(\mathbf{2})][Sb_2F_{11}]$.[4]



(**1**)



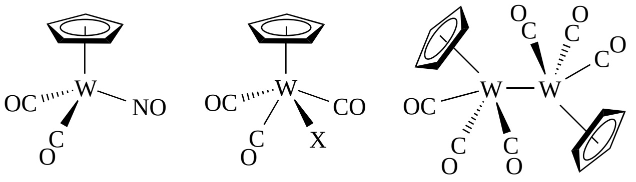
(**2**)

The substitution of carbonyl ligands in $W(CO)_6$ may be effected either thermally or photochemically. Among the more important reactions from a synthetic standpoint are those of $W(CO)_6$ with nitriles (RCN) to generate *fac*-$W(CO)_3(RCN)_3$ (**3**) (equation 1), the nitrile ligands of which may be displaced by other Lewis bases (*see Lewis Acids & Bases*) under mild conditions.[5] The reactions of $W(CO)_6$ with the cyclopentadienyl (*see Cyclopentadienyl*) reagents MCp′ (M = Li, Na, K; Cp′ = Cp,

Cp*, etc.) afford anionic $[Cp'W(CO)_3]^-$ derivatives (**4**)[6,7] (equation 2) that have been used to prepare complexes such as $Cp'W(CO)_2(NO)$ (**5**),[6,7] $Cp'W(CO)_3(X)$ (X = H, halide, alkyl) (**6**),[8] and $[Cp'W(CO)_3]_2$ (**7**).[9] Seven-coordinate halocarbonyl complexes of the type $W(CO)_{5-n}(L)_n(X)_2$ ($n = 1, 2$; X = halide) are obtained upon addition of L to $[W(CO)_4(X)(\mu\text{-}X)]_2$ or from the reactions of halogens with $W(CO)_{6-n}(L)_n$.[10,11]

$$W(CO)_6 \xrightarrow[RCN]{\Delta} \underset{(\mathbf{3})}{W(CO)_3(RCN)_3} + 3CO \quad (1)$$

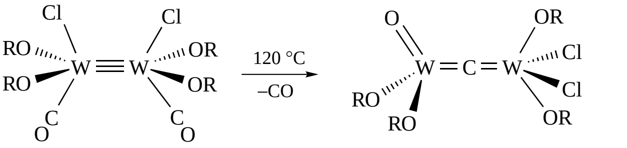
$$W(CO)_6 + MCp' \xrightarrow[THF]{\Delta} \underset{(\mathbf{4})}{M[Cp'W(CO)_3]} + 3CO \quad (2)$$



(**5**) (**6**) (**7**)

The Lewis-acidic (*see Lewis Acids & Bases*) $W(CO)_5$ fragment binds a variety of weakly coordinating ligands. As a result, there are a great many $W(CO)_5(L)$ complexes known, some of which have found applications in catalysis (*see* ***Organic Synthesis using Transition Metal Carbonyl Complexes***). For example, the thiirane complex $W(CO)_5(SCH_2CH_2)$ catalyzes the conversion of thioethers to cyclic disulfides.[12] Of particular interest are transient $W(CO)_5$(alkane) complexes detected by IR spectroscopy at low temperature upon irradiation of $W(CO)_6$ in hydrocarbon solvents; in these σ-alkane adducts, the tungsten atom interacts with a single C–H bond of the alkane ligand.[13] The $W(CO)_5$(alkane) derivatives react rapidly with Lewis bases (*see Lewis Acids & Bases*) to form $W(CO)_5(L)$, which may also be generated directly by photolysis of $W(CO)_6$ in the presence of L. In related $W(CO)_5(\eta^1\text{-}BH_3\cdot L)$ complexes (L = py, NMe_3, PMe_3), the borane-Lewis base adduct coordinates with the tungsten center via a B–H bond in a three-center, 2e interaction (*see* ***Dihydrogen Complexes & Related Sigma Complexes***).[14]

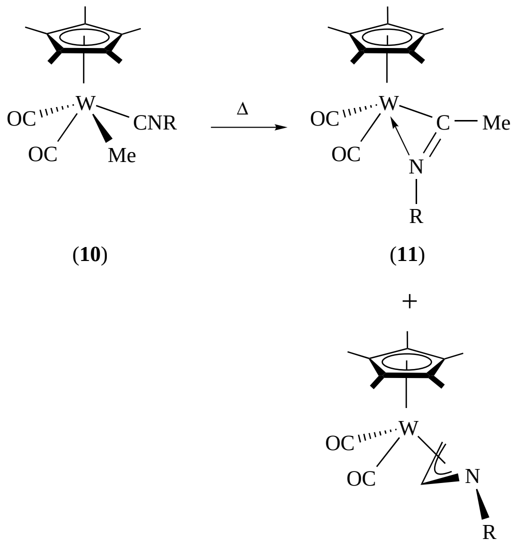
The most common mode of reactivity involving carbonyl ligands in organometallic complexes of tungsten is CO insertion into a W–R bond (R = alkyl, aryl) to form tungsten–acyl complexes. For example, the reaction of *cis*-$Cp^*W(CO)_2(MeCN)(Me)$ with $CNBu^t$ affords a mixture of ligand-substitution products, *cis*- and *trans*-$Cp^*W(CO)_2(CNBu^t)(Me)$, and the CO insertion products, *cis*- and *trans*-$Cp^*W(CO)(CNBu^t)_2(COMe)$.[15] A remarkable 6e reductive cleavage of a CO ligand occurs upon thermolysis of $[WCl(CO)(OR)_2]_2$ (**8**, R = $SiBu^t{}_3$) at 120 °C in toluene to give the oxo-μ-carbido complex $(RO)_2(O)W{=}C{=}WCl_2(OR)_2$ (**9**) (equation 3). An analogous imido-μ-carbido complex $(RO)_2(ArN)W{=}C{=}WCl_2(OR)_2$ is formed when the related aryl isocyanide species, $(RO)_4W_2Cl_2(CNAr)$ (Ar = 2,6-$Me_2C_6H_3$), is heated at 60 °C in the same solvent.[16]



(**8**) (**9**) (3)

2.2 Tungsten–Isocyanide and – Cyanide Complexes

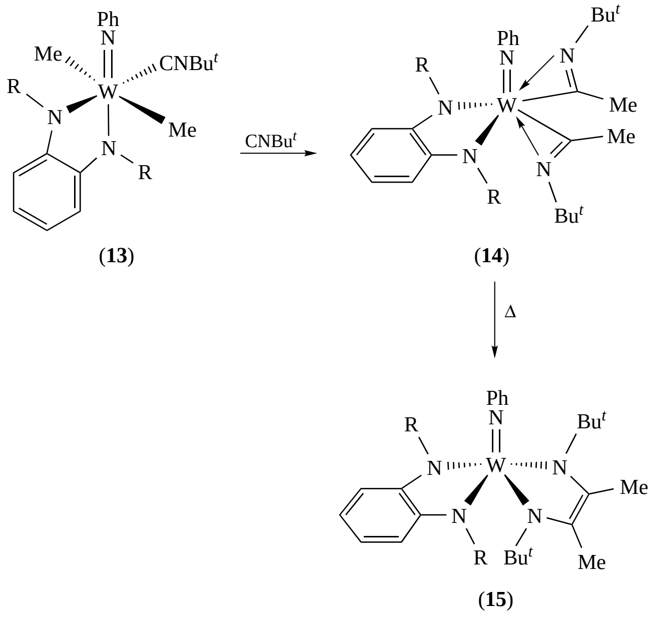
Neutral and cationic homoleptic (*see Homoleptic Compound*) tungsten–isocyanide complexes $W(CNR)_6$ and $[W(CNR)_7]^{2+}$ (R = alkyl, aryl) are known,[17] and $W(CO)_{6-n}(CNR)_n$ ($n = 1–3$) complexes may be prepared from $W(CO)_6$ and excess isocyanide in the presence of catalytic amounts of $CoCl_2$ or PdO.[18,19] Isocyanides are isoelectronic with CO and also insert into the W–R bonds of alkyl complexes (*see Alkyl Complexes*). For instance, the alkyl–nitrosyl complexes $Cp^*W(NO)(X)(CH_2Bu^t)$ (X = $NHBu^t$, OBu^t) react with $CNBu^t$ to afford η^2-iminoacyl complexes,[20] and the isocyanide complexes, $Cp^*W(CO)_2(Me)(CNR)$ (**10**, R = alkyl), rearrange to afford either η^2-iminoacyl $Cp^*W(CO)_2(\eta^2\text{-}MeCNR)$ (**11**) or η^3-1-azaallyl $Cp^*W(CO)_2(\eta^3\text{-}CH_2CHNR)$ (**12**) derivatives, depending upon the reaction conditions (equation 4).[21]



(**10**) (**11**) (**12**) (4)

The coupling of isocyanide ligands (*see Isocyanide Ligands*) via C–C bond formation has also been observed. Thus, $[(Me_3SiN)_2C_6H_4](NPh)WMe_2$ reacts with $CNBu^t$ to form the octahedral adduct $[(Me_3SiN)_2C_6H_4](NPh)WMe_2(CNBu^t)$ (**13**), which in the presence of $CNBu^t$ is converted to a trigonal–bipyramidal bis(η^2-iminoacyl) species (**14**) that

thermally isomerizes to the square–pyramidal metallacyclic complex (**15**) (equation 5, R = $SiMe_3$).[22]



(5)

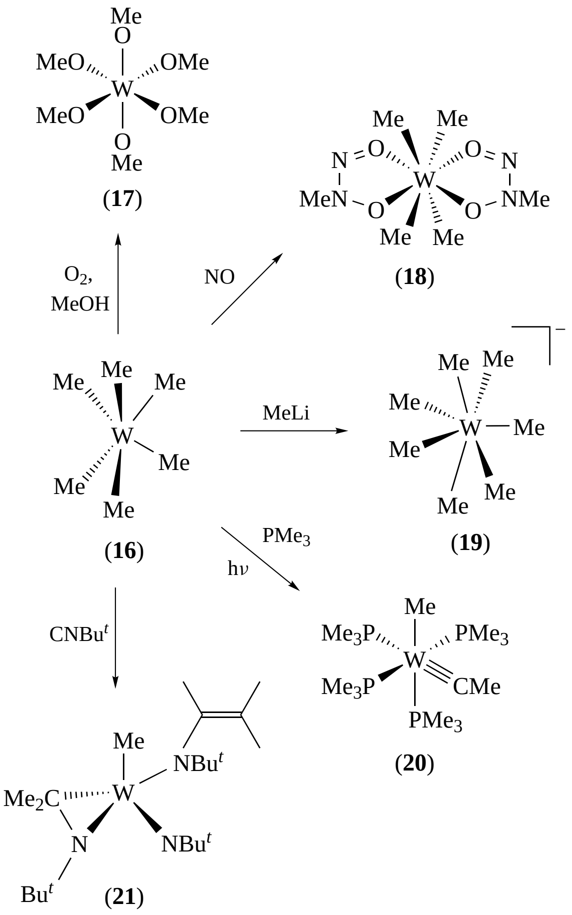
Research involving the octacyanotungstate anions, $[W(CN)_8]^{n-}$ (n = 3, 4), is experiencing a renaissance since these complexes exhibit unusual photochemical behavior and have been used as molecular components for the construction of multidimensional polymeric materials;[23,24] for instance, the reaction of $K_4[W(CN)_8]$ with Me_3SnCl affords the three-dimensional coordination polymer $\{(Me_3Sn)_4[W(CN)_8]\}_n$.[25] The octacyanotungstate anions may possess dodecahedral or square–antiprismatic coordination geometries in the solid state (*see* ***Cyanide Complexes of the Transition Metals***), and the addition of labile (*see Labile*) coordination complexes to solutions of $[W(CN)_8]^{n-}$ often affords compounds that possess potentially useful magnetic properties. Specifically, the reaction of $[HNBu_3]_3[W(CN)_8]$ with $Mn(ClO_4)_2$ in EtOH provides $Mn_9[W(CN)_8]_6\cdot 24EtOH$ that consists of cyanide-bridged $Mn^{II}{}_9W^{V}{}_6$ units with a capped-cubane geometry and exhibits the largest known spin-value $S = 39/2$ ground state.[26]

3 TUNGSTEN COMPLEXES CONTAINING HYDROCARBON LIGANDS

3.1 η^1-Hydrocarbyl Complexes

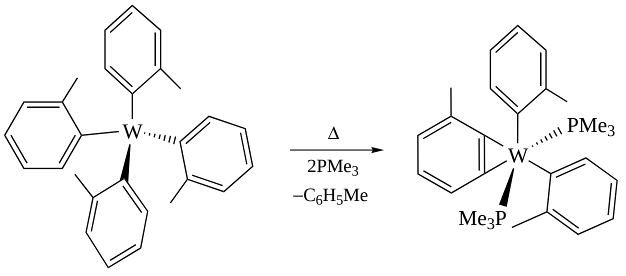
3.1.1 Alkyl and Aryl Complexes

Hexamethyltungsten, WMe_6 (**16**), was first isolated by Wilkinson and coworkers, and it may be prepared by the reactions of WCl_6 with methylating reagents such as MeLi, $AlMe_3$, or $ZnMe_2$. Recent structural analyses have shown that (**16**) has a distorted trigonal–prismatic structure of C_{3v} symmetry with three long and three short W–C bonds,[27] an unusual structural motif found primarily in d^0 (*see d^n Configuration*) complexes containing σ-only donor ligands.[28] The reactions of (**16**) with O_2 or MeOH afford $W(OMe)_6$ (**17**), and treatment with CO forms $W(CO)_6$ and Me_2CO.[29] In contrast, the reaction of (**16**) with NO affords $WMe_4(MeN_2O_2)_2$ (**18**),[30] and the seven- and eight-coordinate alkyl anions $[WMe_7]^-$ (**19**), $[WMe_6(CH_2SiMe_3)]^-$, or $[WMe_8]^{2-}$ are formed when (**16**) is treated with RLi (R = Me, CH_2SiMe_3) reagents (Scheme 1).[31,32] Photolysis of (**16**) in the presence of PMe_3 produces $W(Me)(\equiv CMe)(PMe_3)_4$ (**20**) and CH_4,[33] and an unusual five-coordinate W^{VI} imido complex (**21**) is formed when (**16**) is treated with excess CNBu^t.[29] Mixed complexes WX_nMe_{6-n} are predicted to exhibit a gradual increase in the preference for octahedral geometry as n increases;[34] for instance, WMe_5X (X = Cl, F) species possess a distorted trigonal–prismatic geometry, while $WMe_3(OMe)_2Cl$ and WF_6 are octahedral molecules.[35] Few other homoleptic (*see Homoleptic Compound*) alkyl complexes of tungsten are known, but $W(CH_2Ph)_4$,[36] along with ditungsten complexes $W_2(CH_2R)_6$ (R = Ph, $SiMe_2Ph$) containing a W≡W



Scheme 1

triple bond[37] have been reported. Homoleptic (*see Homoleptic Compound*) aryl complexes $W(aryl)_4$ (aryl = 2-MeC_6H_4 (**22**), 2,5-$Me_2C_6H_3$) may be prepared by treating $W(OPh)_6$ with appropriate Grignard reagents (*see Grignard Reagents*), and they react with PMe_3 to give the η^2-aryne complexes W(η^2-C_6H_3MeR)$(aryl)_2(PMe_3)_2$ (R = H (**23**), Me) (equation 6).[38]

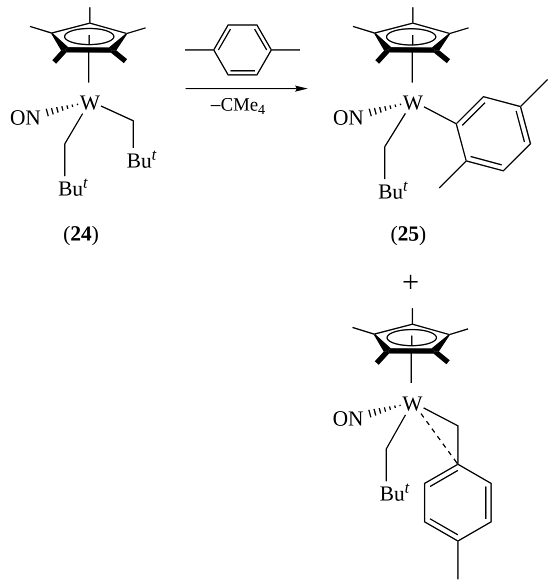


(**22**) (**23**)

(6)

In general, alkyl and aryl complexes of tungsten are prepared by metathesis of suitable halide precursors using various alkylating or arylating reagents. Thus, $Tp^*W(O)_2R$ derivatives (R = Me, CH_2SiMe_3, CH_2Bu^t, CH_2CMePh_2, etc.) are obtained from $Tp^*W(O)_2Cl$ and Grignard reagents (*see Grignard Reagents*),[39] and the 16e dialkyl–nitrosyl complexes $Cp'W(NO)R_2$ are accessed by treating $[Cp'W(NO)Cl_2]_n$ (Cp' = Cp, Cp*; $n = 1$, 2) with dialkylmagnesium reagents, $R_2Mg{\cdot}x$(dioxane).[40] For instance, the reaction of $Cp^*W(NO)Cl_2$ with MeLi affords the monomeric dimethyl complex, $Cp^*W(NO)Me_2$, which reacts with PMe_3 to form an isolable $Cp^*W(NO)Me_2(PMe_3)$ adduct. In the absence of a supporting donor interaction, the dimethyl compound undergoes spontaneous isomerization via nitrosyl N–O bond cleavage to its oxo(imido) form, $Cp^*W(NMe)(O)Me$.[41]

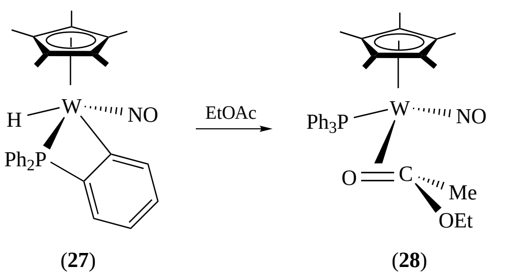
Electron-deficient tungsten–alkyl complexes exhibit some unusual bonding interactions. Specifically, the benzyl complexes $Cp^*W(NO)(\eta^2\text{-}CH_2Ph)(R)$ possess W-η^2-benzyl linkages,[42] and the bis(neopentyl) compound, $Cp^*W(NO)(CH_2Bu^t)_2$ (**24**), contains one strongly agostic and one weakly agostic methylene hydrogen atom in the solid state, and these α-agostic (*see Agostic Bonding*) interactions persist in solutions.[43] In addition, these alkyl complexes undergo thermal or photochemical reactions to give alkene (*see Alkene Complexes*), alkylidene (*see Alkylidene*), or alkylidyne (*see Alkylidyne*) complexes that are discussed further in the appropriate sections (vide infra). Thermolysis of (**24**) in methyl-substituted arenes such as p-xylene results in the α-elimination (*see α-Elimination*) of neopentane and formation of a mixture containing the aryl and the η^2-benzyl complexes, that is, $Cp^*W(NO)(CH_2Bu^t)(2,5\text{-}Me_2C_6H_3)$ (**25**) and $Cp^*W(NO)(CH_2Bu^t)(\eta^2\text{-}CH_2C_6H_4\text{-}4\text{-}Me)$ (**26**), derived from aromatic sp^2 or benzylic sp^3 C–H bond activations of the solvent molecule, respectively (equation 7) (*see* ***Alkane Carbon–Hydrogen Bond Activation***). These and related mixed alkyl-aryl species may also be produced by metatheses from $Cp^*W(NO)(CH_2Bu^t)(Cl)$ and appropriate aryl Grignard reagents (*see Grignard Reagents*).



(**24**) (**25**) (**26**)

(7)

Treatment of $Cp^*W(NO)Cl_2$ with $(aryl)_2Mg$ (aryl = Ph, o- and p-tolyl) affords 16e $Cp^*W(NO)(aryl)_2$ complexes that react with CO, CO_2, CS_2, or aryl isocyanates to produce η^2-acyl, η^2-carboxylate, η^2-thiocarboxylate, and η^2-amide-containing complexes, respectively.[40,44] In a related system, the water-induced isomerization of CpW(NO)(o-tolyl)$_2$ affords the isomeric oxo(imido) complex CpW(O)(N-o-tolyl)(o-tolyl).[45] Furthermore, the ortho-metalated phosphine complex, $Cp^*W(NO)(H)(\eta^2\text{-}PPh_2C_6H_4)$ (**27**), undergoes intramolecular reductive elimination (*see Reductive Elimination*) of the aryl and hydrido ligands to afford the strong π-donor fragment $Cp^*W(NO)(PPh_3)$, which subsequently reacts with unsaturated molecules L = CNR (R = Bu^t, Cy), Me_2CO, and EtOAc to afford $Cp^*W(NO)(PPh_3)(\eta^2\text{-}L)$ adducts, including the η^2-ester complex (**28**, equation 8).[46]



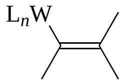
(**27**) (**28**)

(8)

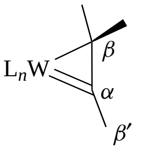
3.1.2 Vinyl and Alkynyl Complexes

Vinyl (or alkenyl) ligands may adopt either η^1- (**A**) or η^2- (**B**) limiting coordination modes depending on the electronic saturation of the tungsten center. In η^2-vinyl complexes, both alkenyl carbon atoms are bound to the metal, and the resulting metallacyclopropene ligand increases the formal electron

count at the metal by two relative to an η^1-vinyl ligand.[47] Typical synthetic routes to vinyl complexes involve transmetallation using vinylmagnesium reagents, deprotonation of η^2-alkene ligands, and nucleophilic addition (e.g. protonation) of η^2-alkyne ligands. The insertion of an alkyne into a W–H bond also affords a vinyl complex, as in the reaction of $Cp^*W(NO)(CH_2SiMe_3)(H)$ with $PhC{\equiv}CH$ to form $Cp^*W(NO)(CH_2SiMe_3)(\eta^2\text{-}CPh{=}CH_2)$.[48] η^1-Vinyl complexes can isomerize via a formal [1,2]-*H* shift to generate alkylidyne complexes; these reactions generally proceed via formation of intermediate metallacyclopropene species (**B**) and therefore require a vacant coordination site at the tungsten center. The isomerization of η^2-vinyl complexes to η^3-allyl complexes via intermediate η^2-allene hydride species has also been documented.[47]

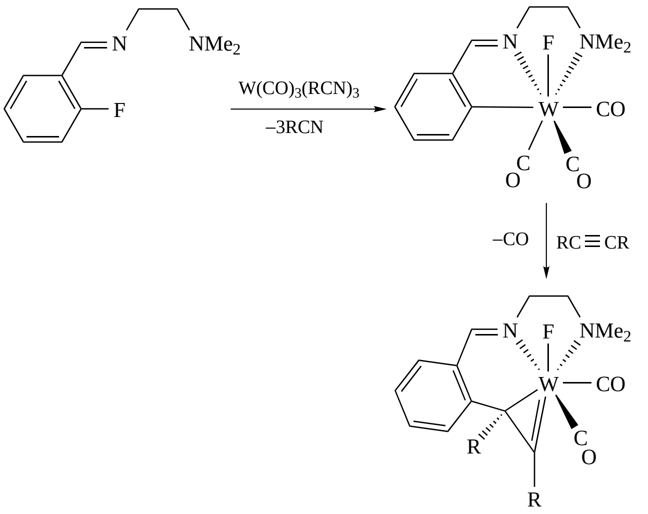


η^1-vinyl
A



η^2-vinyl
(1-metallacyclopropene)
B

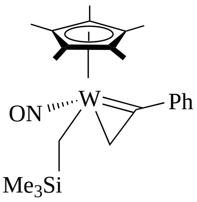
Deprotonation of $Tp^*W(CO)_2(\eta^2\text{-}H_2C{=}C(CH_2R))$ (R = H, Pr, Ph) at the β'-site results in the formation of anionic η^2-allene species $[Tp^*W(CO)_2(\eta^2\text{-}H_2C{=}C{=}CHR)]^-$, which react in turn with MeI to form $Tp^*W(CO)_2(\eta^2\text{-}H_2C{=}C(CHRMe))$.[49] Furthermore, the characteristic chemistry of dioxotungsten–vinyl complexes has been described,[50] and sequential C–F oxidative addition (*see Oxidative Addition*) and migratory insertion of electron-deficient alkynes at a tungsten center gives rise to novel η^2-vinyl complexes (**29**) in which an aromatic C–F bond has been replaced by a C–C bond (equation 9).[51]



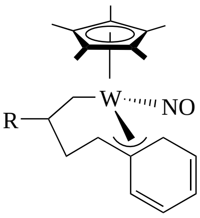
(**29**)

(9)

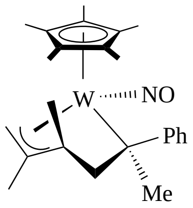
The solid-state molecular structure of $Cp^*W(NO)(CH_2SiMe_3)(CPh{=}CH_2)$ (**30**) reveals that its vinyl ligand exists in a distorted form that cannot readily be described by either of the classic η^1-vinyl (**A**) or 1-metallacyclopropene (**B**) limiting structures. However, the NMR spectroscopic parameters for the $CPhCH_2$ fragment of (**30**) in solutions are characteristic of those of structure **B**, a feature reflecting the metal center's attainment of the favored 18e configuration (*see Eighteen Electron Compounds*). Thermolysis of (**30**) in neat hydrocarbon solutions transiently generates $Cp^*W(NO)(\eta^2\text{-}PhC{\equiv}CH)$, which subsequently activates solvent C–H bonds to afford either 18e $Cp^*W(NO)(R)(\eta^2\text{-}CPh{=}CH_2)$ complexes (e.g. R = phenyl) or 18e η^1,η^3-metallacyclic species (**31**) (R = OEt, Pr^n, Bu^n, Bu^t) (*see* ***Alkane Carbon–Hydrogen Bond Activation***). In the absence of alkyl groups with β-C–H bonds, a different mode of reactivity occurs; for instance, the activation of 2,3-dimethyl-2-butene results in fusion of the olefinic fragment to the vinyl ligand at the α-C of the vinyl moiety, and two C–H bond activations occur at the trans-γ positions of the olefinic substrate to afford (**32**).



(**30**)



(**31**)

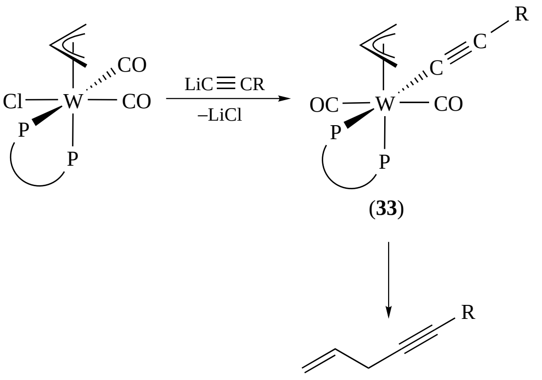


(**32**)

Alkynyl complexes are typically prepared by the reactions of appropriate tungsten precursors with acetylide reagents, for example $LiC{\equiv}CR$, or by deprotonation of η^2-alkyne or vinylidene complexes. The characteristic reactivity of alkynyl complexes most commonly involves electrophilic attack at the β-carbon, a fact rationalized by invoking resonance forms **C** and **D** shown below. Form **D** becomes dominant as the electron density on the complex increases, and therefore anionic complexes of the type $[W(CO)_5(C{\equiv}CR)]^-$, $[W(CO)_4(PPh_3)(C{\equiv}CR)]^-$ or *fac*-$[W(C{\equiv}CR)(CO)_3(dppe)]^-$ react with electrophiles exclusively at the β-carbon atom to yield vinylidene complexes.[52,53] Likewise, the negative charge in $[CpW(CO)_2]_2(\mu\text{-}\sigma{:}C{\equiv}CPh)^-$ is delocalized between the tungsten atom and the β-carbon atom of the bridging alkynyl ligand.[54] Neutral $W(CO)_2(NO)(dppe)(C{\equiv}CR)$ (R = H, Bu^t, Pr^n) compounds have also been described, but these nitrosyl complexes (*see Nitrosyl Complexes*) do not react with electrophiles to afford vinylidene complexes.[55]

$$\underset{\mathbf{C}}{L_nW-\underset{\alpha}{C}\equiv\underset{\beta}{C}-R} \longleftrightarrow \underset{\mathbf{D}}{L_n\overset{+}{W}=\underset{\alpha}{C}=\underset{\beta}{\overset{-}{C}}-R}$$

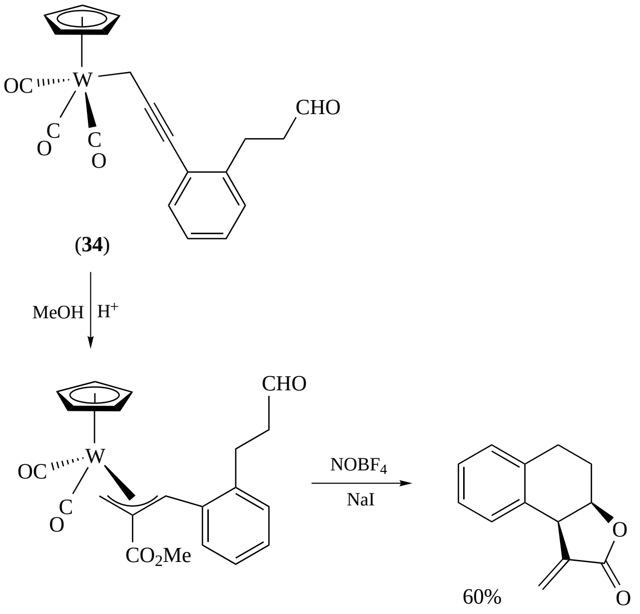
In rare cases, electrophilic attack may occur directly at the metal center of an alkynyl complex, as when anionic $[CpW(NO)(CO)(C{\equiv}CR)]^-$ ($R = SiMe_3$, Bu^t, Ph) is treated with allylic iodides to obtain $CpW(NO)(\eta^3$-allyl)$(C{\equiv}CR)$ via a sequence involving electrophilic attack at the tungsten, CO elimination, and $\eta^1 \rightarrow \eta^3$ isomerization of the allyl ligand.[56] Isolable *trans*-$W(C{\equiv}CR)(CO)_2(\eta^3$-allyl)(dmpm) complexes (**33**) are prepared from *cis*-$WCl(CO)_2(\eta^3$-allyl)(dmpm) and $LiC{\equiv}CR$, and the alkynyl ligand of (**33**) can undergo an intramolecular (*see Intramolecular*) metal-to-allyl migration to produce free eneynes derived from alkynyl–allyl coupling (equation 10).[57]



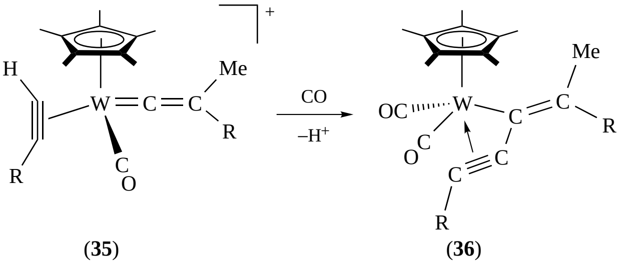
(10)

Photolysis of *trans*-$W(N_2)_2(dppe)_2$ in the presence of $RC{\equiv}CH$ ($R = Ph$, CO_2Me, CO_2Et) gives a mixture of the alkynyl complexes, *trans*-$[M(C{\equiv}CR)_2(dppe)_2]$, and eight-coordinate *trans*-$[W(H)_2(C{\equiv}CR)_2(dppe)_2]$. The latter compounds react with HBF_4 to give either neutral $WF({\equiv}CCH_2R)(dppe)_2$ ($R = CO_2Me$) or cationic $[WF(=CHCH_2R)(dppe)_2]^+$ ($R = Ph$).[58] Reactions of $LiC{\equiv}CR$ with $W_2Cl_4(PMe_3)_4$ afford $W_2(C{\equiv}CR)_4(PMe_3)_4$ complexes of D_{2d} symmetry; however, the alkynyl ligands in these complexes are not oriented parallel to one another due to a combination of steric and electronic effects. The existence of π-δ-π conjugation (involving the π/π^* and δ/δ^* orbitals of the alkynyl and metal–metal quadruple bond, respectively) in these and related complexes has been demonstrated using a variety of spectroscopic techniques, and the IR $\nu(C{\equiv}C)$ frequencies have been shown to be a sensitive probe of orbital mixing.[59] Finally, the unusual methylidyne complexes, $W(C{\equiv}CR)({\equiv}CH)(dmpe)_2$ ($R = H$, Ph, $SiMe_3$), contain linear metallabutadiyne units that exhibit considerable π-$HC{\equiv}W{-}C{\equiv}CR$ conjugation.[60]

The alkynyl complexes $CpW(CO)_3(C{\equiv}CR)$ are versatile reagents for the preparation of organometallic cluster compounds[61] (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***), and they and propargyl complexes of the type $CpW(CO)_3(CH_2C{\equiv}CR)$ (**34**) have found use as templates during the synthesis of heterocyclic and carbocyclic compounds, especially lactones (e.g. equation 11).[62] Treatment of $CpW(CO)_3(CH_2C{\equiv}CH)$ with $[Ph_3C]PF_6$ generates cationic $[CpW(CO)_3(\eta^2\text{-}H_2C{=}C{=}CHCPh_3)]^+$, which eliminates tritylallene, $H_2C{=}C{=}CHCPh_3$, upon treatment with excess Me_3NO.[63] The reaction of $CpW(CO)_3Cl$ with buta-1,3-diyne in the presence of $CuI/NHEt_2$ affords $CpW(CO)_3(C{\equiv}CC{\equiv}CH)$, from which a series of functionalized diynyl derivatives $CpW(CO)_3(C{\equiv}CC{\equiv}CR)$ ($R = Ph$, $SiMe_3$, $P(O)Ph_2$) may be obtained.[64] Furthermore, the alkynyl ligand in $Cp^*W(CO)(C{\equiv}CR)(\eta^2\text{-}HC{\equiv}CR)$ reacts with $[Me_3O]BF_4$ to form the cationic vinylidene complex (**35**) that when deprotonated in the presence of CO affords the coupled product $Cp^*W(CO)_2(\eta^3\text{-}RC{\equiv}CC{=}CMeR)$ (**36**, $R = Bu^t$, equation 12).[65]



(11)

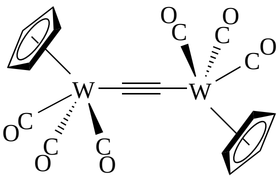


(12)

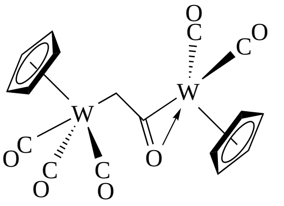
Finally, the reaction of $[CpW(CO)_3]^-$ with CH_2I_2 in MeCN produces the dinuclear acetylide complex $[CpW(CO)_3]_2(\mu\text{-}C{\equiv}C)$ (**37**) along with $CpW(CO)_3Me$ and $CpW(CO)_3I$, but when the same reaction is carried out in MeOH, the dinuclear ketene complex $Cp_2\,W_2(CO)_5(\mu,\eta^1,\eta^2\text{-}CH_2CO)$ (**38**) is obtained.[66]

3.1.3 Carbene Complexes

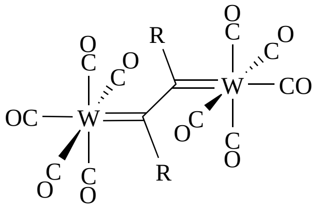
Tungsten–carbene complexes contain W=C linkages, and if they also contain alkyl substituents on the carbene carbon,



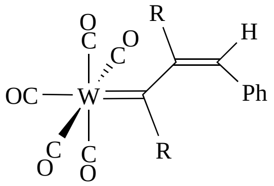
(**37**)



(**38**)

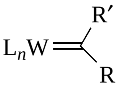


(**42**)

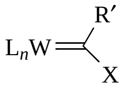


(**43**)

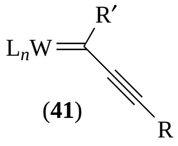
they are frequently referred to as alkylidene complexes (*see* ***Carbene Complexes***). The two extreme types of carbene complexes are the Schrock type (**39**) with at least one alkyl substituent on the α-carbon atom, and the Fischer type (**40**), which possess a π-donor heteroatom substituent on the α-carbon atom. However, many carbene complexes lie between these extremes. Fischer carbenes (*see Fischer-type Carbene Complexes*) contain the metal in a low oxidation state and have π-donor substituents on C_α, which exhibits electrophilic behavior that is generally ascribed to the combined effect of π-acceptor ligands on the metal and inductive effects of the electronegative heteroatom substituent.



(**39**)



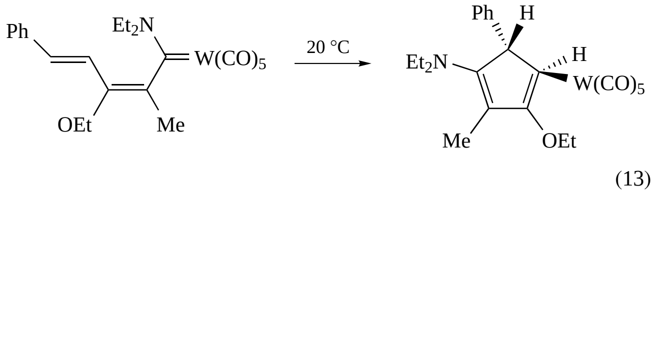
(**40**)



(**41**)

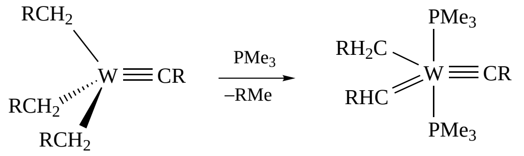
X = OR, SR, NR_2

The first tungsten–carbene complexes were generated by Fischer in 1964 by the addition of alkyllithium reagents to $W(CO)_6$ followed by quenching with an electrophile (*see Electrophile*). Derivatives of these species exhibit a multitude of carbene-centered ligand reactions and interligand coupling reactions,[67,68] and they have been used for the polymerization of alkynes and as a carbene source for the cyclopropanation of alkenes. Related (1-alkynyl)carbene complexes (**41**) have found use in various cyclization reactions,[69] and 1-metalla-1,3,5-hexatriene complexes are key intermediates during the synthesis of heterocyclic compounds (e.g. equation 13); they have also been used as stoichiometric reagents in organic synthesis.[70] Related allenylidene complexes $W(CO)_5(=C=C=CR_2)$ react with amines, imines, and hydrazines via addition of the nitrogen nucleophile (*see Nucleophile*) to the C_α allenylidene atom.[71] Interestingly, the reaction of $W(CO)_5(=CHPh)$ with RC≡CR affords both the dinuclear complex (**42**) and the alkyne insertion product (**43**, R = NMe_2).[72]



(13)

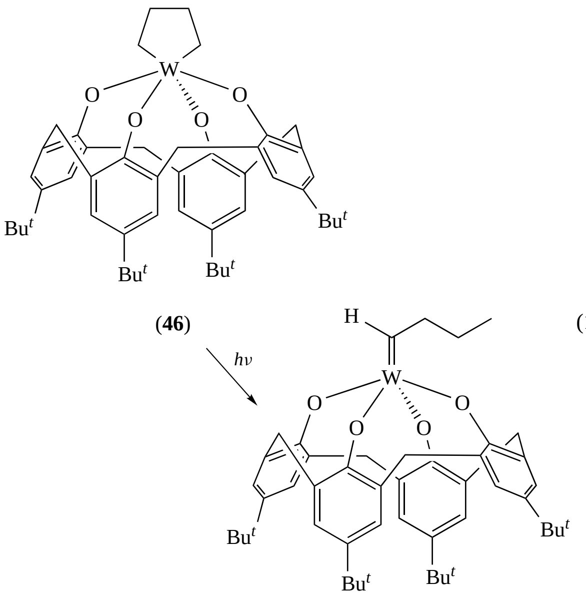
In Schrock-type carbene complexes (*see Schrock-type Carbene Complexes*), the tungsten is typically in a high oxidation state and the C_α substituents are devoid of π-donor character, and the resulting strong $W \rightarrow C_\alpha \pi$-backbonding interaction (*see Back Bonding*) imparts nucleophilic behavior on the complexes. The alkylidene ligands in these complexes are most commonly formed by α-deprotonation of an alkyl group. Such transformations may occur upon coordinative saturation of the metal center, as in the reaction of $W(\equiv CBu^t)(CH_2Bu^t)_3$ (**44**) with PMe_3 to afford $W(\equiv CBu^t)(=CHBu^t)(CH_2Bu^t)(PMe_3)_2$ (**45**) (equation (14), R = Bu^t),[73] or during intramolecular α-H elimination (*see α-Elimination*) reactions induced by thermal or photochemical means. Finally, it should be noted that tungsten–carbene complexes may be prepared by direct carbene transfer, as in the synthesis of $W(=CHR)Cl_2(NPh)(PMePh_2)_2$ from the reactions of $WCl_2(NPh)(PMePh_2)_3$ and $Ph_3P=CHR$ (R = aryl, vinyl).[74]



(**44**) (**45**) (14)

Thermolysis of $Cp^*W(NO)(CH_2Bu^t)_2$ in neat hydrocarbon solutions transiently generates the neopentylidene complex, $Cp^*W(NO)(=CHBu^t)$, which subsequently activates solvent C–H bonds.[75] The trialkyl complexes $Cp'W(NBu^t)(CH_2R)_3$ (R = Me, Et) undergo a similar thermal decomposition to afford the isolable alkylidene derivatives, $Cp'W(NBu^t)(=CHR)(CH_2R)$.[76] Photolysis of the metallacyclopentane complex, $\{p\text{-}Bu^t\text{-calix[4]-(O)}_4\}W(CH_2)_4$ (**46**), affords the alkylidene complex, $\{p\text{-}Bu^t\text{-calix[4]-(O)}_4\}W(=CHPr)$ (**47**, equation 15).[77] The related W^{VI} alkylidene complex, $(NPh)W(=CHSiMe_3)(CH_2SiMe_3)(OR)$ (R = $C(py)Ph_2$), is formed via intramolecular α-H abstraction from the trialkyl complex $(NPh)W(CH_2SiMe_3)_3(OR)$,[78] and the unusual square–pyramidal compound, $[(Me_3SiN)_2C_6H_4](NPh)W(=CHBu^t)(PMe_3)$, reacts with ethene to afford the metallacyclopentane complex, $[(Me_3SiN)_2C_6H_4](NPh)W(CH_2)_4$

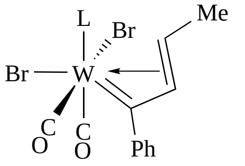
and neohexene.[79]



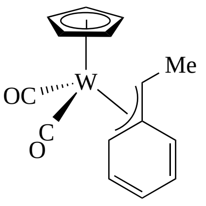
(46) (15)

(47)

Protonation of the η^2-vinyl complex, $Tp^*W(CO)_2(\eta^2$-$CPh{=}CHMe)$, with HBF_4 affords the cationic alkylidene complex, $[Tp^*W(CO)_2({=}CPhCH_2Me)]^+$,[47] and this and related $Tp^*W(CO)_2({=}CMePh)$ complexes contain β-agostic (*see Agostic Bonding*) C–H bonds.[80] In a similar manner, protonation of $W({\equiv}CR)(Cl)(CO)(L)(PMe_3)_2$ ($L = PMe_3$, py) with HCl affords an alkylidene complex, $W({=}CHR)(Cl)_2(CO)(PMe_3)_2$ (R = Me, Et, Ph, *p*-Tol), that contains α-agostic C–H interactions.[81] The related η^3-allylidene complex $W({=}CPhCH{=}CHMe)(Br)_2(CO)_2(L)$ (**48**) contains an alkylidene ligand that coordinates with the metal via a second intraligand donor site involving the β- and γ-carbon atoms.[82] Alternatively, the deprotonation of $Tp^*W(CO)(Me)(\eta^2$-$PhC{\equiv}CMe)$ with trityl cation yields the cationic methylene complex $[Tp^*W(CO)({=}CH_2)(\eta^2$-$PhC{\equiv}CMe)]^+$.[83] Finally, treatment of the anionic alkylidene complex, $[CpW(CO)_2({=}CHPh)]^-$, with MeI affords *trans*-$CpW(Me)(CO)_2({=}CHPh)$ that isomerizes via an intramolecular (*see Intramolecular*) methyl-to-carbene migration to form the η^3-benzyl complex, $CpW(CO)_2(\eta^3$-$CH(Me)C_6H_5)$ (**49**).[84]

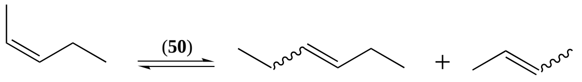


(**48**)

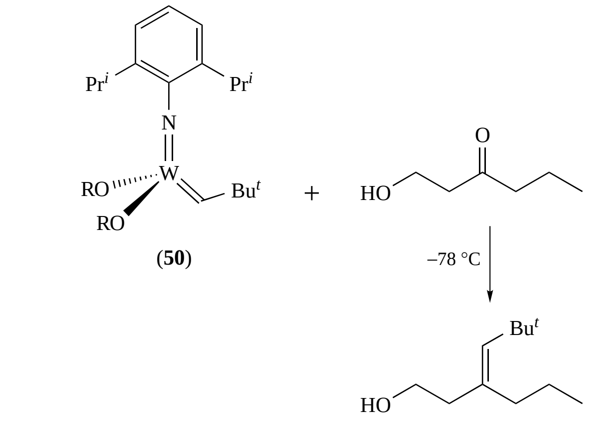


(**49**)

Complexes incorporating a W^{VI} center with supporting alkoxide ligands and an imido ligand, for example $W(NAr)({=}CHBu^t)(OR)_2$ ($R = CMe(CF_3)_2$, **50**) are highly active catalysts for the metathesis of internal alkenes (equation 16),[85] and also effect the stereoselective olefination of hydroxy ketones (equation 17).[86] The reactivity of these catalysts can be tuned by varying the alkoxide ligands; for example, when $R = Bu^t$, the complex acts only upon strained cyclic alkenes and is a highly effective ring-opening metathesis polymerization (ROMP) catalyst (*see* ***Metathesis Polymerization Processes by Homogeneous Catalysis***).



(16)



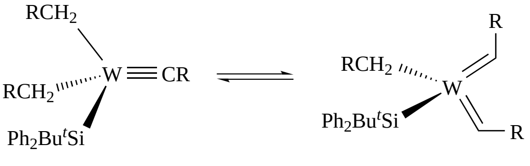
(17)

3.1.4 Carbyne Complexes

Tungsten–carbyne (or alkylidyne) complexes (*see Carbyne Complexes*) contain W≡C–R linkages that are often slightly bent. This bending has been attributed to electronic rather than steric effects,[87] and spectroscopic investigations have revealed carbon p orbital character in these bonds greater than that expected for formal sp-hybridization.[88] The first tungsten–carbyne complexes, *trans*-$W(CO)_4({\equiv}CR)(X)$ (R = alkyl, X = halide), were obtained by Fischer who treated his carbene complexes with BX_3. Using related methodology, alkynylcarbyne complexes $W(CO)_2({\equiv}CC{\equiv}CR)(CF_3CO_2)(bipy)$ ($R = SiMe_3$, Ph, *p*-Tol, Bu^t) may be prepared by treating $W(CO)_6$ with $LiC{\equiv}CR$, trifluoroacetic anhydride, and bipy in a sequential manner.[89]

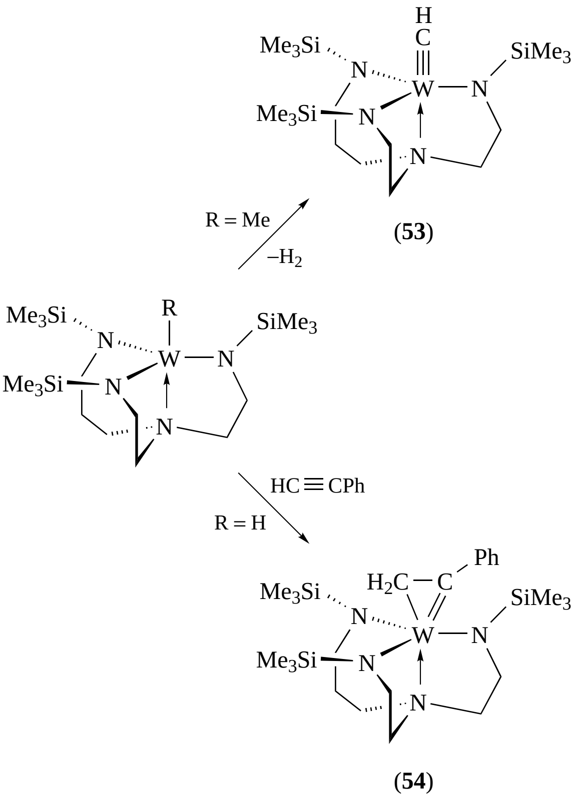
High-valent alkylidyne complexes (*see Schrock-type Carbyne Complexes*) of tungsten are most commonly prepared from alkylidene precursors by α-deprotonation or α-H elimination (*see α-Elimination*). These reactions are often facile, as illustrated by the reaction of WCl_6 with $LiCH_2Bu^t$ to give dimeric $[W(CH_2Bu^t)_3(\mu$-$CBu^t)]_2$ with bridging neopentylidyne ligands. This dimeric compound readily dissociates into monomers that react with PMe_3 to produce neopentane and $W(CH_2Bu^t)({=}CHBu^t)({\equiv}CBu^t)(PMe_3)_2$.[73] In a related manner, treatment of $W({\equiv}CBu^t)(CH_2Bu^t)_2Cl$ with $Li(THF)_3SiPh_2Bu^t$ affords an equilibrium mixture of $W({\equiv}CBu^t)(CH_2Bu^t)_2(SiPh_2Bu^t)$ (**51**) and $W({=}CHBu^t)_2(CH_2Bu^t)(SiPh_2Bu^t)$ (**52**), thereby permitting

the study of direct α-H exchange between alkylidene and alkylidyne species (equation 18).[90]



(51) (52) (18)

Spontaneous loss of H_2 from the W^{IV} methyl complex, $[N_3N]WMe$ affords $[N_3N]W{\equiv}CH$ (**53**, Scheme 2),[91] and higher alkyl complexes $[N_3N]WR$ (R = Et, Bu) undergo a similar α,α-dehydrogenation to afford $[N_3N]W{\equiv}CR$ and H_2. The related hydride complex $[N_3N]WH$ reacts with ethene or propene to yield $[N_3N]W{\equiv}CR$ (R = Me, Et),[92] or with alkynes $RC{\equiv}CPh$ (R = H, Ph) to afford diamagnetic 1-tungstenacyclopropene complexes $[N_3N]W(\eta^2\text{-PhCCHR})$ (**54**, Scheme 2) in which the phenyl ring resides on the alkylidene carbon atom.[92] Among cycloalkyl derivatives, $[N_3N]W$(cyclopropyl) evolves ethene to give $[N_3N]W{\equiv}CH$, and $[N_3N]W$(cyclobutyl) is converted to $[N_3N]W{\equiv}CPr^n$ via an intermediate 1-tungstenacyclopentene complex, $[N_3N]W(CH{=}CH_2CH_2CH_2)$. In contrast, the cyclopentyl complex $[N_3N]W(C_5H_9)$ is more stable, and in solution it exists in equilibrium with its cyclopentylidene hydride isomer, $[N_3N]W({=}C_5H_8)(H)$.[93]

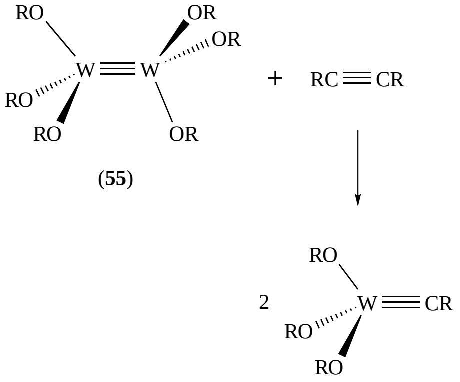


(53)

(54)

Scheme 2

Monomeric alkylidyne complexes, $(Bu^tO)_3W{\equiv}CR$ (**56**), have been prepared from $W_2(OBu^t)_6$ (**55**) and $RC{\equiv}CR$ (R = Me, Et, Pr^n) via the metathesis reaction shown in equation (19), and a related reductive cleavage of acetonitrile provides the alkylidyne complex (**56**) and a terminal nitrido complex, $(Bu^tO)_3W{\equiv}N$.[94] Generation of $W_2(OR)_4$ (R = $SiBu^t{}_3$) in the presence of ethene at low temperature results in cleavage of the ethene C=C bond to give the bridging alkylidyne complex, $W_2(OR)_4(\mu\text{-CH})(\mu\text{-CH}_2)(\mu\text{-H})$, which upon warming converts to $W_2(OR)_4(\mu\text{-CH})_2$ and H_2.[95] The specific alkylidyne complex, $(Bu^tO)_3W{\equiv}CBu^t$, is an important catalyst for the ring-closing metathesis of alkynes.[96] The structure of $W_2(\mu\text{-C}_2)(OBu^t)_6$ exhibits diyne-like connectivity (i.e. W≡C–C≡W) with a short internal C–C bond length (*see Bond Length*) of 1.38(2) Å.[97] Interestingly, $WX_2(PMe_3)_4$ (X = Cl, Br) compounds react with vinylsilanes, $H_2C{=}CHSiR_3$ (R = Me_3, OMe), to yield R_3SiX and $W({\equiv}CMe)(X)(PMe_3)_4$,[98] and these alkylidyne complexes react further with alkynes to form $W({\equiv}CMe)(X)(PMe_3)_2(\eta^2\text{-alkyne})$ derivatives.[99] The unusual silyl complex, $W(CH_2Bu^t)_2({\equiv}CBu^t)[Si(SiMe_3)_3]$, is synthesized by the reaction of $W(CH_2Bu^t)_2({\equiv}CBu^t)Cl$ with $LiSi(SiMe_3)_3(THF)_3$.[100]

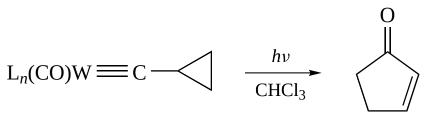


(55) (56) (19)

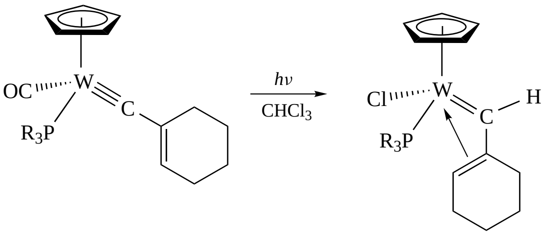
Treatment of $[Tp^*W(CO)_2({\equiv}CPPh_3)]^+$ with $Na[HBEt_3]$ in THF affords the amphoteric methylidyne complex, $Tp^*W(CO)_2({\equiv}CH)$, via the intermediate formyl and carbene complexes, $Tp^*W(CO)(C(O)H)({\equiv}CPPh_3)$ and $Tp^*W(CO)_2({=}CH(PPh_3))$, respectively. Protonation of $Tp^*W(CO)_2({\equiv}CH)$ yields the cationic α-agostic (*see Agostic Bonding*) methylidene complex $[Tp^*W(CO)_2({=}CH_2)]^+$, while deprotonation with alkyllithium reagents provides the terminal carbido complex, $Tp^*W(CO)_2({\equiv}CLi)$, which reacts with electrophiles to generate $Tp^*W(CO)_2({\equiv}CR)$ derivatives (R = Me, $SiMe_3$, I, $C(OH)Ph_2$, CH(OH)Ph, and C(O)Ph).[101] Deprotonation of $Tp^*W(CO)_2({\equiv}CMe)$ forms the nucleophilic vinylidene anion, $[Tp^*W(CO)_2({=}C{=}CH_2)]^-$, that reacts with MeI or PhC(O)R (R = H, Me) to afford $Tp^*W(CO)_2({\equiv}CCH_2Me)$

or Tp*W(CO)$_2$(≡CCH$_2$CR(OH)Ph), respectively,[102] and protonation of CpW(CO)$_2$(≡CC≡CR) with HI produces the alkylidene complexes, CpW(CO)$_2$(=CHC≡CR)(I) (R = Bu^t, *p*-Tol).[103] Similarly, protonation of the [{*p*-Bu^t-calix[4]-(O)$_4$}W(≡CR)]$^-$ anion (R = Ph, Pr^n, SiMe$_3$) leads to the corresponding neutral alkylidene complexes, {*p*-Bu^t-calix[4]-(O)$_4$}W(=CHR), which may be reversibly deprotonated back to the starting alkylidyne anions by using BuLi.[77] Zwitterionic (*see Zwitterion*) alkylidene complexes, Tp*W(CO)$_2$(=C(CH$_2$R)(PPhMe$_2$)) (R = Ph, CH=CH$_2$), readily lose PPhMe$_2$ to form neutral Tp*W(CO)$_2$(≡CCH$_2$R), and deprotonation of these complexes with a strong base occurs at C$_\beta$ to form the reactive vinylidene anions, [Tp*W(CO)$_2$(=C=CHR)]$^-$.[104]

The photooxidation of tungsten–alkylidyne complexes results in the formation of organic products derived from the carbyne substituent (e.g. equation 20). These reactions involve a 1e oxidation of the alkylidyne reactant to form a 17e radical cation species, followed by H atom abstraction from the solvent, to yield a cationic alkylidene complex that may undergo a [1,2]-H shift to afford an η^2-alkene compound. Photooxidation of the cyclohexenyl alkylidyne complex, CpW(CO)(PR$_3$)(≡CC$_6$H$_{10}$) (R = OMe) (**57**), in CHCl$_3$ affords the stable η^3-vinylcarbene complex, CpWCl(PR$_3$)(=CHC$_6$H$_{10}$) (**58**) (equation 21), thereby providing the first direct evidence for alkylidene intermediates in the single-electron oxidation reactions of alkylidyne complexes.[105,106]



(20)



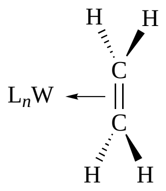
(21)

(**57**) (**58**)

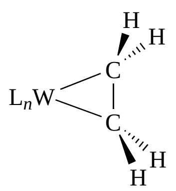
3.2 η^2-Hydrocarbon Complexes

3.2.1 Alkene Complexes

Tungsten-alkene bonding is best described by the Dewar–Chatt–Duncanson model (*see Dewar–Chatt–Duncanson Bonding Model*) in which σ-type electron donation from the alkene π orbital occurs along with π-backbonding (*see Back Bonding*) from a metal dπ orbital into the empty π^* orbital of the alkene. According to this synergistic bonding model, η^2-coordination results in a decrease in the alkene C–C bond order (*see Bond Order*). For this reason, complexes containing η^2-alkene ligands may be viewed in the limit as either planar alkene adducts (**E**) or metallacyclopropane (**F**) complexes.

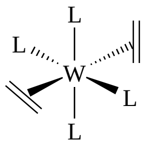


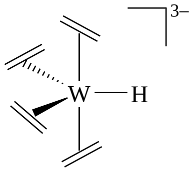
η^2-alkene
E



metallacyclopropane
F

Tungsten–alkene complexes (*see Alkene Complexes*) are typically prepared by ligand-substitution reactions under thermal or photolytic conditions. For example, photolysis of W(CO)$_6$ in the presence of an alkene provides simple W(CO)$_{6-n}$(η^2-alkene)$_n$ (n = 1, 2) complexes, and irradiation of these species gives rise to two competitive primary photoprocesses, that is, alkene and CO dissociation.[107] The labile (*see Labile*) ethene complexes, W(CO)$_5$(η^2-C$_2$H$_4$) and *cis*-W(CO)$_4$(η^2-C$_2$H$_4$)$_2$, have been characterized only at low temperatures in ethene-saturated hydrocarbon solutions. However, *trans*-W(CO)$_4$(η^2-C$_2$H$_4$)$_2$ (**59**, L = CO) is thermally stable and possesses D_{2d} symmetry, with the ethene ligands in a trans, orthogonal conformation that maximizes the efficiency of tungsten to alkene (π^*) back donation.[108] Photolysis of (**59**) (L = CO) in the presence of H$_2$ at −90 °C results in the formation of the dihydrogen complexes, *mer*-W(CO)$_3$(η^2-H$_2$)(η^2-C$_2$H$_4$)$_2$ and *cis*-W(CO)$_4$(η^2-H$_2$)(η^2-C$_2$H$_4$).[109]





(**59**) (**60**)

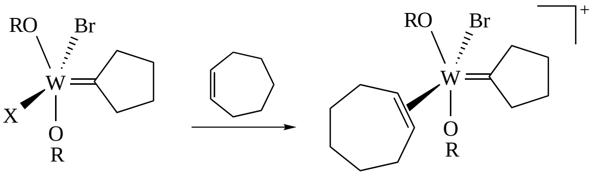
The alkene derivatives, *cis*-W(CO)$_4$(PR$_3$)(η^2-alkene) (R = alkyl or aryl), are typically prepared by ligand substitution (*see Ligand Substitution*) from W(CO)$_4$(L)(PR$_3$) (L = Lewis base), whereas the related compounds, W(CO)$_3$(PR$_3$)$_2$(η^2-alkene), are readily accessed via photolysis of W(CO)$_4$(PR$_3$)$_2$ in the presence of an alkene. The bis(ethene) complex, *trans*-W(PMe$_3$)$_4$(η^2-C$_2$H$_4$)$_2$ (**59**, L = PMe$_3$), reversibly eliminates PMe$_3$ in solution,[110] and the coordinatively unsaturated W(PMe$_3$)$_3$(η^2-C$_2$H$_4$)$_2$ fragment reacts with Lewis bases, L, to yield complexes of the type *mer,trans*-W(L)(PMe$_3$)$_3$(η^2-C$_2$H$_4$)$_2$ or *trans*-W(L)$_2$(PMe$_3$)$_2$(η^2-C$_2$H$_4$)$_2$ (L = CNR, CO). More interesting are the reactions of (**59**) (L = PMe$_3$) and related complexes containing bidentate (*see Bidentate*

Ligand) phosphine ligands with CS_2 or CO_2, which lead to coupled products containing η^3-C_2S_4 or acrylate ligands, respectively.[111,112] The reactions of $WCl_2(PR_3)_4$ with alkenes provide the bis(alkene) complexes, *cis,trans*-$WCl_2(PR_3)_2(\eta^2$-alkene$)_2$, in which the *cis*-alkene ligands are oriented parallel to one another. The oxo, sulfido, and imido complexes, $WCl_2(E)(PR_3)_2(\eta^2$-alkene) (E = O, S, NPh) possess alkene ligands that are cis to the π-ligand E and are oriented perpendicular to the W=E linkage.

Alkene complexes (*see Alkene Complexes*) can also be formed from tungsten–alkyl complexes via β-H migration. Thus, photolysis of $CpW(CO)_3(Et)$ results in the elimination of CO and the transient formation of $CpW(CO)_2(H)(\eta^2$-$C_2H_4)$, and time-resolved infrared spectroscopic (*see Infrared Reflection Adsorption Spectroscopy*) studies indicate that this species undergoes cis to trans isomerization prior to the elimination of ethene and uptake of CO to yield $CpW(CO)_3(H)$.[113] Although a vacant coordination site is usually required for such transformations to occur, examples of ligand-induced β-H transfer have been reported for a series of W^{VI} dialkyl complexes.[114] Finally, the reaction of $W(OMe)_3Cl_3$ with excess EtLi followed by the addition of tmeda yields $[Li(tmeda)]_3[WH(\eta^2$-$C_2H_4)_4]$ (i.e. $[Li(tmeda)]_3[(\mathbf{60})]$), presumably via thermal decomposition of an undetected ethyl complex. The anion $[(\mathbf{60})]^{3-}$ is trigonal–bipyramidal in the solid state, with two mutually perpendicular ethene ligands in the axial sites and two coplanar ethene ligands and a hydride ligand constituting the equatorial plane.[115]

Protonation of *trans*-$W(dppe)_2(\eta^2$-$C_2H_4)_2$ with HX (X = Cl, Br) results in the formation of the cationic hydrido complexes, $[trans$-$WH(dppe)_2(\eta^2$-$C_2H_4)_2]X$, and stopped-flow kinetic studies have shown that these reactions proceed via two parallel pathways involving either slow protonation at tungsten or rapid protonation of the ethene ligand followed by slow β-H elimination (*see β-Elimination*) from an intermediate ethyl complex.[116] The interesting reaction of $Cp_2W(\eta^2$-$C_2H_4)$ with perfluoro-*tert*-butyl iodide results in fluoroalkylation of the ethene ligand and formation of $Cp_2W[CH_2CH_2C(CF_3)_3]I$.[117]

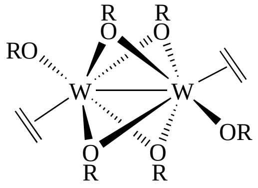
Metallacyclopentane complexes are obtained similarly by reductive coupling (*see Reductive Coupling*) of alkene ligands,[77,79] by reduction of the ester functionalities in $CpW(\eta^2$-$C_2H_2R_2)$ (R = CO_2Me),[118] or via intramolecular (*see Intramolecular*) hydrogen transfer in an alkyl–vinyl complex.[119] Formal addition of an alkene across a W=C bond gives rise to metallacyclobutane complexes that are intermediates in catalytic alkene metathesis (*see Alkene Metathesis*) reactions.[85,120,121] Cycloalkene adducts are believed to be intermediates in ROMP reactions (*see Ring Opening Metathesis Polymerization Reactions*), and the solid-state molecular structure of the cycloheptene adduct (**61**) (X = $GaBr_4$) provides convincing evidence for the existence of intermediate alkene complexes in ROMP catalysis (equation 22).[122]



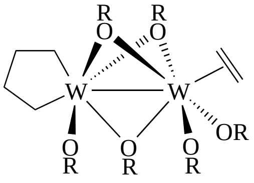
(22)

(**61**)

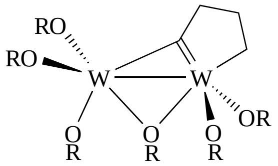
The ditungsten–hexakis(alkoxide) complexes, $W_2(OR)_6$, react with ethene to give initially the bis(ethene) adduct (**62**) when R = CH_2Bu^t or the metallacylopentane complex (**63**) when R = Pr^i. These isolable intermediates are eventually converted to the 1-metallacyclopentene complex (**64**), which is formed by α-H transfer from the metallacyclopentane ring of (**63**) to the coordinated ethene ligand.[94] A variety of alkene rearrangements also occur in tungsten complexes containing calixarene (*see Calixarenes*) ligands, including deprotonation of an η^2-alkene ligand to give 1-metallacyclopropene or alkylidyne derivatives, and reductive coupling (*see Reductive Coupling*) to form metallacyclopentanes.[77]



(**62**)

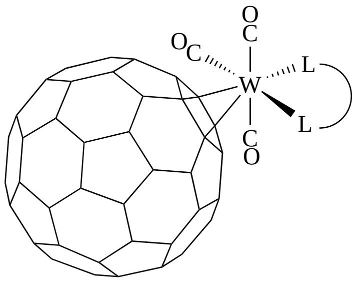


(**63**)

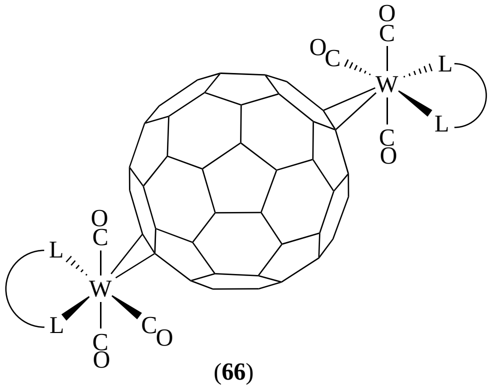


(**64**)

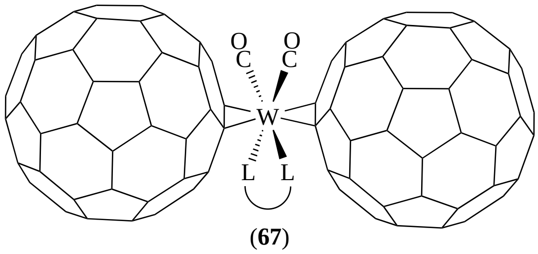
Other types of tungsten–alkene complexes that merit mention include the first group six η^2-benzene complex, $TpW(NO)(PMe_3)(\eta^2$-$C_6H_6)$, that contains a π-bound benzene ligand activated toward Diels–Alder cycloaddition.[123] Also, the η^2-fullerene complexes, *mer*-$W(CO)_3(L$-$L)(\eta^2$-$C_{60})$ (**65**), have been prepared from $W(CO)_4(L$-$L)$ (L-L = a bidentate N- or P-donor ligand) in the presence of C_{60}.[124,125] In some cases, a bimetallic complex in which two metal centers are attached to a single fullerene (*see Buckminsterfullerene*) moiety, that is, $[mer$-$W(CO)_3(L$-$L)]_2(\eta^2,\eta^2$-$C_{60})$, (**66**) is also formed, and analogous complexes containing C_{70} have also been prepared.[125] The dumbbell-shaped complex, $W(\eta^2$-$C_{60})_2(CO)_2(L$-$L)$ (**67**, L-L = 4,4′-di(butylcarboxyl)-2,2′-bipyridine), contains two C_{60} ligands, each of which is coordinated to the metal center in an η^2-fashion.[126]



(**65**)



(**66**)

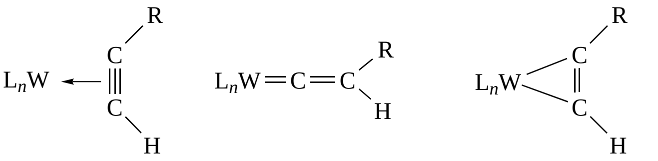


(**67**)

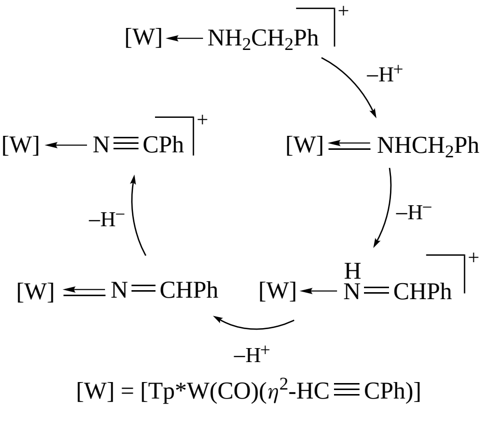
3.2.2 Alkyne Complexes

Alkynes may function as 2e alkene analogues or as formal 4e donor ligands. This situation arises because an alkyne can engage a metal center using not only the π and π^* orbitals involved in σ-donor and π-acceptor bonding, but also by employing a second π orbital oriented perpendicular to the tungsten-alkyne bond axis; these are known as $\pi_{\parallel}$ and $\pi_{\perp}$ interactions, respectively. In low-valent, d^6 (*see d^n Configuration*) tungsten complexes, alkyne ligands generally act as 2e donors since repulsive interactions between the alkyne $\pi_{\perp}$ orbital and filled metal dπ orbitals dictate the geometry and reactivity of the complexes. In d^4 and d^2 tungsten complexes, the $\pi_{\perp}$ orbital may interact with an empty metal d orbital to form an additional π-donor bond, and the alkyne then acts as a formal 4e donor ligand.[127] In complexes containing more than one alkyne ligand, the $\pi_{\perp}$ orbitals may donate electron density into the same metal dπ orbital, thus giving rise to formal electron donor counts between two and four. The unique ability of an ancillary alkyne ligand to function as a variable (i.e. three or four) electron donor in the presence of competing π-ligands can lead to very interesting reaction chemistry, for example, in the stepwise oxidation of a benzylamine ligand to a benzonitrile ligand via isolable amido, imine, and azavinylidene intermediate complexes on the $[Tp^*W(CO)(\eta^2\text{-HC}{\equiv}\text{CPh})]^+$ fragment (Scheme 3).[128] Regio- and stereoselective reactions of η^2-alkyne ligands, followed by their removal from the metal fragment, have provided synthetic routes to chiral alkynes that are difficult to prepare by conventional means.[129] The subsequent material in this section is divided into W^0, W^{II}, and $W^{IV/VI}$ subsections.

Zero-valent tungsten complexes containing one, two, or three alkyne ligands are known. Photochemical and thermal reactions of $W(CO)_6$ with alkynes lead to thermally unstable $W(CO)_{6-n}(\eta^2\text{-alkyne})_n$ ($n = 1, 2$) species, and those containing terminal alkyne ligands (**G**) often undergo a formal [1,2]-*H* shift to afford vinylidene complexes $W(CO)_5(=C=CHR)$ (**H**).[130] This mode of reactivity also occurs during the isomerization of *fac*-$[W(CO)_3(dppe)(\eta^2\text{-HC}{\equiv}\text{CR})]$ (R = H, Ph, *n*-Bu) to *mer*-$[W(=C=CHR)(CO)_3(dppe)]$, and it is attributed to unfavorable repulsion between the alkyne $\pi_{\perp}$ orbital and a filled metal dπ orbital.[131] Theoretical studies of the mechanism of acetylene–vinylidene rearrangement have shown that model tungsten complexes containing these ligands are best formulated as metallacyclopropene (**I**) and metallaallene species, respectively,[132] and it should be noted that vinylidene complexes may also be prepared by the addition of electrophiles to tungsten–alkynyl complexes or by deprotonation of alkylidyne complexes.[133] Vinylidene ligands are among the



η^2-alkyne **G** | vinylidene **H** | metallacyclopropene **I**

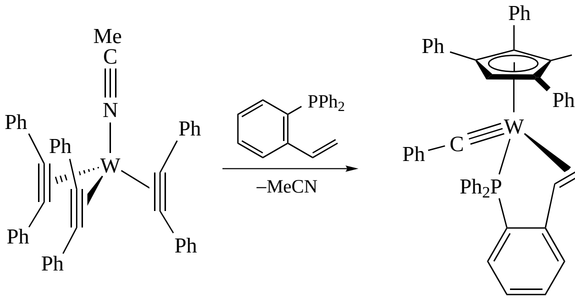


Scheme 3

strongest π-acceptor ligands known, and they have found use as catalysts in [2 + 2] cycloaddition and alkyne dimerization reactions.[134]

Bis(alkyne) complexes of W^0 generally have the compositions $W(CO)_2(L\text{-}L)(\eta^2\text{-}RC{\equiv}CR)_2$ (L-L = a bidentate N- or P-donor ligand) and invariably contain cis CO ligands and mutually trans, orthogonal alkyne ligands.[135] The crucial presence of electron-withdrawing alkyne substituents (i.e. R = CO_2Me, CO_2Et) is thought to enhance tungsten dπ to alkyne $\pi_{||}{}^*$ backbonding (*see Back Bonding*) and delocalize alkyne $\pi_\perp$ electron density. Consequently, the alkyne ligands in these complexes function as formal 2e donors.

Thermally stable $W(CO)(\eta^2\text{-alkyne})_3$ complexes, in which the three alkyne ligands contribute a total of 10 electrons to the metal center, may be prepared from suitable tricarbonyl precursors,[136] and the apical CO ligand can be replaced with other neutral Lewis bases (*see Lewis Acids & Bases*).[137] $W(PMe_3)(\eta^2\text{-}HC{\equiv}CPh)_3$ may be prepared via this method or by the reduction of $WCl_4(PMe_3)_2$ in the presence of HC≡CPh.[138] Alkyne–alkyne coupling occurs when $W(L)(\eta^2\text{-}PhC{\equiv}CPh)_3$ (L = CO, MeCN) is treated with excess PhC≡CPh, resulting in the formation of $(\eta^4\text{-}C_4Ph_4)W(L)(\eta^2\text{-}PhC{\equiv}CPh)_2$ and related carbocyclic derivatives.[137] The labile (*see Labile*) acetonitrile complex, $W(MeCN)(\eta^2\text{-}PhC{\equiv}CPh)_3$ (**68**), undergoes rearrangement upon reaction with *o*-$Ph_2PC_6H_4CH{=}CH_2$ via cleavage of both C=C and C≡C bonds to yield $(\eta^5\text{-}C_5Ph_4H)W({\equiv}CPh)(Ph_2PC_6H_4CH{=}CHPh)$ (**69**) (equation 23).[139]



(**68**) (**69**)

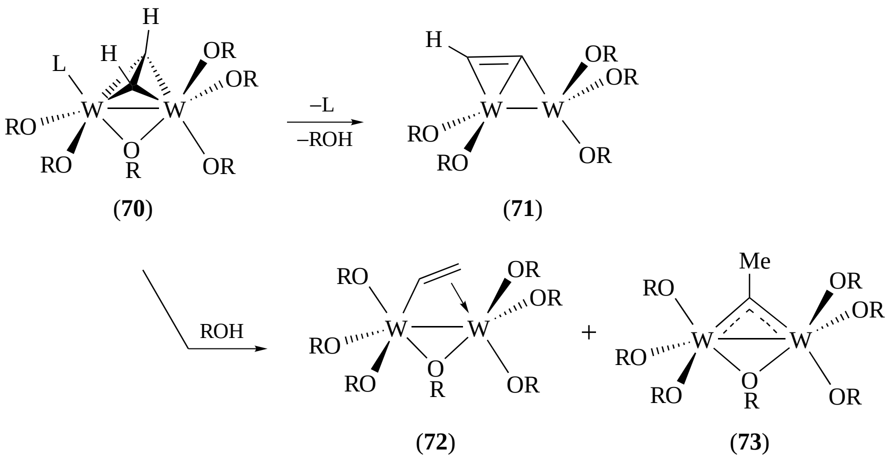
(23)

Numerous W^{II} complexes of the type $W(CO)_{3-n}(L)_n(X)_2(\eta^2\text{-alkyne})$ (n = 1, 2) are known, most of which have been prepared from reactions of appropriate W^{II} or W^{III} precursors with an alkyne.[127] Thus, reduction of $WCl_3(PMe_3)_2(\eta^2\text{-alkyne})$ in the presence of a Lewis base (*see Lewis Acids & Bases*) generates $WCl_2(PMe_3)_2(L)(\eta^2\text{-alkyne})$. Alkyne ligands may also be prepared via intramolecular (*see Intramolecular*) coupling of alkylidyne, isocyanide, and carbonyl ligands, or by treating the alkynyl anions, $[CpW(NO)(CO)(C{\equiv}CR)]^-$, with an electrophile (*see Electrophile*).[140] Simple alkyne complexes such as $CpW(CO)(X)(\eta^2\text{-alkyne})$ or $W(S_2CNR_2)_2(L)(\eta^2\text{-alkyne})$ react with excess alkyne under forcing conditions to yield bis(alkyne) derivatives, $CpW(X)(\eta^2\text{-alkyne})_2$ and $W(S_2CNR_2)_2(\eta^2\text{-alkyne})_2$, in which the alkyne ligands are oriented parallel to one another in order to facilitate π donation from both alkynes into the same dπ orbital (i.e. each alkyne ligand acts as a formal 3e donor). Related W^{II} bis(alkyne) complexes, $W(CO)(X)_2(L)(\eta^2\text{-}RC{\equiv}CR)_2$, are prepared by the reactions of $W(CO)_3(X)_2(L)_2$ with alkynes, and ligand substitution generates cationic $[W(CO)(X)(L\text{-}L)(\eta^2\text{-}RC{\equiv}CR)_2]^+$ derivatives. Alternatively, reduction of Cp^*WX_4 in the presence of two equivalents of an alkyne affords $Cp^*WX(\eta^2\text{-alkyne})_2$.[141]

Alkyne ligands are susceptible to attack by nucleophiles, which typically leads to the formation of η^2-vinyl complexes;[47] this is particularly true in the case of electron-deficient alkynes. Noteworthy in this regard are the reactions of $[Tp^*W(CO)_2(\eta^2\text{-}RC{\equiv}CR')]^+$ cations with hydride reagents that yield η^2-vinyl, η^2-allene, or η^3-allyl complexes depending upon the nature of the alkyne substituents.[49]

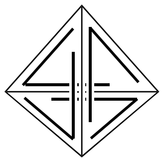
Interestingly, the properties of some high oxidation state tungsten–alkyne complexes indicate that there has been considerable transfer of electron density to the alkyne ligands. For instance, the $W(4f_{7/2})$ binding energy (determined by X-ray photoelectron spectroscopy) of $[WCl_4(\eta^2\text{-}PhC{\equiv}CPh)]_2$ is similar to that measured for the d^0 (*see d^n Configuration*) imido complex, $[WCl_4(NPh)]_2$, and is in agreement with a W^{VI} oxidation state.[142] Similarly, computational investigations support the experimental evidence that $WCl_3(\eta^2\text{-}PhC{\equiv}CPh)(PMe_3)_2$ and $WCl_2(\eta^2\text{-}PhC{\equiv}CPh)(PMe_3)_3$ are appropriately formulated as complexes of W^V and W^{IV}, respectively. Given these observations, the description of the related $[WCl_2(\eta^2\text{-}HC{\equiv}CH)(MeCN)_3]^+$ as a monomeric W^{III} complex is by no means certain.[143] Consistent with their anionic character, the alkyne ligands in $[WCl_4(\eta^2\text{-}PhC{\equiv}CPh)]_2$ undergo ready hydrolysis to form free *cis*-stilbene. A great many W^{IV} alkyne complexes containing alkylidene, imido, oxo, and sulfido ligands are also known, and the alkyne ligands in these complexes, like the alkene ligands in related complexes described in a previous section (vide supra), are generally coordinated cis to the π-donor ligand and perpendicular to its multiple bond with tungsten.

The ditungsten–hexakis(alkoxide) complexes, $W_2(OR)_6$, exhibit a wide range of reactivity toward alkynes. Thus, when R = Bu^t, reaction with PhC≡CPh yields a mixture of $W_2(OR)_4(\mu\text{-}PhC{\equiv}CPh)_2$ and $W_2(OR)_4(\mu\text{-}CPh)_2$, but the analogous reaction with ethyne produces $W_2(OR)_6(\mu\text{-}HC{\equiv}CH)(L)$ (**70**) in the presence of L = pyridine. When R = $OSiMe_2Bu^t$, the elimination of ROH from complex (**70**) affords the μ-η:η^2-ethynyl complex, $W_2(OR)_5(\mu\text{-}C_2H)$ (**71**), and the liberated alcohol converts any remaining (**70**) to a mixture of the vinyl and ethylidyne isomers, $W_2(OR_7)(\mu\text{-}CHCH_2)$ (**72**) and $W_2(OR)_7(\mu\text{-}CMe)$ (**73**), which are related by a [1,2]-*H* shift but do not interconvert in solution



Scheme 4

(Scheme 4).[94] In contrast, the addition of ethyne to $W_2(OR)_8$ ($R = CH_2Bu^t$) yields an unusual 1:1 adduct in which the bridging μ,η^2-HC≡CH ligand is neither parallel nor perpendicular to the W–W bond.[144]

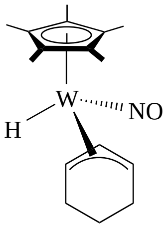


(**74**)

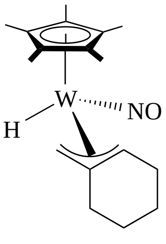
3.3 η^3-Hydrocarbon Complexes

Tungsten–allyl complexes may be prepared by metathesis from suitable halide precursors using allyl Grignard reagents (*see Grignard Reagents*) or from the reactions of $[CpW(NO)(CO)(C{\equiv}CR)]^-$ (R = Ph, Bu^t, $SiMe_3$) with allylic halides.[56] The homoleptic (*see Homoleptic Compound*) allyl complex, $W(\eta^3\text{-}C_3H_5)_4$, has been known for many years, but questions as to its exact structure have remained unanswered until recently. A thorough analysis by Casey and coworkers has shown that the molecular structure that best agrees with the NMR spectroscopic data is one in which the complex has S_4 symmetry (**74**).[145] The tris(allyl) dimer, $[(\eta^3\text{-}C_3H_5)_3WCl]_2$, reacts with methyl-substituted allylmagnesium halides to form $(\eta^3\text{-}C_3H_5)_3$ $W(\eta^3\text{-}MeC_3H_4)$ and $(\eta^3\text{-}C_3H_5)_3$ $W(\eta^3\text{-}1,3\text{-}Me_2C_3H_3)$ as a mixture of isomers and with alkylmagnesium halides to give β-agostic (*see Agostic Bonding*) alkyl complexes, $(\eta^3\text{-}C_3H_5)_3W(R)$. The reaction of $(\eta^3\text{-}C_3H_5)_3$ W(Et) with PMe_3 initiates an intramolecular (*see Intramolecular*) protonation of an allyl group to give $(\eta^3\text{-}C_3H_5)_2$ $W(\eta^2\text{-}CH_2{=}CH_2)(PMe_3)_2$ and propene, and the ethyl complex also readily inserts $CNBu^t$ into its W–C link to form $(\eta^3\text{-}C_3H_5)_3$ $W(\eta^2\text{-}EtC{=}NBu^t)$.[146] Finally, the reaction of $WCl_2(PMe_3)_4$ with $Me_3SiOCH_2CH{=}CH_2$ affords Me_3SiCl and the oxo allyl complex, $WCl(O)(\eta^3\text{-}C_3H_5)(PMe_3)_2$.[147]

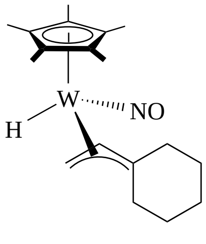
Thermal α-elimination (*see α-Elimination*) of neopentane from the dimethylallyl complex, $Cp^*W(NO)(CH_2Bu^t)(\eta^3\text{-}Me_2C_3H_3)$, generates a reactive 16e η^2-allene intermediate that activates hydrocarbon solvent C–H bonds to yield $Cp^*W(NO)(R)(\eta^3\text{-}Me_2C_3H_3)$ (R = Ph, CH_2SiMe_3).[75] In cyclohexane, three C–H bonds of the solvent are activated to give the η^3-cyclohexenyl complex, $Cp^*W(NO)(\eta^3\text{-}C_6H_9)(H)$ (**75**),[148] and related η^3-allyl hydrido complexes, $Cp^*W(NO)(\eta^3\text{-}C_7H_{11})(H)$ (**76**) and $Cp^*W(NO)(\eta^3\text{-}C_8H_{13})(H)$ (**77**), are formed from $Cp^*W(NO)(CH_2Bu^t)_2$ upon thermolysis in methylcyclohexane or ethylcyclohexane, respectively.[75] Irradiation of $Tp^*W(CO)_3(H)$ in the presence of unconjugated dienes or alkynes generates η^3-allyl complexes, that is, $Tp^*W(CO)_2(\eta^3\text{-}CHRCHCHR')$, via insertion into the W–H bond.[149] The reactions of *cis*-$Cp^*W(CO)_2(Me)(MeCN)$ with $HSiMe_2(CH{=}CR_2)$ (R = H, Me) afford novel η^3-1-silaallyl complexes, $Cp^*W(CO)_2(\eta^3\text{-}Me_2SiCHCR_2)$, via thermal Si–H bond activation.[150] Reaction of $[Tp^*W({=}CH_2)(CO)(L)]^+$ with excess base yields the unusual allyl-bridged dimer, $[Tp^*W(CO)(L)]_2(\mu\text{-}C_3H_5)^+$ (**78**, L = η^2-PhC≡CMe), which is inert toward a variety of nucleophiles.[151]



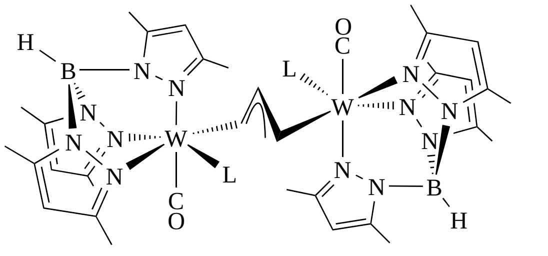
(**75**)



(**76**)

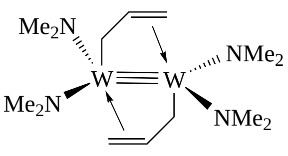


(**77**)

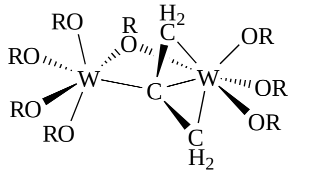


(**78**)

The ditungsten complex, $W_2(C_3H_5)_2(NMe_2)_4$ (**79**), has C_2 symmetry in the solid state with bridging allyl ligands that exhibit an unusual μ-η^1:η^2-2-propenyl coordination mode,[152] and the reaction of $W_2(OR)_8$ with allene generates the $W_2(OR)_8(\mu$-η^1,η^3-$C_3H_4)$ adduct (**80**, R = CH_2Bu^t).[153]

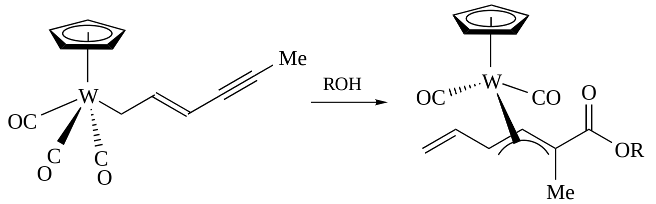


(**79**)



(**80**)

Substituted allyl complexes of the type $Cp'W(CO)_2(\eta^3$-allyl) are useful synthetic reagents, and their organic chemistry has been reviewed.[62] The reaction of $CpW(CO)_3(\eta^1$-*trans*-$CH_2CH{=}CHC{\equiv}CMe)$ (**81**) with ROH (R = H, Me) over SiO_2 affords $CpW(CO)_2(\eta^3$-3-*syn*-CO_2R-3-*anti*-Me-1-vinylallyl) compounds (**82**), thereby providing the only direct evidence available for tandem 1,3-metal shifts across conjugated allyl and alkyne bonds (equation 24).[154]

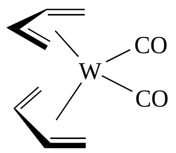


(**81**) (**82**)

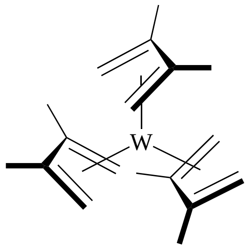
(24)

3.4 η^4-Hydrocarbon Complexes

The complexes $W(\eta^4\text{-diene})_n(CO)_{6-2n}$ ($n = 2$, diene = 1,3-butadiene, (**83**); $n = 3$, diene = 2,3-dimethylbutadiene, **84**) have been prepared, and their solid-state molecular structures have been determined. Interestingly, the two diene ligands in (**83**) are twisted relative to one another, imparting C_2 symmetry to the complex.[155] Homoleptic (**84**) has been the subject of a detailed theoretical investigation[156] in an attempt to explain its rare trigonal–prismatic coordination geometry.[157] The related carbonyl species, $W(CO)_4(\eta^4$-1,3-butadiene), can be generated transiently in solution, but it has not yet been isolated.[158]

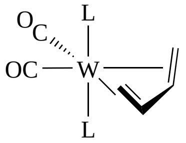


(**83**)

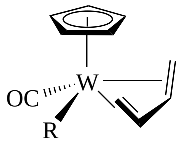


(**84**)

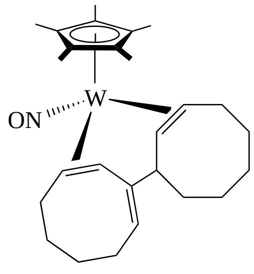
Many diene complexes (*see Diene Complexes*) having the general composition $W(\eta^4\text{-diene})(CO)_{4-n}(L)_n$ (e.g. $n = 2$, **85**) are known, as are $CpW(\eta^4$-diene)(CO)(R) species (**86**, L = Lewis base, R = alkyl, acyl). Hydrogenation of $Cp^*W(NO)(CH_2SiMe_3)_2$ in the presence of acyclic, conjugated dienes leads to the formation of a variety of $Cp^*W(NO)(\eta^4$-*trans*-diene) complexes, and when 1,3-cyclooctadiene is employed as the diene substrate, it undergoes an unprecedented coupling to afford the triene complex (**87**).



(**85**)

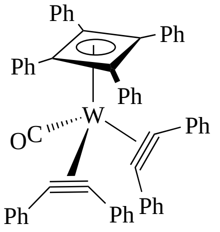


(**86**)



(**87**)

Several η^4-norbornadiene (nbd) complexes containing the $W(CO)_x$ fragment are also known, among them $W(CO)_4(\eta^4$-nbd) and complexes of the type $W(CO)_2(X)_2(\eta^4$-nbd).[159] Finally, several tungsten–cyclobutadiene complexes have been described, and they are generally formed by the coupling of two alkyne ligands, as in the case of $(\eta^4\text{-}C_4Ph_4)W(\eta^2\text{-}PhC{\equiv}CPh)_2(CO)$ (**88**).[160]

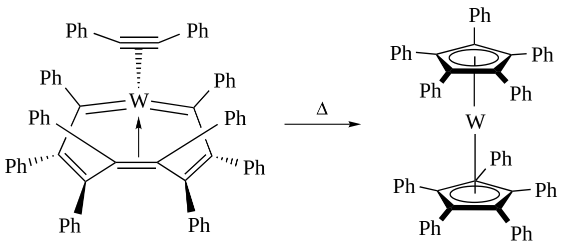


(**88**)

3.5 η^5-Hydrocarbon Complexes

3.5.1 Tungstenocene-derived Complexes

Tungstenocene (Cp_2W) is very reactive once generated by photolysis of Cp_2WH_2 or by thermolysis of $Cp_2W(Me)H$,[161] and it inserts readily into C–H, O–H or B–B[162] bonds. The dihydride, Cp_2WH_2, is a strong Lewis base (*see Lewis Acids & Bases*), and it reacts with Lewis acids including $AgBF_4$ to form adducts, for example $[(Cp_2WH_2)_2Ag]BF_4$, bridged by the hydrido ligands.[163] Chlorination of Cp_2WH_2 with $CHCl_3$ (or the reaction of $WCl_4(DME)$ with LiCp) affords Cp_2WCl_2, which can be oxidized to $[Cp_2WCl_2]^{2+}$.[164] The dichloro complex serves as an excellent entry point into related tungstenocene chemistry;[165] for example, alkyl derivatives are prepared by halide metathesis, and the electronic structures of Cp_2WR_2 species have recently been described in detail.[166] The related oxo complex, $Cp_2W(O)$, has been the subject of a detailed thermochemical and theoretical investigation in order to understand its [2 + 2] cycloaddition reactions.[167] The intramolecular (*see Intramolecular*) thermal rearrangement of $W(\eta^2\text{-PhC}{\equiv}\text{CPh})(\eta^8\text{-}C_8Ph_8)$ (**89**) results in the formation of the isolable perphenylated tungstenocene, $(\eta^5\text{-}C_5Ph_5)_2W$ (**90**) (equation 25),[137] and the tungstenocenium cations, $[(\eta^5\text{-}C_5Ph_5)_2W]^+$ and $[(\eta^5\text{-}C_5Ph_5)_2W]^{2+}$, may be generated by oxidation of the neutral compound.[168]

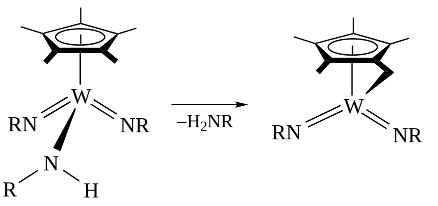


(**89**) (**90**) (25)

The *ansa*-tungstenocene complex, $[Me_2Si(\eta^5\text{-}C_5Me_4)_2]W(Me)H$, also eliminates methane upon thermolysis in benzene and forms the phenyl complex $[Me_2Si(\eta^5\text{-}C_5Me_4)_2]W(Ph)H$. Careful experimental work by Parkin and coworkers has established the existence of an inverse equilibrium isotope effect (*see Isotope Effect*) during this reaction.[169] This work follows a related study by Norton and coworkers on $Cp_2W(Me)H$ that revealed similar results.[170] This C–H activation chemistry has also attracted the interest of theoretical chemists.[166] The intramolecular (*see Intramolecular*) H/D exchange observed in $[Me_2C(\eta^5\text{-}C_5H_4)_2]W(R)H$ complexes containing adjacent alkyl and hydrido ligands has provided compelling evidence for the existence of intermediate σ-alkane complexes of tungsten.[171]

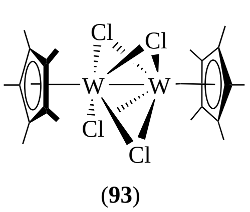
3.5.2 Non-tungstenocene-derived Complexes

As amply illustrated throughout this article, the pentamethylcyclopentadienyl ligand (Cp*) effectively stabilizes many types of organometallic complexes of tungsten. However, on occasion, it can undergo intramolecular (*see Intramolecular*) C–H activation to afford so-called 'tuck-in' complexes. For instance, upon reaction of $Cp^*W(NR)_2Cl$ with LiNHR, the initially formed amido complex, $Cp^*W(NR)_2(NHR)$ (**91**), eliminates amine to afford the $\eta^1,\eta^5\text{-}CH_2C_5Me_4$ complex (**92**) (equation 26, R = 2,6-$Pr^i{}_2C_6H_3$).[172]

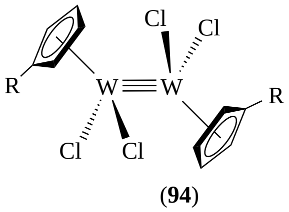


(**91**) (**92**) (26)

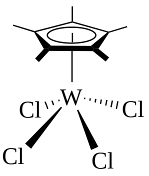
The cyclopentadienyl tungsten–chloro complexes, $[Cp^*W]_2(\mu\text{-Cl})_4$ (**93**) and $Cp'Cl_2W{\equiv}WCl_2Cp'$ (**94**, Cp′ = $\eta^5\text{-}C_5H_4R$),[173] are important precursors for the synthesis of other organometallic compounds.[174] High-yield syntheses of $Cp'WCl_4$ and related imido complexes, including $Cp'WCl_3(NBu^t)$ and 17e $Cp'WCl_2(NBu^t)$, have also been reported (Cp′ = Cp, Cp*).[161,175] The tetrachloro complex, Cp^*WCl_4 (**95**), has been used to prepare the organometallic fluoride complex, Cp^*WF_5 (**96**),[176] and the square–pyramidal tetramethyl complex, Cp^*WMe_4 (**97**),[177] that rearranges upon oxidation to give the trigonal–bipyramidal cation, $[Cp^*WMe_4]^+$.[178] Terminal chalcogenide derivatives $[Cp^*WE_3]^-$ (E = O, S, Se) are known, and chiral $[Cp^*W(O)(S)(Se)]^-$ can be prepared by treating $Cp^*W(S)_2Cl$ sequentially with H_2O and diselenide reagents.[179] Finally, related oxo and sulfido derivatives including $Cp^*W(O)_2Cl$ and $[Cp^*WS_3]^-$ have been used as reagents for the synthesis of cluster complexes[180–182] (*see* ***Cluster Compounds: Inorganometallic Compounds Containing Transition Metal & Main Group Elements***).



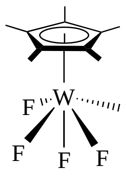
(**93**)



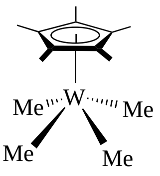
(**94**)



(**95**)

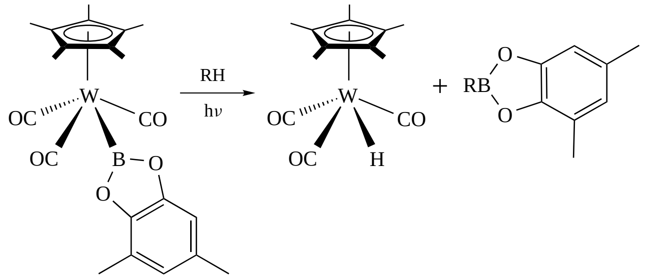


(**96**)



(**97**)

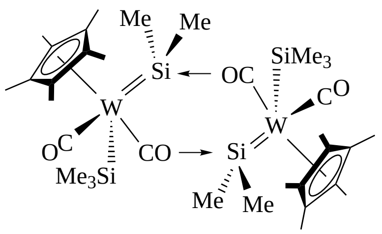
Important advances in the field of C–H bond activation have involved the photochemical reactions of boryl complexes such as Cp*W(CO)$_3$(Bcat) (**98**, cat = 1,2-O_2-3,5-$Me_2C_6H_2$). Transient species derived from these complexes efficiently activate the C–H bonds of alkanes and arenes (*see **Alkane Carbon–Hydrogen Bond Activation***), and they can convert hydrocarbon solvents into alkylboronate esters (equation 27).[183,184] Experimental and theoretical studies have shown that these reactions proceed via a boron-assisted, σ-bond metathesis (*see σ-Bond Metathesis*) pathway involving back donation of electron density from the tungsten atom to a formally unoccupied p orbital centered on the boryl ligand.[185]

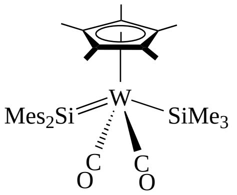


(**98**)

(27)

Photolysis of Cp*W(CO)$_3$Me in the presence of excess $HSiMe_2SiMeR_2$ affords dimeric [Cp*W(CO)$_2$(=SiR$_2$)(SiMe$_3$)]$_2$ (**99**) when R = Me. However, the novel silylene complex, Cp*W(CO)$_2$(=SiR$_2$)(SiMe$_3$) (**100**), is obtained when R = Mes.[186] Kinetic analyses (*see Kinetic Methods*) of hydride abstraction from Cp′W(CO)$_3$H using $[Ph_3C]BF_4$ have revealed that when Cp′ = Cp*, a normal kinetic isotope effect (*see Isotope Effect*) is observed, but when Cp′ = η^5-$C_5H_4CO_2Me$, an inverse isotope effect results.[187]





(**99**) (**100**)

3.6 η^6-Hydrocarbon Complexes

Surprisingly, little new research on the prototypal tungsten–arene complex (*see Arene Complexes*), (η^6-C_6H_6)$_2$W, has appeared, possibly because of the low-yielding and elaborate experimental procedures required for its synthesis.[188,189] Photolysis of W(CO)$_6$ in the presence of ethyne leads to the formation of benzene and (η^6-C_6H_6)W(CO)$_3$ (**101**),[130] and the solid-state molecular structure of this complex was only recently reported.[190] Related (η^6-arene)W(CO)$_3$ complexes catalyze the cyclotrimerization and polymerization of alkynes.[191] Intramolecular (*see Intramolecular*) capture of aryl-containing ligands by an unsaturated metal center also leads to the formation of η^6-arene complexes; for instance, hydrogenolysis of [(Me$_3$SiN)$_2$C$_6$H$_4$](NPh)WR$_2$ (R = CH_2CH_2Ph, $CH_2CH_2CH_2Ph$) in toluene affords [(Me$_3$SiN)$_2$C$_6$H$_4$](NPh)W(η^6-C_6H_5R) (R = Et, Pr^n), and the arene ligands adopt an unusual η^4-coordination mode in the solid state.[192] Furthermore, Na reduction of W(OAr)$_2$Cl$_4$ (Ar = 2,3,5,6-C_6HPh_4) in the presence of a Lewis base generates W(OC$_6$HPh$_3$-η^6-C$_6$H$_5$)(OAr)(L) (**102**, L = NC$_5$H$_4$Bu^t),[193] and a closely related complex (L = PMe$_2$Ph) effects an unprecedented 4e reduction of azobenzene at a single metal center.[194]

Glossary

Acetogen: a strictly anaerobic bacterium that produces acetate as the sole fermentation product
Methanogen: a strictly anaerobic bacterium that produces methane
Hyperthermophile: a microorganism that grows at or above 90 °C

Abbreviations

FDH = Formate dehydrogenase; CAR = Carboxylic acid reductase; FMDH = Formylmethanofuran dehydrogenase; MFR = Methanofuran; AOR = Aldehyde ferredoxin oxidoreductase; MPT = Molybdopterin; Fd_{ox} = Oxidized ferredoxin; Fd_{red} = Reduced ferredoxin; FOR = Formaldehyde ferredoxin oxidoreductase; EXAFS = X-ray absorption edge fine structure; kDa = Kilodaltons; EPR = Electron paramagnetic resonance.

1 INTRODUCTION

The element Tungsten (W, atomic number 74) has long been prized for its high melting point, good conductivity, and strength. It is used in the manufacture of a wide variety of industrial and household products including light bulb filaments. W is relatively scarce in natural environments, the usual source for this metal being oxo-rich mineral ores such as wolframite ($[Fe/Mn]WO_4$, scheelite ($CaWO_4$) or the more reduced form tungstenite (WS_2)). The concentration of W in soil and freshwater is very low (less than 0.5 nM). In contrast, significantly higher amounts (>50 nM) can be found in alkaline brine lakes, hot springs, and marine hydrothermal vents.[1,2]

Tungsten is a 5d series element and its ionic electronic configuration is $[Xe]4f^{14}5d^{4}6s^{2}$ (*see* ***Tungsten: Inorganic & Coordination Chemistry***). The 4d series element Molybdenum (Mo), situated above W in the periodic table, shares similar chemical properties. The atomic and ionic radii of W and Mo, as well as their electron affinity, are identical. In aqueous solution, both elements are more stable at higher oxidation states and the reduction potentials of their (V/VI) and (IV/V) couples are in the same range, being slightly more negative for W. However, these two analogous elements differ considerably with regard to their role in biology. Molybdoenzymes are ubiquitous in nature and are found in virtually all life forms from microorganisms to eukaryotes (*see* ***Molybdenum: MPT-containing Enzymes***). They play intrinsic roles in the global cycles of nitrogen, carbon, and sulfur metabolism, and their biochemical, structural, and spectroscopic properties have been extensively analyzed.[3,4] In contrast, a functional role for tungsten in biological systems was not realized until the 1970s. Traditionally W had been regarded as an antagonist of the biological function of Mo. Thus microorganisms grown in the presence of W typically try to incorporate W into their molybdoenzymes. This results in the production of either inactive molybdoenzymes lacking any metal or tungsten-substituted molybdoenzymes that have little or no catalytic activity.[5–7] The one notable exception is an enzyme (DMSO reductase) from a photosynthetic bacterium (*Rhodobacter capsulatus*). In this case, the substitution of Mo, the metal that occurs naturally at the active site, by W resulted in an enzyme that retained its three-dimensional structure as well as enzymatic properties.[8] However, this still remains very much an exception and in spite of the high degree of chemical similarity between these two elements, nature is highly selective. Even if tungsten does become incorporated into a molybdoenzyme, its properties are different enough from those of molybdenum to preclude significant catalytic activity.

The first indications that W has a positive role in biology came from reports in the early 1970s when the growth of certain acetate- and methane-producing microorganisms was shown to be stimulated by the addition of tungstate to their growth media.[9] Subsequently, the first naturally occurring tungsten-containing protein was isolated from an acetogen.[10] Since then this field has grown and at present more than a dozen, naturally occurring tungsten-containing enzymes are known. Tungstoenzymes can be found in a variety of microorganisms including those that grow at extreme (hyperthermophiles) as well as conventional temperatures (mesophiles), in archaea and bacteria, and in organisms that reduce sulfur or sulfate, produce methane or acetate, or use acetylene during growth. However, a functional role for W has not been recognized in any eukaryote.

So, what types of organisms have evolved to use tungsten-dependent rather than molybdenum-dependent enzymes, what reactions do these enzymes catalyze, and why is tungsten utilized rather than molybdenum? In the following we address these questions, the answers to which are only just beginning to emerge.

All known tungstoenzymes can be classified into three functionally, phylogenetically, and evolutionarily distinct families. These are: (1) the FMDH family that has two members; formate dehydrogenase (FDH), found in methanogens and acetogens, and N-formylmethanofuran dehydrogenase (FMDH), from methanogenic species; (2) the Aldehyde ferredoxin oxidoreductase (AOR) family, which is represented by the prototypical member, aldehyde ferredoxin oxidoreductase (AOR), and also includes formaldehyde ferredoxin oxidoreductase (FOR), glyceraldehyde-3-phosphate ferredoxin oxidoreductase (GAPOR), the recently identified WOR4 from hyperthermophilic archaea, carboxylic acid reductase (CAR) from acetogens, and aldehyde dehydrogenase (ADH) from sulfate-reducing bacteria; and (3) the acetylene hydratase (AH) family, which has a single member from an acetylene-utilizing bacterium.

2 MOLECULAR AND CATALYTIC PROPERTIES OF TUNGSTOENZYMES

2.1 F(M)DH Family

It was shown in the mid-1970s that tungstate stimulated the growth of certain acetogenic *Clostridia*, such as *C. thermoaceticum*[11] and *C. formicoaceticum*.[11] These organisms grow by the fermentation of sugars to produce acetate as the sole product. The addition of tungstate to their growth media resulted in a substantial increase in the NADP-dependent formate dehydrogenase activity of cell-free extracts. In addition, the metabolism of formate by the methane-producing organism, *Methanococcus vannielii*, appeared to be tungsten-dependent.[12] Its growth was stimulated by tungstate when formate was used as the carbon and energy source, but not when the organism was grown on H_2 and CO_2. Partial purification of the formate dehydrogenase activity of *M. vannielii* in the early 1980s showed that it contained two types of formate dehydrogenase:[12] one contained molybdenum, while the other seemed to utilize tungsten. The first highly purified form of a tungsten-containing enzyme was reported in 1983 from *C. thermoaceticum.* Its formate dehydrogenase (FDH) contained tungsten, iron and the unusual amino acid selenocysteine, as well as acid-labile sulfur,[10] see Table 1. The tungsten-containing FDHs of methanogens are similarly complex enzymes that contain W, iron–sulfur centers and selenium. Recently two tungsten- and selenium-containing FDHs were isolated from another type of anaerobic bacterium (*Eubacterium acidacminophilum*).[13] FDHs catalyze the reversible reduction of CO_2 to formate (Table 2), with the concomitant transfer of two electrons from the appropriate electron carrier. This reaction has a very negative reduction potential (−420 mV, SHE). The syntrophic bacterium *Syntrophobacter fumaroxidans* constitutively expressed two W-containing FDH's (FDH-1 and FDH-2) when grown on fumarate or propionate.[14] The purified enzymes exhibit high formate-oxidation and CO_2-reduction rates and very low K_m values for formate.

In 1984, a newly isolated methanogen, *Methanobacterium wolfei*, was also shown to require tungsten for growth,[29] although in contrast to *M. vannielii*, *M. wolfei* grew only on H_2 and $CO_2{}^-$ it did not utilize formate. A subsequent and extensive survey[30] of the incorporation of radiolabeled tungstate (^{185}W) into methanogenic species showed that several accumulated significant amounts of the element into their protein fractions. An additional role for tungsten in some methanogens, however, remained unknown until the discovery of the enzyme FMDH. FMDH is found only in the methanogens where it catalyzes the reduction and addition of CO_2 to the organic, methanogenic cofactor, methanofuran (Table 2). The physiological electron donor for this reaction is not known. Methanogens grow on H_2 and CO_2 and generate methane. FMDH catalyzes the first step in the conversion of CO_2 to methane. FMDHs are complex multisubunit enzymes (Table 1) that are intrinsically labile and extremely oxygen sensitive. Usually these enzymes have a Mo cofactor, however, in several thermophilic and hyperthermophilic methanogens, the enzyme contains W.

2.2 AOR Family

The AOR family has been the most extensively studied and the majority of tungstoenzymes known at present belong to this family.[2,31] AOR was first isolated from the hyperthermophilic archaeon *Pyrococcus furiosus*.[15,16] Subsequently, three other members of this family FOR, GAPOR, and WOR4 were purified and characterized from *P. furious*.[17,19,21] All four enzymes consist of a single type of subunit of ∼70 Kilodaltons (kDa) in size, but they differ in their quaternary structures (Table 1). Whereas GAPOR is monomeric, AOR and WOR4 are dimeric and FOR is a tetramer. Each of their subunits contains a mononuclear W site and one iron–sulfur cluster (*see* ***Iron–Sulfur Proteins***). A comparison of their complete amino acid sequences show that AOR, FOR, and WOR4 are most closely related (40% sequence identity with each other) while GAPOR is more distant (23% identity).[21] AOR, FOR, and GAPOR catalyze the conversion of various types of aldehyde to the corresponding acid (Table 2). The reaction involves two-electron oxidation and *in vivo* ferredoxin serves as the electron acceptor. In contrast to other members of the family *P. furiosus* WOR4 does not appear to oxidize

Table 1 Molecular properties of tungsten-containing enzymes

Organism/enzyme[a]	Holoenzyme M_r (kDa)	Subunits/M_r(kDa)	W content[b]	FeS or cluster content[c]	Pterin cofactor[d]

[c]Cluster content expressed per mole of holoenzyme. [d]Indicates whether the pterin is with (Nuc) or without (Nonnuc) an appended nucleotide. NR, not reported. [e]Appended nucleotide is GMP.

Table 2 Catalytic properties of tungstoenzymes

Enzyme/source[a]	Reaction catalyzed	K_m (mM)	V_{max}[b]
AOR (*P. furiosus*)	$RCHO^c + H_2O + 2Fd^d(ox) \longrightarrow RCOOH + 2H^+ + 2Fd(red)$	0.04[e]	67 (80 °C)
FOR (*P. furiosus*)	$HCHO^f + H_2O + 2Fd(ox) \longrightarrow HCOOH + 2H^+ + 2Fd(red)$	25.00[g]	62 (80 °C)
GAPOR (*P. furiosus*)	$R'CHO^h + H_2O + 2Fd(ox) \longrightarrow R'COOH + 2H^+ + 2Fd(red)$	0.03	350 (70 °C)
CAR (*C. formicoaceticum*)	$RCHO + MV^{++i} + OH^- \longleftrightarrow RCOO^- + 2H^+ + MV^+$	0.14[j]	500 (40 °C)
ADH (*D. gigas*)	$RCHO + BV^{++k} + H_2O \longrightarrow RCOOH + 2H^+ + BV^+$	0.01[l]	38 (30 °C)
FDH (*C. thermoaceticum*)	$CO_2 + NADPH + H^+ \longrightarrow HCOOH + NADP^+$	0.11	880 (55 °C)
FMDH (*M. wolfei*)	$CO_2 + MFR^m + 2H^+ \longrightarrow CHO\text{–}MFR + H_2O$	0.01	11 (65 °C)
AH (*P. acetylenicus*)	$C_2H_2 + H_2O \longrightarrow CH_3CHO$	0.01	69 (30 °C)

[a]The sources of data are given in Table 1. [b]μ mole of substrate utilized min^{-1} mg^{-1} of protein at the indicated temperature. [c]R = H, C1–C4, Ar. [d]Fd, ferredoxin. [e]The K_m value was obtained using crotonaldehyde as the substrate for AOR. [f]R = H, C1–C3, C4–C6 di/semialdehydes. [g]The K_m value was obtained using formaldehyde as the substrate for FOR. [h]$R' = CHOHCH_2OPO_3{}^{2-}$. [i]Methyl viologen. [j]The K_m value was obtained using butyraldehyde as the substrate for CAR. [k]Benzyl viologen. [l]The K_m value was obtained using acetaldehyde as the substrate for ADH. [m]N-formylmethanofuran.

aldehydes or 2-hydroxyacids or catalyze the reverse reaction of acid reduction.[21]

CAR was discovered in acetate-producing bacteria based on its ability to catalyze the reverse reaction, the reductive activation of carboxylic acids, though it can also catalyze aldehyde oxidation (Table 2). The acid/aldehyde couple has an extremely low reduction potential, for example, E'_0 value for acetaldehyde/acetate is −580 mV (SHE) and therefore, aldehyde oxidation is much more thermodynamically favorable than acid reduction. The electron carrier for the enzyme inside the cell is not known. CAR isolated from *C. formicoaceticum* has molecular properties very similar to that of *P. furiosus* AOR whereas CAR from *C. thermoaceticum* has a more complex organization[22] (Table 1). The final member of this family is ADH from sulfate-reducing bacteria.[24] Its molecular properties closely resemble those of AOR (Table 1).

2.3 Acetylene Hydratase

This family is represented by just one member, AH from the acetylene-utilizing anaerobic bacterium, *Pelobacter acetylenicus*.[27] It comprises a single type of subunit that contains one W and a single iron–sulfur cluster (Table 1).

In contrast to reactions catalyzed by other tungstoenzymes, this enzyme does not appear to catalyze an overall oxidation or reduction. AH catalyzed the hydration of acetylene to acetaldehyde (Table 2). However, AH was found to be active only in the presence of a strong reducting agent, therefore, acetylene hydration might involve consecutive reduction, hydration, and oxidation steps, wherein the W site and the FeS center are required to carry out the redox chemistry. When *P. acetylenicus* was grown in the presence of Mo a fully functional Mo-containing AH was obtained, suggesting that W is not essential for the catalysis of acetylene hydration.[27]

3 PHYSIOLOGICAL ROLES

Most tungstoenzymes isolated so far have been from obligate anaerobes that are also thermophilic to a greater or lesser extent. Moreover, the enzymes have similar catalytic properties. They all catalyze a redox reaction involving conversions at the level of carboxylic acids and aldehydes (with the exception of AH). However, their physiological roles are distinctly different.

FMDH is found only in methane-producing organisms and catalyzes the first step in the conversion of CO_2 to methane. Using methanofuran as the C–1 carrier, FMDH catalyzes the reduction of CO_2 to N-formylmethanofuran. The formyl group is then reduced by a complex series of enzymes and novel cofactors to methane. FMDH is a molybdoenzyme in almost all methanogens so far examined. The notable exception is the moderate thermophile, *M. wolfei*, which grows optimally at 65 °C, in which the enzyme contains tungsten.[26] In fact, this organism contains two FMDHs: one (FMDH II) contains tungsten while the other (FMDH I) contains molybdenum.[32] The latter has also been purified as a catalytically active, 'tungsten-substituted molybdoenzyme' from cells grown in the absence of molybdenum and presence of tungsten.

Like methanogens, the acetogenic clostridia also grow on H_2 and CO_2 (as well as on sugars) but in these organisms CO_2 is ultimately reduced to acetate rather than methane. The first step in the conversion of CO_2 to the methyl group of acetate is catalyzed by FDH. This generates formate, which is subsequently activated and reduced by a series of enzymes using tetrahydrofolate as the C–1 carrier.[33] Acetogens vary in their responses to the addition of tungsten and molybdenum to their growth media, and in some species FDH appears to contain molybdenum while in others FDH seems to be dependent upon tungsten.[34,35] Tungsten-containing FDHs have been purified from the moderate thermophile *C. thermoaceticum*, which grows optimally near 60 °C, and from the mesophile *C. formicoaceticum*.[35] The effects of these two elements on the growth of acetogens is complicated by the finding, in at least some of these organisms, of a second tungstoenzyme, CAR, which reduces carboxylic acids. So far CAR has been purified from the same two acetogens as FDH, *C. thermoaceticum* and *C. formicoaceticum*.[22,36] In fact, *C. formicoaceticum* has been shown to produce two distinct CARs, one containing molybdenum and one containing tungsten.[23] Neither the role of CAR nor its physiological electron carrier are known.[37] This is in spite of the fact that CAR represents about 4% of the total cytoplasmic protein in *C. formicoaceticum*.

It is now evident that tungsten has as at least four different physiological roles in hyperthermophilic microorganisms. In the saccharolytic fermenters such as *P. furiosus*, tungsten-containing GAPOR is known to catalyze a key step in the unusual glycolytic pathway that this microorganism uses to convert glucose to pyruvate.[19,20] GAPOR is absolutely specific for glyceraldehyde-3-phosphate, which is oxidized to 3-phosphoglycerate. Under proteolytic growth conditions of *P. furiosus* or *T. litoralis*, AOR is thought to play a role in the degradation of amino acids.[38] The enzyme shows the highest catalytic efficiencies (and low K_m values) with acetaldehyde (from alanine), isovaleraldehyde (from valine), indoleacetaldehyde (from tryptophan), and phenylacetaldehyde (from phenylalanine). These aldehydes are derived by the transamination (conversion of an amino acid to a keto acid) and decarboxylation (conversion of a keto acid to an aldehyde) of the common amino acids alanine, valine, tyrptophan, and phenylalanine, respectively. A third role for tungstoenzymes comes in the form of FOR, which also appears to be involved in the breakdown of amino acids by *P. furiosus*.[17] Originally isolated based on its ability to oxidize formaldehyde, FOR can also use other short-chain (C_1–C_4) aldehydes as substrates. However, the K_m values for such substrates are very high (>10 mM), especially for formaldehyde (25 mM), indicating that these are unlikely to be physiological substrates (Table 2). The lack of significant activity with longer chain aldehydes (≥C–5) or with aromatic aldehydes indicates that the catalytic site of FOR is probably accessible to only short-chain aldehydes. Interestingly, this tungstoenzyme shows high activity (and low K_m values) with C4–C6 di- and semialdehydes. Such compounds are intermediates in the metabolic pathways of amino acids such as arginine, lysine, and proline. Since the organisms in which FOR has been found, such as *P. furiosus* and *T. litoralis*, grow using proteins as a primary carbon source, FOR may well have a role in amino acid metabolism, although this has yet to be established.[17] Neither GAPOR, FOR, nor AOR can utilize the nicotinamide nucleotides, NAD and NADP, as electron carriers. Instead, these enzymes couple substrate oxidation to the reduction of the extremely thermostable redox protein, ferredoxin. Excess reductant generated from the fermentative metabolism is then disposed of as H_2 by a thermostable hydrogenase which uses reduced ferredoxin as the electron donor.[39] Despite sharing high homology with AOR the fourth tungstoenzyme isolated from *P. furiosus* WOR4[21] does not appear to catalyze aldehyde oxidation or acid reduction. In fact, the reaction catalyzed by this novel enzyme, the fourth for a

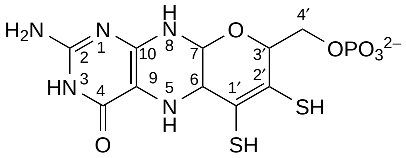

Figure 1 Structure of pterin cofactor found in tungstoenzymes such as *P. furiosus* AOR

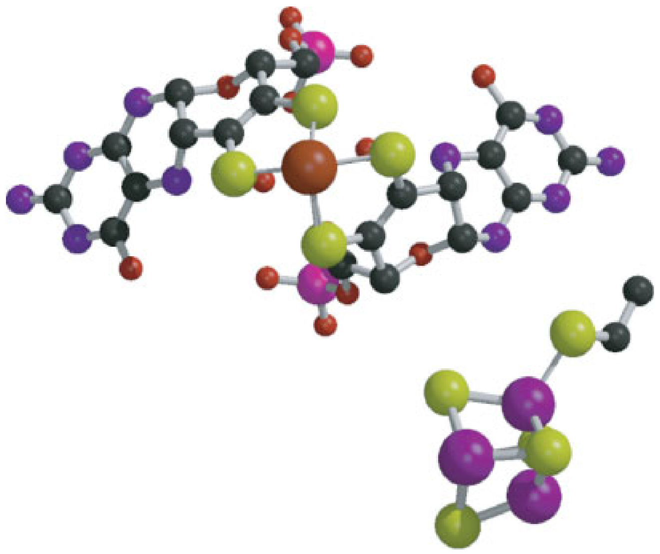

Figure 2 Ball-and-stick representation of the pterin cofactor and the adjacent [4Fe–4S] cluster in *P. furiosus* AOR. The side chain of a Cys residue that coordinates the cluster and hydrogen bonds with an N atom of the pterin cofactor is indicated[40]

tungstoenzyme in this organism, and thereby its physiological role, remains unknown.

4 STRUCTURAL PROPERTIES OF TUNGSTOENZYMES

The W atom in tungstoenzymes is coordinated by the same cofactor that coordinates the Mo in molydbdoenzymes: An organic moiety known as the pterin cofactor that is based on the two-ring pteridine nucleus that is present in the vitamin folic acid (Figure 1; *see* ***Molybdenum: MPT-containing Enzymes***). The crystal structure of *P. furiosus* AOR was the first for a tungsten-containing protein and for a pterin-containing protein (and the first for an enzyme from an organism that can grow at 100 °C).[16] Interestingly, the structure revealed that the cofactor in the W-enzymes is a *three*-ring system. The third ring contains a dithiolene group, where the two sulfur atoms coordinate the W atom (Figure 2). Subsequent structural analyses of molybdoenzymes have shown that the pterin cofactor in the two types of enzyme are the same. Analyses of the cofactor from the protein indicated that in molybdoenzymes from bacteria the pterin is usually modified with a mononucleotide (AMP, GMP, CMP, or IMP) attached to a terminal phosphate, which is typically lacking in Mo-enzymes from higher organisms. Such an appended nucleotide is also absent in the members of the AOR family of tungstoenzymes (Table 1) but the dinucleotide form of the cofactor is present in FMDH and FDH.

P. furiosus AOR is a homodimer in which each subunit contains an iron–sulfur cluster and coordinates a single mononuclear Fe site at the dimer interface. The W atom in AOR was found to be coordinated not by two S atoms from one pterin cofactor, but by four S of the dithiolene side chains from two pterins (Figure 2). The geometry of the W site in the enzyme displays a distorted square pyramidal arrangement, with an angle of 97° between the planes of the pterin ligands. The pterins are linked to each other through their phosphate groups, which coordinate the same Mg^{2+} ion. The W atom is buried deep inside the protein approximately 10 Å away from the iron–sulfur cluster (Figure 2). A hydrophobic channel leads from the W site to the surface of the protein. This channel is lined with apolar residues and is large enough to accommodate even aromatic substrates, consistent with the ability of AOR to oxidize a broad range of substrates. The iron–sulfur cluster is located close to the protein surface consistent with its role as an intermediary electron carrier between the W atom and the redox protein ferredoxin. The cluster is coordinated by the protein via four cysteine ligands. One of these Cys is positioned to accept a hydrogen bond from a pterin ring nitrogen, hinting at pterin's role as an active participant in the redox chemistry of the enzyme (Figure 2).

The crystal structure of FOR from *P. furiosus* has been solved at 1.8 Å resolution.[18] The overall folding of the FOR subunit is very similar to that of AOR, consistent with their high sequence similarity. However, FOR is a homotetramer with the four subunits arranged around a central cavity approximately 27 Å in diameter. Like AOR, each subunit of FOR comprises an iron–sulfur cluster and one W atom coordinated to a bis-pterin cofactor. FOR does have an additional metal site, a Ca ion situated close to one of the pterin cofactors, but it appears to play a purely structural role (*see* ***Calcium-binding Proteins***). The active site cavity in FOR has two distinctive parts: a large chamber at the bottom and a much narrower channel leading toward the protein surface. The bottom chamber that contains the tungstopterin site is lined with amino acids with bulky side chains. Consequently, the active site cavity in FOR is much smaller than that in AOR, and these variations contribute to the differences in substrate specificity between these two enzymes. Although the structures of the other tungstoenzymes from *P. furiosus*, GAPOR and WOR4, is not known, their amino acid sequence, size, and W and Fe contents suggest that these enzymes are probably closely related in structure to AOR and FOR. The molecular properties of *C. formicoaceticum* CAR are similar

to those of *P. furiosus* AOR, although its larger counterpart isolated from *C. thermoaceticum* contains additional subunits, FAD and a much higher Fe content (Table 1). The same is probably true for ADH, whose quaternary structure, subunit size, and W and Fe contents also match those of *P. furiosus* AOR (Table 1).

Structures have yet to be reported for the FDH and FMDH class of tungstoenzyme. However, the structure of the Mo-containing FDH_H from *E. coli*,[25] which shows 20% similarity in its amino acid sequence to that of the catalytic subunit of *Methanopyrus kandeleri* FMDH, has recently been elucidated. FDH_H is a component of the anaerobic formate hydrogen lyase complex and is a monomer of 79 kDa. It contains an iron–sulfur cluster and one Mo atom coordinated by a bis-pterin-MGD cofactor and the selenium atom of a selenocysteine residue (*see* ***Selenium Proteins Containing Selenocysteine***). The coordination geometry of Mo in the reduced enzyme is square pyramidal where the four sulfur atoms form the equilateral ligands and the Se site is at the axial position. Sequence comparisons suggest that W-containing FMDH may have a similar active site, especially since FMDHs of some methanogens also appear to contain selenium.

5 SPECTROSCOPIC PROPERTIES

By analogy with the redox behavior of molybdenum in molybdoenzymes (*see* ***Molybdenum: MPT-containing Enzymes***), a monomeric tungsten site in a tungstoenzyme could be reasonably expected to exist in oxidized (W(VI)), intermediate (W(V)), and reduced (W(IV)) states, where only the intermediate state is paramagnetic and thus Electron paramagnetic resonance (EPR) active. In recent years, the tungstoenzymes listed in Table 1 have been subjected to detailed studies using electron paramagnetic resonance (EPR), X-ray absorption (XAS), resonance Raman, and variable temperature magnetic circular dichroism (MCD) spectroscopies, in an effort to investigate their structure and mechanism. The reduced form of *P. furiosus* AOR is red in color and exhibits broad visible absorption peaks near 400 and 540 nm. When oxidized either by exposure to air or by treatment with ferricyanide, the protein turns a greenish-brown color and the absorption at 400 nm increases by about two-fold. This increase in visible absorption is characteristic of the Fe–S chromophore (*see* ***Iron–Sulfur Proteins***). FOR, GAPOR, ADH, and CAR all exhibit similar absorption spectra in their oxidized and reduced forms. Any contribution of the tungstopterin cofactor to the visible spectrum in these enzymes is probably masked by the broad peak from their Fe–S cluster.

During catalysis the W center is thought to undergo a two-electron cycle between the (IV)/(V)/(VI) oxidation states. W(V) has a d^1-configuration, is paramagnetic and exhibits electron paramagnetic resonance (EPR) signals with g-values less than 2. These signals are typically slow-relaxing and observable at temperatures above 100 K. W(IV) and W(VI), on the other hand, are diamagnetic and do not display EPR signals. Enzymes from all three classes of tungstoenzyme, AOR, FM(D)H, and AH, show resonances attributed to W(V) species.[31] The spectra are assigned to W(V) based on their relaxation properties and g-values. Unambiguous identification of the resonances come from hyperfine interactions arising from ^{183}W, which has a nuclear spin I = 1/2. The enriched enzymes are obtained from cells grown in the presence of ^{183}W-tungstate.[31]

Extensive EPR studies of AOR and FOR from *P. furiosus* show that the W site in these enzymes is not homogeneous. As many as four distinct W species are present and each has a distinctive W(V) EPR signal.[41,42] For example, the catalytically active form of the W site is thought to represent less than 50% of the total, and this gives rise to a 'low-potential' magnetically isolated W(V) species, that cycles between the W(IV)/W(V)/W(VI) states at physiologically relevant potentials (−450 mV to −250 mV at 25 °C). The signal has a rhombic lineshape with g-values, which are directly related to the electronic properties of the W atom, of 1.98, 1.90, 1.85. This low-potential signal is observed in all active AOR and FOR samples. A further 30% of the total W gives rise to a 'high-potential' W(V) signal at potentials (>0 mV) that are considered not to be physiologically relevant. The presence of up to four different W species in the same sample, representing active and inactive forms of these enzyme, explains the ambiguity observed in conclusively identifying the ligands to the W atom by crystallographic analyses.[16,18] The W centers of ADH and CAR also give rise to multiple EPR signals.[11] The source of the heterogeneity at the active center of members of the AOR group of tungstoenzymes is not clear.

The [4Fe–4S] cluster in AOR and FOR is paramagnetic in its reduced form and displays characteristic EPR resonances, although the spin relaxation rate is very fast and the spectra are observed only at very low temperatures (*see* ***Iron–Sulfur Proteins***). Hence, at 4K, the EPR spectrum of AOR is dominated by resonances from its reduced Fe–S cluster. However, this gives rise to a rhombic signal from a $S = 3/2$ ground state, while reduced 4Fe-clusters typically have an $S = 1/2$ ground state. In fact, while mixed spin, $S = 3/2$ and $S = 1/2$ reduced [4Fe–4S] clusters are sometimes observed in some iron–sulfur proteins (*see* ***Iron–Sulfur Proteins***), clusters that have exclusively $S = 3/2$ ground states are so far unique to AOR.[41] Indeed, the reduced 4Fe-cluster of FOR has a mixed spin state with $S = 3/2$ (80%) and $S = 1/2$ (20%) components. The factors that determine the spin state of a [4Fe–4S] center have yet to be elucidated.

FDH provided the first example of W(V) EPR resonances from a biological system.[43] At lower temperatures, resonances are seen from reduced iron–sulfur centers (both [2Fe–2S] and [4Fe–4S]), whereas at higher temperatures the reduced enzyme exhibits a slow-relaxing signal with unusually high g-values ($g = 2.1$, 1.98, 1.95). These anomalous EPR properties

have been attributed to the S-rich environment of the W comprising four S from two dithiolene side chains, a coordinated selenocysteine and the lack of an oxo ligand in the W(V) state.[31] On the other hand, simple rhombic-type EPR spectra from a W(V) site were reported in the mid 70s from catalytically inactive, tungsten-substituted sulfite oxidase,[44] and more recently from the catalytically active, tungsten-substituted form of *M wolfei* FMDH I. The latter enzyme in its air-oxidized form exhibited a rhombic EPR signal ($g_z = 2.049$, $g_y = 2.012$, $g_x = 1.963$) from the W(V) site and this had the expected isotope splitting (^{183}W, 14.4%, $I = 1/2$). Since this enzyme is rapidly inactivated in air, the catalytic significance of the air-oxidized form is not known, although the results suggest that the active enzyme as isolated under reducing conditions contains a reduced W(IV) center. The EPR properties of FMDH have not been reported but the sole member of the third class of tungstoenzyme, AH, also gives rise to a slow-relaxing EPR signal with relatively high g-values ($g = 2.04$, 2.02, 2.00) that is assigned to W(V).[28] These properties suggest that the enzyme contains a W site coordinated by the S atoms of two pterins and possibly a cysteine ligand. Unfortunately the latter cannot be substantiated by sequence comparisons with F(M)DH and the FDH family of molybdoenzymes. Tungstoenzymes can therefore be classified into two distinct groups based on their EPR properties. In the AOR class, the active site W is coordinated by the dithiolene side chains from two nonnucleotide pterin cofactors and an oxo (or possibly an hydroxyl) ligand in the W(V) state, but there is no direct interaction with any protein side chain. AOR, FOR, GAPOR, ADH, and CAR all appear to fit in this group, despite considerable heterogeneity of their active sites by EPR analyses. In contrast, it appears that the FM(D)H class contain a W center coordinated by the nucleotide form of pterin cofactor with an additional cysteine or selenocysteine ligand from the protein. The latter property leads to an increase in the g_{av} value of the W(V) EPR signal. This second category may also include AH.

6 EVOLUTIONARY CONSIDERATIONS

The tungstoenzymes known so far (Table 1) all catalyze reactions of very low potential (≤ -420 mV) and have been found only in strictly anaerobic organisms, the majority of which grow at moderate or extreme temperatures. The moderately thermophilic organisms appear not to be obligately dependent upon tungsten for growth as analogous molybdoenzymes seem to be synthesized if tungsten is omitted and molybdenum is added to the culture medium. Whether the hyperthermophiles are the first organisms to absolutely require tungsten for growth remains to be established. Nevertheless, tungstoenzymes appear to play key roles in the primary metabolic pathways for the catabolism of both carbohydrates and peptides in the hyperthermophiles. If one compares the properties of the mononuclear W and Mo synthetic complexes,[6,45] it is evident that the relevant W complexes are much more oxygen sensitive than the equivalent Mo compounds, indicating that such a W site within an enzyme would be active only under anaerobic conditions. Similarly, the W complexes display enhanced thermal stability compared to Mo complexes, suggesting that the former rather than the latter would be preferred at temperatures near the normal boiling point. This enhanced bond strength of W complexes may also account for the observation that such complexes are generally kinetically slower than the equivalent Mo complexes. In addition, the much lower redox potentials (typically by more than 300 mV) for the W complexes compared to the Mo ones indicate W is better suited to catalyze lower potential redox processes.[6] Lastly, availability of these metals may play a major role in which of these metals is utilized in different ecosystems. For example, in freshwater and marine environments the concentration of W is typically several orders of magnitude lower than Mo, although in deep-sea hydrothermal vent systems W is much more prevalent than Mo.[2] Hence, it might be expected that W would only be utilized in biological systems to catalyze low-potential reactions under anaerobic conditions, and that significant catalytic rates would be observed only at high temperatures. Conversely, Mo complexes would be unstable at high temperatures but at lower temperatures they would be catalytically competent over the whole biological range of potentials under both aerobic and anaerobic conditions.[6] In fact, most of the W-utilizing microorganisms produce functional Mo-containing isoforms of their tungstoenzymes when they are grown in the presence of Mo rather than W. For example, functional Mo-containing isoenzymes exist for W-containing FMDH, CAR, FDH, and AH in their respective mesophilic or thermophilic organism.[31] The notable exception is the AOR family of tungstoenzymes found in hyperthermophiles such as *P. furiosus*.[2,31] So far they are the only known organisms that obligately require W for growth. They do not contain Mo-analogs of the AOR family, and they appear not to utilize Mo. Such organisms carry out chemical reactions near the limits of biology, at extremely low potentials and at high temperatures. It is possible that catalysis under such extreme conditions is a feat that can be accomplished by W but not by Mo. As yet, a Mo-containing enzyme has not been isolated from an organism that can grow at the normal boiling point.

1 INTRODUCTION

It is now well established that the element vanadium, which is universally distributed in the soil,[1] plays a role in biological systems. This metal is essential for the functioning of the bacterial nitrogen fixation system (*see* ***Nitrogenase Catalysis & Assembly***) and vanadate is the prosthetic group in the vanadium haloperoxidases from seaweeds and dematiaceous hyphomycetes. As a result, the chemistry of model compounds[2,3] for these biomolecules has been investigated in detail. Furthermore, some vanadium compounds mimic most of the metabolic effects of insulin and the number of publications dealing with the subject has increased exponentially. Four books[4–7] and a large number of reviews[8–10] have appeared which cover several aspects such as the role of the metal in the biosphere, the inorganic and redox chemistry of vanadium, and the insulin mimetic effect of vanadate. An international symposium on chemistry and biological chemistry of vanadium is also organized regularly. In this chapter, the role of the metal in vanadium haloperoxidases will be discussed and the status of the high concentration of vanadium in fan worms and its possible role in the blood cells of Ascidians will be reviewed. It is clear that the field of vanadium biochemistry has rapidly developed and further discoveries and surprises are expected.

Vanadium has 4 oxidation states of which only vanadium^{III,IV} and V occur in biological systems. Vanadium^{V} and IV are the most common and vanadium^{III} has been detected only in tunicates and fan worms.[11] At neutral pH, vanadium is mostly found as vanadate and depending upon pH and concentration, vanadate oligomers including the dimer, tetramer, and decamer forms are found. At low concentrations such as in seawater,[12] only the monomeric species will be present, probably in the diprotonated state. Vanadate, by virtue of being a structural analogue of phosphate, has inhibitory, stimulatory, and regulatory effects on biochemical processes that in a number of cases are due to the formation of enzyme-vanadate intermediates.[9] Vanadate is easily reduced to the IV state by common reducing agents under physiological conditions. In aqueous solutions, most of the reduced vanadium species found exists as vanadyl (VO^{2+}), which forms strong complexes with a great variety of ligands including proteins (*see* ***Vanadium: Inorganic & Coordination Chemistry***). At neutral pH values the vanadyl species are easily oxidized by air to vanadium^{V}. As a d^1 metal ion, vanadium^{IV} has one unpaired electron which is strongly coupled to the ^{51}V nucleus ($I = 7/2$) giving rise to either 8 or 2 sets of 8 overlapping lines in axial symmetric complexes. This typical signal is easily detectable and it is possible by the EPR technique (*see Electron Paramagnetic Resonance*) to observe relatively low concentrations of the metal.

2 VANADIUM BROMOPEROXIDASES

2.1 Occurrence

A striking array of halogenated products produced by natural sources is found in the biosphere. The majority are probably formed by the enzymatic activity of haloperoxidases.[13] The detailed mechanism by which haloperoxidases catalyze the insertions of a halogen into organic molecules is still a point of debate. However, for most of these enzymes a simple reaction mechanism has been observed that consists of a two-electron oxidation of the electron donor (Cl^-, Br^-, I^-) by H_2O_2 to hypohalous acids (equation 1):

$$H_2O_2 + X^- + H^+ \longrightarrow HOX + H_2O \qquad (1)$$

By definition enzymes that are able to oxidize chloride, bromide, and iodide are called chloroperoxidases and those able to oxidize bromide and iodide, bromoperoxidases. If a nucleophilic acceptor (RH) is present, a reaction will occur with HOX and halogenated compounds (*see Halocarbons & Halocarbon Complexes*) are produced (equation 2).

$$HOX + RH \longrightarrow RX + H_2O \qquad (2)$$

HOX will react with a broad range of acceptors (RH) to form a diversity of halogenated reaction products (RX). As we know now, most of the marine haloperoxidases contain

vanadate in the active site.[14,15] These enzymes, which have been detected in a great variety of brown and red seaweed samples, are widespread in the marine environment and have been found in seaweeds from the Great Barrier Reef in Australia, the Sea of Japan, the East Pacific, and the North Atlantic Ocean. Vanadium iodoperoxidases have also been identified in some brown seaweeds but they have hardly been studied. Also diatoms have been reported to contain haloperoxidases. The vanadium peroxidases are probably also responsible for the formation of huge amounts of bromoform by seaweeds and phytoplankton. Some oceans are even saturated with this compound with the result that ventilation to the atmosphere occurs and this volatile organohalogen participates in chemical processes in the atmosphere.[13] The biological function of the formation of bromoform by these algae is not clear. Some of the organohalogens formed and also HOBr have biocidal effects and prevent biofilm formation by bacteria on the surface of seaweeds. It is likely that formation of these compounds is part of a host defense system.[13]

2.2 Catalytic Properties

The vanadium peroxidases differ from the heme-containing peroxidases (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***) in their specificity for halides. The vanadium enzymes do not oxidize classical organic electron donors such as guaiacol, *o*-dianisidine, and benzidine. Thus assay systems used are those that detect the formation of HOCl, HOBr, or HOI. Routinely, the halogenating activity of these enzymes is determined by measuring the bromination or chlorination of the cyclic diketone monochlorodimedon to the dihalogenated compound. At more alkaline pH values and in particular at high concentrations of H_2O_2, a competing reaction (equation 3) between H_2O_2 and HOX occurs. This results in singlet oxygen formation and an apparent decrease in the rate of bromination or chlorination of monochlorodimedon.

$$H_2O_2 + HOX \longrightarrow {}^1O_2 + H_2O + HX \qquad (3)$$

Therefore it is also possible to measure enzyme activity without a HOX scavenger by monitoring the rate of dioxygen formation directly using an oxygen electrode.[16] This is at high pH a more accurate measure of bromoperoxidase activity. ${}^1O_2$ production can also be measured at 1268 nm (*see* ***Dioxygen & Related Ligands***).[17] A convenient qualitative method to assay the haloperoxidase activity is following the bromination of phenol red to bromophenol blue; this results in a marked color change taking place which allows screening of haloperoxidase activity of large numbers of samples by simple visual inspection.[18] The turnover values of the bromoperoxidases vary considerably among the various seaweed species. Extensive steady-state kinetic studies have been carried out that show that hydrogen peroxide and bromide (as a substrate) react with the enzyme in a sequential order and the kinetic mechanisms for the bromoperoxidases from various sources are all very similar.[10] Slight inhibition of bromoperoxidase by high concentrations of H_2O_2 (120–400 mM) with stronger inhibition at higher pH has been observed. Interestingly, the K_M value for H_2O_2 increases with increasing proton concentration. This appears to be due to protonation of a group with a pK_a of 5.7–6.7 that upon protonation prevents binding of peroxide. In contrast the K_M for bromide is hardly affected by pH.

On the basis of kinetic studies the presence of a peroxo-intermediate was postulated and spectroscopic evidence for such an intermediate has been obtained.[10,19] Br_3^-, Br_2, or HOBr appear to be the primary reaction products of the enzyme-mediated peroxidation of bromide.[19] The vanadium enzyme also uses phenylperacetic acid, *m*-chloroperoxybenzoic acid, and *p*-nitroperoxybenzoic acid as oxidants, but alkyl peroxides such as ethylhydroperoxide, tert-butyl hydroperoxide, and cuminyl hydroperoxide are not substrates for the enzyme in the oxidation of bromide.[20] The enzyme from the brown seaweed *Ascophyllum nodosum* does not display any specificity with regard to bromination of various organic nucleophilic acceptors which suggests a mechanism in which the oxidized bromine species are released into solution by the enzyme.[21] Figure 1 gives a simple model for the reaction mechanism of the enzyme.

However, it is clear that during catalysis an enzyme-bound bromonium intermediate is formed which binds specifically indoles and catalyzes a regio-selective bromoperoxidative oxidation.[22] This brown seaweed produces highly volatile and simple halohydrocarbons such as CH_2Br_2 and CH_3Br. These halohydrocarbons are formed by reaction of enzymatically generated HOBr with organic matter that slowly decays to form these halohydrocarbons.[13,23] Thus the reported oxidation of indoles[22] is most probably not related to the known physiological role of the enzyme.

2.3 Nature of the Active Site

Vanadium bromoperoxidases lose their enzymic activity at low pH in buffers containing phosphate and EDTA. Also during purification procedures, the enzyme slowly

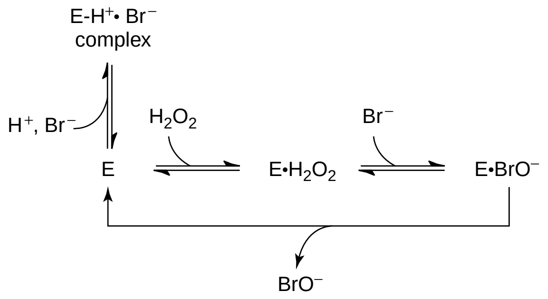

Figure 1 Simplified model for the reaction mechanism of the vanadium bromoperoxidases. As we will see later this mechanism may be slightly different for the vanadium chloroperoxidases

inactivates if phosphate buffers are used.[10] However, in the absence of phosphate-containing buffers, the enzyme retains its activity for months.[10] To inactivate the enzyme completely the presence of phosphate in the procedure is essential.[14] Incubation of the apoenzyme at neutral pH with orthovanadate (VO_4^{3-}, which is the vanadium^V oxy-anion) results in recovery of the enzymatic activity as discovered originally by Vilter.[14] Reconstitution is inhibited competitively by structural analogs such as phosphate (PO_4^{3-}), arsenate (AsO_4^{3-}), molybdate (MoO_4^{2-}), fluoroberyllate, and fluoroaluminate.[10] The reconstitution of the apoenzyme by vanadate suggests that vanadate is present in the active site. The X-ray structures show that vanadate is indeed the prosthetic group in these enzymes.[24] The affinity of the apobromoperoxidase for vanadate is quite high. Values of 35–55 nM have been reported[10,14] that are close to the concentration of vanadate in seawater of 35 nM[12] suggesting that for incorporation of vanadate into the apoenzyme, in vivo, no additional enzyme system is required.

Since the enzyme is nearly colorless and displays only a weak band around 315 nm in the optical absorption spectrum,[10] it is difficult to gain information by optical spectroscopy. EPR, Electron Spin Echo Envelope Modulation Spectroscopy (ESEEM), X-ray spectroscopy, and ^{51}V NMR have been used to probe the nature of the active site in these peroxidases. EPR studies on the bromoperoxidase from the brown seaweed *A. nodosum* have shown that the oxidation state of the metal in the native form is vanadium^V and that its redox state does not change during turnover.[25,26] The role of the vanadium^V in the enzyme is probably to coordinate and to activate hydrogen peroxide resulting in reaction of the halide with this activated peroxide to yield hypohalous acid. Owing to its low radius/charge ratio vanadium may act as a Lewis acid in which the metal effectively withdraws electron density from the bound peroxide in such a way that the halide is able to react with this activated peroxide intermediate of the enzyme to yield hypohalous acid. In this mechanism, no redox changes occur in the vanadium metal center. These spectroscopic methods have not only yielded insight into the mechanism but structural data have also been obtained. For example, based on the results of EXAFS studies the conclusion was reached that the geometry of the metal oxide bound in the active site was five-coordinate.[27] EPR and ESEEM studies on the reduced enzyme demonstrated clearly that water is in the direct coordination sphere of the metal oxide.[25,26] The EXAFS data showed the presence of multiple scattering effects from outer atoms of a group corresponding to a histidine ligated to vanadium. Also the ESEEM experiments[26] clearly indicated the presence of a histidine residue in the active site as confirmed now by the X-ray structure of the vanadium bromoperoxidase from *Ascophyllum nodosum.*[24]

2.4 X-ray Structures of Vanadium Bromoperoxidases

The homo-dimeric structure of the enzyme from *A. nodosum* consists of 1111 amino acids with a calculated molecular mass of 120 kDa.[24] The primary sequence was determined by combining the results of DNA sequencing, protein sequencing, and electron density interpretation. The dimeric enzyme is a compact ellipsoid of approximately 90 Å in length and with a diameter of about 76 Å (Figure 2). The monomer of the enzyme consists of a predominantly helical secondary structure, being composed of 18 α-helices and eight short β-strands. Two four-helix bundles and six long helices (each monomer donating a four-helix bundle and three long helices) form the highly rigid and compact core of the dimeric structure. This includes the two vanadium active sites, which reside at the N-terminal end of one of the four helices of each monomer. The monomers are linked covalently in the N-terminal region by two disulfide bridges, four well-defined salt bridges and a large number of hydrogen bonds involving both side-chain and main-chain residues. The two long helices at the N-terminus in each monomer are aligned antiparallel with respect to each other. Additionally, each monomer has three intramolecular disulfide bridges. Thus each dimer contains eight disulfide bridges in line with previous estimates.[10]

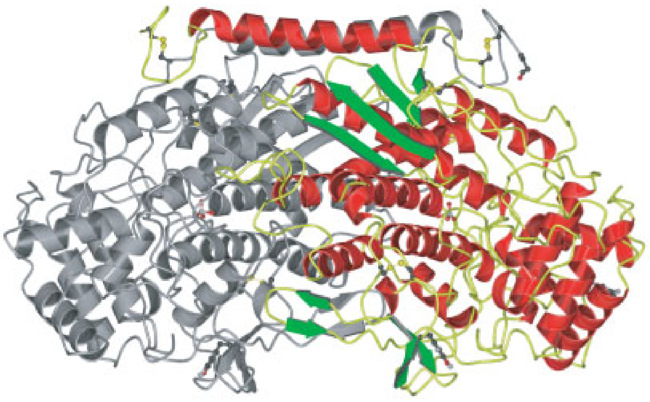

Figure 2 Ribbon type representation of the vanadium bromoperoxidase dimer from *A. nodosum*. The α helices on the top are linked together by two disulfide bridges. (Reprinted from Ref. 24, © 1999, with permission from Elsevier)

Vanadate is bound on the N-terminal side of a four-helix bundle and the vanadium metal is the center of a trigonal bipyramid with three oxygen atoms coordinated in the equatorial plane, one oxygen in the axial position (Figure 3), and a covalent linkage to the $N^{\varepsilon 2}$ of His486. The negative charge of the oxygen atoms in the equatorial plane is compensated by hydrogen bonds donated by several hydrophilic and positively charged amino acids in the vicinity, including Lys341, Arg349, Ser416, and Arg480. The axial oxygen atom forms a hydrogen bond with the $N^{\delta 1}$ of distal His418, which is the proposed conserved catalytic residue in vanadium peroxidases.[10]

Both hydrophilic and hydrophobic residues cover the entrance channel with hydrophobic residues dominating the lower part near the vanadate-binding site. Interestingly, amino acid residues from both monomers contribute to the substrate

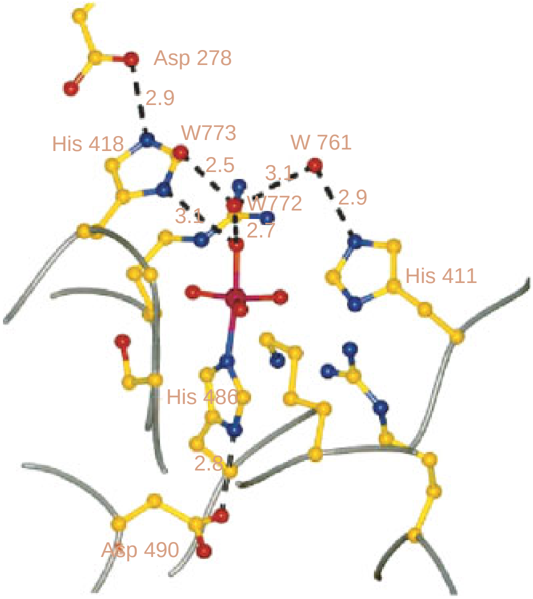

Figure 3 The active site residues around the vanadate center of vanadium bromoperoxidase from *A. nodosum*. There are also three water molecules (W772, W773 and W761) in the active site. (Reprinted from Ref. 24, © 1999, with permission from Elsevier)

access channel of each active center. The channel to the active site of each monomer is 15 Å deep with a diameter of 12 Å at the entrance, decreasing to 8 Å near the axial oxygen of the vanadate prosthetic group, where the channel exhibits a more hydrophobic character.[27]

The X-ray structures of vanadium bromoperoxidases from the red seaweeds *Corallina pilulifera* and *C. officinalis* have also been determined and their structures are almost identical.[28,29] The native structure of these enzymes is dodecameric and the structure is made up of 6 homo-dimers. The secondary structure of the chloroperoxidase from the fungus *Curvularia inaequalis* that will be discussed later can be superimposed with the *Corallina* bromoperoxidase dimer. Many of the α helices of each chloroperoxidase domain are structurally equivalent to the α helices in the *Corallina* bromoperoxidase dimer. This is in line with the evolutionary relationship between the haloperoxidases that will be discussed later. The disulfide bridges in the enzyme from *A. nodosum* are not found in the enzyme from *Corallina* and the two remaining cysteine residues are not involved in disulfide bonds. Additionally, in this enzyme binding sites are present for divalent cations that seem to be necessary to maintain the structure of the active site cleft. All the residues directly involved in the binding of vanadate are conserved in the algal bromoperoxidases.[30]

An extraordinary feature of these enzymes is their remarkable stability.[18] The bromoperoxidase from the brown seaweed *A. nodosum* remains completely functional upon storage in up to 60% methanol, ethanol, and isopropanol for up to a month, and remains fully active when exposed to temperatures up to 70 °C. The enzyme was observed to be unaffected by detergents and reagents such as guanidine-HCl and to withstand oxidative inactivation in the presence of high concentrations of highly reactive oxidants, including hydrogen peroxide and hypohalous acid.[10] The high stability of this enzyme can be attributed to the highly rigid core of the dimeric enzyme and to the fact that more than 46% of the surface of each monomer is part of the dimer interface. In addition, 2 intermolecular salt bridges contribute to the stability of the homo-dimeric enzyme structure. The stability of the enzyme from *Corallina* appears to be the result of the dodecameric structure that shields the solvent accessible area. These fascinating features are of considerable interest for the potential application of the vanadium peroxidase as (industrial) biocatalyst in organic synthesis.

3 VANADIUM CHLOROPEROXIDASES

3.1 Discovery and Physiological Function

During the course of screening for haloperoxidases with tolerance to high pH environments and high temperatures, it was observed that dematiaceous hyphomycetes isolated from plant material and soils collected in Death Valley possessed haloperoxidase activity.[31] In 1993, it was shown[32] that the nonheme chloroperoxidase produced by one such hyphomycete, the fungus *Curvularia inaequalis* also contains vanadate as the prosthetic group in the enzyme. These peroxidases escape detection if classical peroxidase assay systems (e.g. guaiacol) are used and consequently it took a long time to identify the peroxidases in hyphomycetes. Furthermore, when the fungus is grown in vanadate-deficient media, the enzyme is secreted in an inactive apoform.[10] Expression studies showed that the vanadium enzyme is produced in the secondary growth phase, when nutrients become limiting and the expression appears to be mainly regulated at transcription level.[33] Several species in the group of the dematiaceous hyphomycetes produce haloperoxidases (e.g. *Drechslera biseptata*, *D. subpapendorfii*, *Embellisia didymospora*, and *Ulocladium chartarum*), which are vanadium chloroperoxidases.[10] Thus, vanadium chloroperoxidases occur widely in nature. Many of these hyphomycetes are phytopathogenic and/or saprophytes and this raises the question of the physiological function of the vanadium chloroperoxidases. It has been proposed that the generated HOCl is used by the fungus as an attack mechanism to oxidize the lignocellulose in the cell walls of the plant in order to facilitate penetration of the fungal hyphae into the host.[33] It may well be that HOCl which is generated by fungi in soils also reacts with organic matter resulting in the formation of these organohalogens in plants and soil. This may explain the presence of chlorinated compounds in soils that are of nonanthropogenic origin.

3.2 Kinetic and Other Properties of Chloroperoxidases

Research on the vanadium chloroperoxidase obtained a large impetus by cloning of the gene encoding vanadium chloroperoxidase[31] and successful expression of the recombinant enzyme.[33,34] The gene encodes a protein of 609 amino acids with a calculated molecular mass of 67 488 Da. The apoform of the enzyme, either secreted by the fungus or produced as recombinant enzyme, can easily be activated upon addition of vanadate to the growth medium.[10,32] Thus, these enzymes do not require an additional enzyme system for the incorporation of vanadate. In most soils, a high concentration (100 ppm) of vanadium is present and considering the reported affinity of the apochloroperoxidase for vanadate (K_d 140 nM), the amount of vanadium is not a limiting factor in the conversion of the apoenzyme into the holo-enzyme. Additionally, in the presence of H_2O_2 the affinity of the apoenzyme for vanadate increases at least 200-fold. This appears to be due to the formation of pervanadate that binds much more strongly to the active site than vanadate.[35]

Steady-state kinetic studies[36,37] showed that the kinetics of the enzyme resemble those of the vanadium bromoperoxidases.[16,19] The chloroperoxidase exhibits a pH profile similar to vanadium bromoperoxidases although the optimal pH of 4.5–5.0 is at a lower value. At low pH the enzyme is inhibited by chloride in a competitive way whereas at higher pH values the activity displays normal Michaelis-Menten type of behavior (*see Michaelis Constant*). The log K_M for chloride increases linearly with pH whereas that for hydrogen peroxide decreases with pH demonstrating that in the catalytic mechanism protons are involved. These observations have led to a simplified ping-pong type of mechanism for the chloroperoxidase similar to that shown in (Figure 1).

The enzyme will first react with peroxide to form a peroxointermediate, after which a chloride ion and a proton react resulting in the formation of an enzyme-HOCl, which decays in a rate-determining step to enzyme and free HOCl.[35] The linear dependency of the logK_M for hydrogen peroxide on pH suggests that an ionizable group is involved in the binding of hydrogen peroxide. When this group is protonated hydrogen peroxide is unable to bind. The linear dependence of the logK_M for chloride on pH shows that for binding of chloride to occur, protonation of a group is essential.[10]

The binding of substrates to the chloroperoxidase has also been studied using substrate-induced spectral changes. Figure 4 illustrates the UV–VIS absorption spectra of the vanadium chloroperoxidase. A band is present at 315 nm ($\Delta\varepsilon = 2.8\,\mathrm{mM^{-1}\,cm^{-1}}$) in the native enzyme which is not found in the apoenzyme. The absorption of this band decreases upon addition of hydrogen peroxide.[35] When chloride is added, the original intensity of the band is reformed as a result of halide oxidation. Stopped-flow studies were also carried out confirming the catalytic sequence of events and evaluation of the first-order rate constant for the binding of hydrogen peroxide to the enzyme ($0.8 \times 10^5\,\mathrm{M^{-1}\,s^{-1}}$ at pH 5). Sequential mix studies show the first direct monitoring of the decay of the peroxo intermediate to the native enzyme during chloride oxidation, which consists of at least two steps.

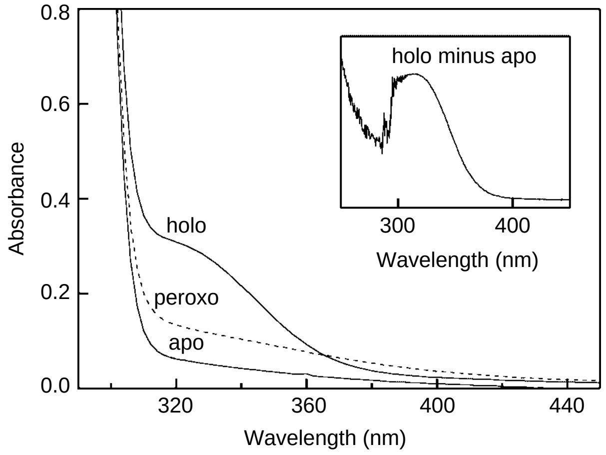

Figure 4 UV-VIS absorption spectra of 100 μM chloroperoxidase at pH 8.3. Holo-enzyme was obtained by addition of 100 μM vanadate to the apoenzyme and the peroxo form by addition of 100 μM H_2O_2 to the holo-enzyme. (Reprinted with permission from Ref. 35. © 2000 American Chemical Society)

The chloroperoxidase also has bromoperoxidase activity.[34,37] Compared to the vanadium bromoperoxidases the chloroperoxidase has a very high affinity for bromide (K_M about 5 μM). The enzyme is strongly inhibited by excess bromide and hardly any activity is observed at 100 mM bromide. An interesting difference is also observed between the bromo- and chloroperoxidase activity of this enzyme. As discussed before, the K_M for chloride is strongly pH dependent, whereas the K_M for bromide is hardly affected by pH as is also observed for the bromoperoxidase from *Ascophyllum nodosum*. An X-ray study proved that during turnover a peroxo intermediate is formed.[38] The peroxide is bound side-on and it has been proposed[37,39] that protonation of one of the oxygen atoms of the peroxide is required to allow the more difficult oxidation of the chloride. Protonation of the bound peroxide is not required for bromide oxidation since bromide is more easily oxidized. Based upon the effects of mutations of the active site residues, the following mechanism has been proposed.[34] By the Lewis acid properties of vanadium and the two positively charged arginine residues (Arg490 and Arg360), electron density is withdrawn from the bound peroxide. The bound peroxide is further polarized and activated by a conserved lysine residue (Lys353) that forms a hydrogen bond to one of the oxygen atoms. The kinetic studies suggest that protonation of the bound peroxide occurs thereby increasing its reactivity. The model to explain the difference in reactivity between a bromo- and a chloroperoxidase is shown in Figure 5.

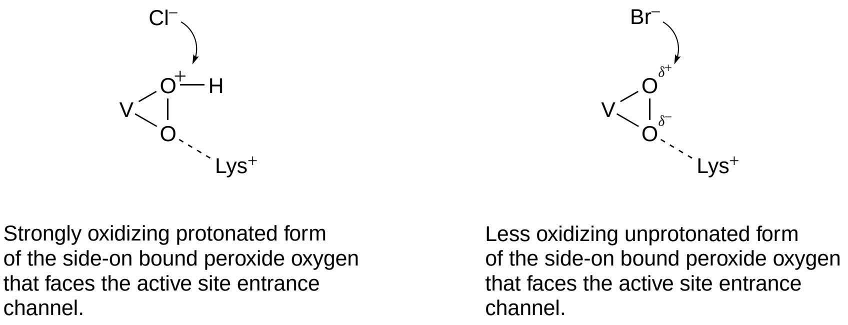

Figure 5 A possible explanation for the difference in reactivity between vanadium chloroperoxidase and bromoperoxidase[39]

After formation of the peroxide intermediate, the next step in catalysis is the nucleophilic attack by the halide breaking the oxygen–oxygen bond, resulting in formation of HOX or XO^-.

All mutations of the active site residues result in enzymes that are dead or kinetically crippled. Most or all of the chloroperoxidase activity is lost; however, some mutants retain bromoperoxidase activity.[10] A similar effect has been observed in the bromoperoxidase from *Fucus distichus*. Mutation of a phenylalanine in the active site of the bromoperoxidase to an alanine yielded a mutant that only showed iodoperoxidase activity.[40] Satisfactory explanations have not been offered for these observations and neither the question regarding the factors important in tuning the reactivity of the haloperoxidases has been answered. Mutagenesis studies on both bromoperoxidase and chloroperoxidase of the only residue that differs in the two enzymes (Phe in chloroperoxidase versus His in bromoperoxidase) have not clarified this either.[37,41] It can only be concluded that the difference in oxidative ability between VBPO and VCPO as modeled in Figure 5 is not simply due to a single residue. This protonation of the bound peroxide may only occur when a specific hydrogen-bonding network is present that involves bound water molecules and that plays an important role in tuning the reactivity of these enzymes and thus many factors are involved.

3.3 Sulfoxidation Reactions

The haloperoxidases in the absence of halides but in the presence of hydrogen peroxide are also capable of catalyzing the sulfoxidation of organic sulfides with a very high enantioselectivity.[41,42] The bromoperoxidase from the brown seaweed *A. nodosum* produces the R-enantiomer of methyl phenyl sulfoxide (96% e.e.) under slightly acidic conditions, while the bromoperoxidase from the red seaweed *C. pilulifera* produces the S-enantiomer of this sulfoxide (55% e.e.). The bromoperoxidase from the seaweed *C. officinalis* was also observed to convert organic sulfides that structurally resemble indenes to the S-enantiomer of the corresponding sulfoxides showing high selectivities. Also, small sulfides, possessing a *cis*- positioned carboxyl group with respect to the sulfur atom, are rapidly converted to the corresponding sulfoxides with selectivities exceeding 95% e.e. The vanadium bromoperoxidase from *A. nodosum* catalyzes the sulfoxidation of racemic nonaromatic cyclic thioethers with kinetic resolution.[43] By using ^{18}O-labeled hydrogen peroxide, it was shown that the vanadium bromoperoxidases mediates the direct transfer of the peroxide oxygen to the sulfide in a selective manner, strongly suggesting that the aromatic sulfide binds near or at the active site with a relatively low affinity.[43] The k_{cat} for the sulfoxidation reactions is low ($1\,min^{-1}$) compared to the brominating activity of the bromoperoxidase from *A. nodosum* ($166\,sec^{-1}$). Vanadium chloroperoxidase in contrast to vanadium bromoperoxidase appears not to be capable of mediating the direct and selective transfer of peroxide oxygen to methyl phenyl sulfide. This may be due to the high reactivity of the chloroperoxidase resulting in electron abstraction from the substrate and formation of a positively charged sulfur radical. This radical migrates from the enzyme and is subsequently converted to the sulfoxide via reaction with water.

3.4 Stability of Chloroperoxidase

The vanadium chloroperoxidases are highly resistant towards elevated temperatures; the midpoint temperatures determined from thermal denaturation curves range from 82 to 90 °C. It is also possible to store the enzyme at elevated temperatures and it has even been reported that incubation at 75 °C for 8 hours resulted in only a 20% loss of activity.[40] The factors contributing to the thermostability are the compactness of the molecule and the large amounts of α helical structure found in the chloroperoxidase.[30] Pronounced chemostability and resistance towards oxidative agents such as H_2O_2, HOCl, and singlet oxygen have been reported.[17,36] Heme-containing peroxidases with their electron-rich aromatic ring system are much more easily oxidized and inactivated by oxidative agents (*see* ***Iron: Heme Proteins, Peroxidases, Catalases & Catalase-peroxidases***). In this respect, the vanadium haloperoxidases are unique and the ability of the

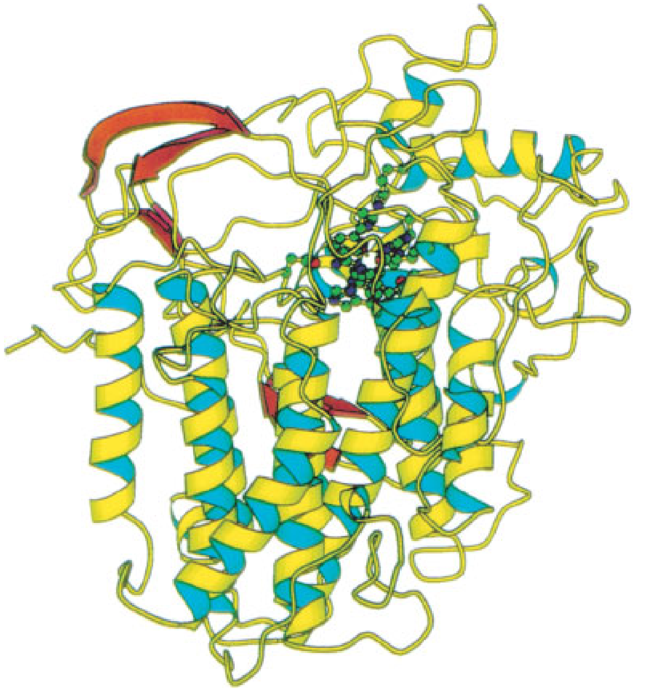

Figure 6 Ribbon type representation of the vanadium chloroperoxidase from *C. inaequalis*. (Reproduced from A. Messerschmidt and R. Wever, *Proc. Natl. Acad. Sci USA*, 1999, **93**, 392. © 1996 National Academy of Sciences, U.S.A.)

enzymes to handle the oxidative substrate and product are the consequences of the nature of the active site.

3.5 X-ray Structure of the Vanadium Chloroperoxidase and Details of the Active Site

Both the 2.1 Å crystal structure of the native chloroperoxidase and recombinant chloroperoxidase at 1.66 Å resolution have been reported.[30,44] The enzyme molecule has an overall cylindrical shape (Figure 6) with a length of about 80 Å and a diameter of 55 Å. The protein fold is mainly α helical with two four-helix bundles as the main structural motifs. The structure also contains some antiparallel β sheets. The very compact packing of the helical structure is different from other known protein structures. There are no disulfide bridges which is in contrast to the vanadium bromoperoxidase from *A. nodosum*.[28] The vanadium-binding center is located on top of the second four-helix bundle and the residues binding the prosthetic group span a length of approximately 150 residues in the primary structure.

The X-ray structure analysis of the active site (Figure 7a) shows that vanadium is bound as orthovanadate^{V} in the same way as in the bromoperoxidases in which three oxygen atoms form a plane (bond length about 1.65 Å), the fourth oxygen is found at the apex (bond length 1.93 Å) which is in the range of a vanadium^{V} hydroxyl bond. It is hydrogen bonded to the nitrogen $N^{\delta 1}$ of His404.

The $N^{\varepsilon 2}$ atom from a histidine (His496) ligating directly to the metal completes the trigonal bipyrimidal coordination. The negative charge of the vanadate group is compensated by hydrogen bonds to three positively charged residues (Arg360, Arg490, Lys353). Further, the vanadate forms hydrogen bonds with a glycine (Gly403) and a serine residue (Ser402). There is also a histidine residue (His404) close to the apical hydroxyl moiety of the vanadate which may act as an acid/base group in catalysis. These residues are in fact the same as in bromoperoxidase and the active sites are structurally nearly superimposable.[10] The pocket where vanadate is bound is at the end of a channel which supplies access and release of the small substrates and products of the reaction. Part of the surface of the channel is mainly hydrophobic with Pro47, Pro221, Trp350, Phe393, Pro395 as contributing side chains. The other half of the channels is predominantly polar with several carbonyl oxygens and the ion pair Arg490-Asp292. It is interesting to note that the Arg490 is also directly bound to the orthovanadate. A prominent difference in the active site architecture of the bromo- and chloroperoxidase is the presence of a second histidine in the bromoperoxidase, a residue substituted by a phenylalanine in chloroperoxidase.[24] Site-directed mutagenesis of this residue into a histidine partially abolished the chlorinating activity and surprisingly the mutant showed a higher k_{cat} in the bromination reaction at high pH values than the native enzyme.[37]

3.6 Homology Between Haloperoxidases and Acid Phosphatases

The vanadate-binding residues in the active site of the vanadium chloroperoxidase were shown to be conserved in two bromoperoxidases from seaweeds and a large group of phosphatases including glucose-6-phosphatase.[45] Based on the sequence similarity, it was concluded that the architecture of the active sites in the two classes of enzymes is very similar.[45] The X-ray structure of the acid phosphatase from *Escherichia blattae* (Figure 7b) confirmed the remarkable similarity of the residues binding the oxyanions.[46] Sulfate cocrystallizes with the acid phosphatase and its binding site is comparable to that of vanadate in the chloroperoxidase. Remarkably, the apochloroperoxidase has some phosphatase activity though the turnover with *para*-nitrophenyl phosphate as a substrate is about 10 000 times slower than that of the various acid phosphatases. However, the K_M for the substrate is of the same order of magnitude as various acid phosphatases. The data show that the active site of the haloperoxidase has a good affinity for the substrate but is not optimized for phosphatase activity.

Similarly, when vanadate is introduced in the active site of the acid phosphatases, these artificial enzymes are able to oxidize bromide in the presence of H_2O_2 and to sulfoxidize sulfides in an enantioselective manner. The turnover frequency

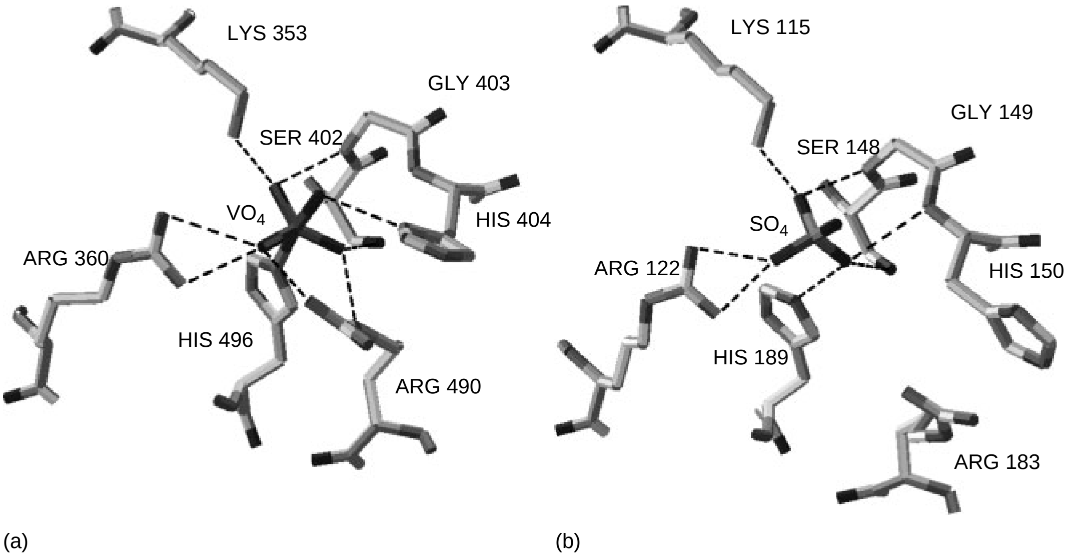

Figure 7 The active site of vanadium chloroperoxidase from *C. inaequalis* (a) and the acid phosphatase from *E. blattea* (b)

of the bromide oxidation and the specificity constant are however very low. The family of acid phosphatases that contains this active site is very large. These include glucose-6-phosphatase, lipid phosphatases from bacteria and yeast, and lipid phosphatases from higher eukaryotes that are involved in signal transduction and secreted bacterial acid phosphatases. Proteins from this superfamily have different physiological functions and are found in species varying from *E.coli* to humans. However, vanadium-containing haloperoxidases have thus far only been isolated from eukaryotes and are not detected yet in prokaryotes. Since phosphate and phosphate-metabolizing enzymes have entered evolution in an early stage it seems likely that vanadate was coined by nature to become the prosthetic group in the vanadium-containing haloperoxidases at a more recent stage and thus that these enzymes have evolved from the phosphatases.

4 VANADIUM IN TUNICATE VANADOCYTES

4.1 Introduction

Ascidians or tunicates (Phylum Chordata) belong to the class of Ascidiacea and are common marine animals whose body is enclosed in a jacket or tunic. The animals are attached to rocks and are either solitary or colonial. They continuously filter seawater to obtain minute organisms and particulate organics. As was originally discovered by Henze[47] the animals concentrate vanadium from seawater to levels about 10^6 times that present in seawater (35 nM), a phenomenon that has attracted considerable interest. The transition metal is present in very high concentrations (up to 150 mM) in certain blood cells of the animal.

4.2 Cell Types

There is considerable confusion concerning the cells that contain vanadium. Tunicates possess several types of blood cells: lymphocytes, leucocytes, pigment cells, and cells containing vacuoles, that is, signet ring cells, morula cells, and compartment cells. The bulk of the vanadium is contained within the signet ring cells and compartment cells. Morula cells were originally thought to be involved in the accumulation of vanadium and thus were named vanadocytes. However, from a comparison of vanadium distribution over the 4 bands of blood cells from *Ascidia gemmata* and *A. ahodori* with the main population of the various cells in these bands, it was concluded that the morula cell contains little or no vanadium.[11] This was confirmed recently by scanning X-ray microscopy at the European Synchrotron Radiation Facility.[11] The data also clearly show that vanadium is present in the vacuoles in the signet ring cells of *P. mammallita* blood cells. In contrast, in *A. ceratodes* and *A. mentula* a significant amount of vanadium is also found in the morula cells. Clearly the presence of vanadium in a cell type depends on the species investigated and there is not a specific vanadocyte in the various *Ascidia*. Thus care should be taken not to extrapolate results from one species to another even if they are closely related.

4.3 Valence State and Intracellular pH

A number of biophysical techniques have been used to probe the valence state of vanadium in blood cells and their intracellular pH. Most data suggest a predominance

of vanadium^{III}; the vanadium^{IV} state which can be detected by EPR, is probably due to oxidation by oxygen.[48] Similarly, Magnetic Susceptibility Measurements show that vanadium^{III} is the predominant species in the blood sample of *A. nigra*.

pH measurements showed that for signet ring cells of *A. gemmata*, *A. ahodori*, and *A. sydneinsis*, which contain the highest concentration of vanadium, pH values of 2.4, 2.7, and 4.2, respectively, were found. These low pH values support the X-ray absorption spectroscopy (XAS) measurements,[11,49] which indicate that nearly all the vanadium is present in the form of unchelated vanadium^{III} coordinated only to water. Whole blood cells also contain large amounts of intracellular sulfate as is evident from sulfur X-ray Absorption Near Edge Structure (XANES), suggesting that the vanadium^{III} is present as a sulfato complex ion.[11] An aliphatic sulfonic acid analogous to cysteic acid was also identified, the overall concentration of which is unprecedented in marine organisms and is comparable to that of sulfate in the blood cells and further, is approximately equal to that of vanadium. There are no clues as to the role of the high levels of the sulfate in vanadocytes.

The acidity of the blood cells is due to the low pH within the vacuole and a clear correlation between the acidity of the vacuoles and the concentration of vanadium in the vacuole has been shown.[11] An ATPase appears to be involved in generation and maintenance of the low pH. Addition of an ATPase inhibitor neutralizes the vacuole content. If one accepts that there is a link between the low pH in the blood cells and accumulation of vanadium, there is no need to invoke a mechanism stabilizing the vanadium^{III} state since oxidation at low pH will not occur. Obviously there should be a mechanism to accumulate vanadium and to reduce the vanadate from seawater to the vanadium^{III} state. A vanadium-binding protein vanabin has been identified that has a very high content of cysteine residues, its role may be trapping vanadium^{V} and subsequent reduction to the IV state.[50] These vanadium-binding proteins bind up to 20 vanadium^{IV} ions per mol of vanabin; however, the affinity for vanadium^{IV} is not very high (K_d 21 µM) in view of the concentration of vanadium in seawater. The affinity of the vanabins for vanadium^{V} has not yet been reported and may be much higher. The suggestion has been made that NADPH generated by the pentose phosphate pathway is involved in the reduction step. However, vanadium^{V} is easily reduced to the IV state by most biological reductants. The reductant involved to reduce the IV state to the III state, however, remains a mystery.

Tunicates not only contain a considerable amount of vanadium but also contain the biomolecule tunichrome which is mainly present in morula cells. Tunichrome makes up 50% of the dry weight of these cells. This blood pigment consists of a class of tripeptides containing di- and trihydroxybenzene substituents with strong chelating and reducing properties towards transition metals such as iron and vanadium.[11] These compounds coordinate and reduce vanadium^{V} and also vanadium^{IV} to the III oxidation state. However, the signet ring cells from the tunicates (*A. ahodori*) do not seem to contain tunichrome and its role in the reduction of vanadate remains doubtful.[11]

The physiological role of the vanadium accumulation is still a mystery. Several proposals have been made in the last 5 decades. One proposal suggests that vanadium acts as an electron sink.[51] This sink for electrons may be used by the animals to regenerate $NADP^+$ when they are exposed to anaerobic conditions. It should be noted that there is apparently no oxygen transport system in the circulation of these animals and oxygen may often be limiting. Under aerobic conditions, the vanadium^{III} may reoxidize to a higher oxidation state. It is clear that still many pieces of the puzzle relating vanadium uptake, redox reactions and low pH in the vacuoles are missing. However, the approach[11] to elucidate the functions of genes and proteins obtained from ascidian blood cells may well lead to clarification of the entire mechanism involved in accumulation and reduction of vanadium in ascidian vanadocytes.

4.4 Vanadium in Fan Worms

Fan worms belonging to the genus *Pseudopotamilla* also contain a high concentration of vanadium.[52] Most of the vanadium in this worm is located in the branchial crown and more specifically in the vacuoles of the epidermal cells. Sulfur seems to be colocalized with vanadium. EXAFS spectral data on living *P. occelata* indicate that most of the vanadium *in vivo* exists in the vanadium^{III} state. Analysis of the XANES data indicates that the vanadium is present in solution in the form of an aqua complex with symmetrical octahedral coordination. Vanabin may also be present since the animal possesses antigens recognized by a monoclonal antibody raised against vanabin from *Ascidia sydneinsis*. The physiological role of vanadium in the animal is not known.

4.5 Vanadium as a Terminal Electron Acceptor in Bacteria

Microbial reduction of metals of variable valence is a universal method by which microorganisms are able to regenerate NADH and this process is in general coupled to ATP synthesis. Vanadium has all the properties necessary for utilization by microorganisms in respiratory processes. The metal occurs in different oxidation states and it occurs extensively in the earth's crust. A search for bacteria in habitats rich in vanadium, like wastewater from a plant processing vanadium-containing slags, resulted in the finding that *Pseudomonas* strains under anaerobic conditions reduce vanadate to the tetra and trivalent states with organic electron donor as well as with molecular hydrogen and carbon monoxide.[53] Clearly, under anaerobic conditions, vanadate may act as the terminal electron acceptor in these bacteria. These observations give some weight to the hypothesis that vanadate in tunicates is also used as an electron sink under anaerobic conditions.

5 AMAVADIN

The first report that vanadium occurs in fungal species dates back to 1931 when it was reported[54] that the fly agaric *Amanita muscaria* contains a high concentration of this element. Also in other *Amanita* species, such as *A. regalis* and *A. velatripes*, high amounts (up to 400 ppm) were found. Most other mushroom species have much lower vanadate concentrations. Apparently, vanadium is present in the IV state. The first EPR spectrum reported of an extract of the cap of the mushroom showed clearly an EPR signal characteristic of vanadium^{IV}. The pale blue vanadium-containing compound from *A. muscaria* which was isolated later was named amavadine.[55] Structural elucidation has been controversial and many model complexes analogous to amavadine were reported.[9] Crystallization of the amavadine and structure determination gave the final clue to the peculiar structure of amavadin (Figure 8).[56]

The vanadium^{IV} is eightfold coordinated to nitrogen in an unusual geometry and a V=O group is lacking. Amavadine possesses five chiral centers: four chiral centers all have the S configuration and the fifth chiral center is generated by the manner in which the ligands to the vanadium wrap around the vanadium atom.[56] The electrochemistry of amavadine is such that the compound may have a role in electron transfer reactions involving the vanadium$^{V/IV}$ redox couple. Studies have shown that amavadine can catalyze thiol oxidation.[57] Amavadine also has some peroxidase-like activity. In the presence of hydrogen peroxide it is able to oxidize halides and catalyze the hydroxylation and oxygenation of alkyl and aromatic substrates.[9] Interestingly, it was reported recently by the Portuguese group that amavadine could convert methane into acetic acid in the presence of peroxodisulfate and trifluoroacetic acid. Other vanadium complexes could replace amavadine.[58] Despite all these studies, the physiological function of amavadine in mushrooms is still elusive.

1 INTRODUCTION

This article is essentially an update of the article of the same name published in the first volume of this Encyclopedia.[1] The present article includes a survey of the literature from the years 1992 to 2002 inclusive, but a number of references from the prior literature are included for continuity and completion. For ease of cross-reference, the format of the first article has also been retained as far as possible, with additions and deletions to reflect the advances in the chemistry of vanadium that have occurred since the period surveyed by the first article.

2 THE ELEMENT

2.1 Occurrence, Uses, and Properties

2.1.1 Occurrence and Properties

Although the existence of vanadium was first claimed in 1801 by del Rio, it was identified independently in 1831 by Sefstrom who named the element vanadium after the Scandinavian goddess Vanadis. In 1869, Roscoe succeeded in isolating pure metallic vanadium by the reduction of VCl_2 with H_2 under conditions that required rigorous exclusion of air and moisture.

Vanadium is widely distributed in nature, it forms up to 0.05% of the earth's crust and there are over 60 vanadium ores. Vanadium occurs widely in coal and certain petroleums, especially those from Venezuela (up to 1%), in the form of oxovanadium(IV) porphyrins.[1,2] The major world producers of vanadium in recent years have been the United States, South Africa, and Finland.

The major industrial use of vanadium is in alloy steels and cast iron, to which it lends ductility and shock resistance. Commercial production is mainly as the iron alloy ferrovanadium, a tough, high-speed steel containing around 4−5% V. In ferrovanadium manufacture, vanadium pentoxide is reduced in an airtight electric furnace by ferrosilicon.[1,3]

The pure metal is much more difficult to obtain because of its reactivity with C, N_2, H_2, and O_2. There are four different routes to its production; reduction of chlorides, reduction of the oxide, thermal dissociation of the iodide, and an electrochemical process.[1,4,5]

Vanadium has atomic number 23, atomic mass 50.94, and a density of 6.0 g cm^{-3}. Bulk samples are inert to air, moisture, alkalis, and other nonoxidizing acids other than HF at 25 °C. However, the metal is attacked by conc. H_2SO_4, HNO_3, and aqua regia. At elevated temperatures, vanadium combines with most nonmetals including N_2, C, Si, and B to give a variety of products such as VC, VSi_2, V_3Si, VB, and VB_2. Most of these compounds are nonstoichiometric and interstitial. In air, V_2O_5 is formed along with lower oxides.[1,6]

Vanadium metal forms definite compounds with several other metals and forms a solid solution in all proportions with titanium. It shows catalytic activity in a wide number of applications.[1,6]

Vanadium is an essential element[7,8] and the biochemistry of vanadium is dealt with elsewhere (*see* ***Vanadium in Biology***). Here it is worth pointing out that the importance of vanadium in several biological systems has led to an upsurge in the extent and breadth of the coordination chemistry of the element.

The toxicity of vanadium is well known. No matter by which route the metal is absorbed, it acts by depressing the respiratory center, constricting the peripheral arteries of the viscera, and causing hyperperistalsis and enteritis. It has also been shown to be one of the few metals that can modify amino acid secretion. The effects of the vanadate(V) ion on the

cardiovascular system have been studied. Numerous enzymes are inhibited by vanadium ions or their complexes.[1]

2.1.2 *Analytical Chemistry*[1,9,10]

Analytical methods for the quantitative determination of vanadium by volumetric, colorimetric, or gravimetric techniques are all available.

Chemical Methods. In general, vanadium is reduced to the +II oxidation state by zinc amalgam, the vanadium can then be determined volumetrically by oxidation with a standard oxidizing agent (e.g. $KMnO_4$) to the +V state. The formation of the reddish-brown peroxo-complex is used as the basis of a colorimetric technique for the determination of vanadium. Gravimetric techniques are not as useful for the determination of vanadium as the volumetric and colorimetric techniques.

Spectroscopic Techniques. In absorption spectroscopy, Vanadium(V), a d^0 system, shows no transitions in the visible region. The yellow color of some V^V complexes can be ascribed to the tail of an intense absorption in the ultraviolet. Absorption spectroscopy is more useful for V^{IV} systems ($3d^1$), where electronic energies of transitions generally correlate well with ligand type and with electron spin resonance (ESR) parameters.

^{51}Vanadium NMR is a useful diagnostic tool for the detailed investigation of V^V coordination environments. The large magnetic moment of the ^{51}V nucleus, its high natural abundance (99.76%), and favorable relaxation properties make it a useful probe for the investigation of vanadium in its isolated complexes and in biological systems. This area has been reviewed recently.[11–13]

ESR spectroscopy is often used to study the VO^{2+} ion and its complexes. The unpaired electron is strongly coupled to the ^{51}V nucleus to give ESR spectra consisting of eight-line manifolds in frozen solution. The hyperfine coupling constants and g-factors are sensitive to the ligand field of the vanadium atom.[1,7]

Superhyperfine interactions are rarely observed in the ESR spectrum of the VO^{2+} ion because the unpaired electron interacts only weakly with the ligand nuclei, so that often the size of the coupling is less than the ESR bandwidth. This problem has been surmounted through the use of ENDOR spectroscopy.[1,7] In ENDOR spectroscopy, molecules with their V=O axes either parallel or perpendicular to the direction of the static magnetic field are selectively irradiated. In this way, the anisotropic superhyperfine coupling constants of ^1H and ^{14}N and the ^{14}N quadrupolar coupling constants can be obtained.

EXAFS has recently become more extensively used in the study of vanadium in complexes and in biology to investigate the nature of the local environment around the vanadium atom.[14,15]

3 BINARY COMPOUNDS

3.1 Hydrides

Vanadium can absorb hydrogen reversibly up to the final composition $VH_{0.94}$ when heated at 300 °C in a 48.4% hydrogen atmosphere at 1 atm pressure.[1] The product is a gray metallic material whose brittleness increases with increasing hydrogen content. The structure is of a single phase having a tetragonal unit cell and lattice parameters $a = 3.02$, $c = 3.36$.[2] A recent review on vanadium hydrides is available.[16] Stoichiometric vanadium hydrides such as VH_4 have been observed spectroscopically[17] in an H_2 matrix at 2–4 °K and coordination compounds containing V–H bonds are described later in this article (see Sections 4.3.2 and 4.4.2).

3.2 Halides

The halides are extremely important compounds providing convenient starting materials for other species. Their preparations and properties have been comprehensively reviewed elsewhere[1,4,18] and references to individual synthetic methods can be found in these works. The halides are discussed here in order of decreasing oxidation state.

3.2.1 *Pentavalent State*

Vanadium Pentafluoride, VF_5. Vanadium pentafluoride is the only pentahalide so far reported. It is best prepared by direct reaction between metallic vanadium and fluorine in a flow system at 300 °C under moisture free conditions. It is an extremely reactive white solid at room temperature and an extremely powerful oxidizing and fluorinating agent.

Crystalline VF_5 is isomorphous with $MoOCl_4$ and the pentafluorides of Cr, Tc, and Re. The structure consists of infinite chains of octahedrally coordinated vanadium atoms linked by shared fluorine atoms.[19] In the gas phase, electron diffraction has shown VF_5 to exist as a monomeric molecule having D_{3h} symmetry.[20]

3.2.2 *Tetravalent State*

VF_4, VCl_4, and VBr_4 are all well documented, but VI_4 has been detected only in equilibrium mixtures and to date has not been isolated.

Vanadium Tetrafluoride. VF_4 is formed along with VF_5 and VF_3 in the fluorination of metallic vanadium and the difference in volatilities of the three fluorides allows their separation by fractional sublimation. It can also be prepared by treatment of VCl_4 with anhydrous HF in an inert solvent such as CCl_3F at −78 °C. Pure VF_4 is a bright green hygroscopic solid, which disproportionates at 100 °C to VF_5 and VF_3. Its structure consists of octahedrally coordinated VF_6 units linked

by shared F atoms into polymeric strings.[1,21] VF_4 reacts with BF_3 or F_2 to give VF_5, but is a weaker fluorinating agent than the latter.

Vanadium Tetrachloride. VCl_4 is produced in the reaction between dry chlorine and vanadium or by the action of chlorinating agents such as $COCl_2$, $SOCl_2$, S_2Cl_2, or CCl_4 on V_2O_5 or the metal itself.[1] It is a reddish-brown, viscous liquid, mp = −26 °C, bp = 153 °C, which is hydrolyzed readily in moist air. It is soluble in nonpolar solvents such as CCl_4 and reacts violently with electron donor solvents to form adducts. VCl_4 is monomeric in the vapor phase having a regular tetrahedral structure.[1] Decomposition of the tetrachloride to VCl_3 and Cl_2 occurs slowly at room temperature, even under a positive pressure of chlorine.

Vanadium Tetrabromide. VBr_4 has been isolated by quenching (−78 °C) the vapor obtained from heating the solid tribromide to 325 °C. Although it is stable only up to −45 °C, decomposing to VBr_3 and Br_2, its absorption spectrum in the range 200–600 nm has been obtained.[22]

Vanadium Tetraiodide. VI_4 is unstable and has not been isolated, but its absorption spectrum has been observed in the range 230–500 nm in the vapor, and thermodynamic data for its dissociation into VI_3 and I_2 have been determined[23] ($\Delta H^\circ = 104.8\,\text{kcal m}^{-1}$, $\Delta S^\circ = 98.4\,\text{kJ m}^{-1}$).

3.2.3 Trivalent State

Vanadium Trifluoride. VF_3 is prepared by passing anhydrous HF in N_2 over VCl_3 or VCl_2 at 600 °C in a platinum crucible. The structure is rhombohedral, each vanadium atom having an almost regular octahedron of fluorine atoms with the octahedra joined by shared corners.[1] Pure anhydrous VF_3 is yellowish-green in color. It is slightly soluble in water, giving acidic solutions, and is virtually insoluble in organic solvents. It sublimes without decomposition at 800 °C.

Vanadium Trichloride. VCl_3 can be prepared by decomposition of vanadium tetrachloride under reflux or by heating the trioxide, V_2O_3, with thionyl chloride.[1] Its structure is similar to that of α-$TiCl_3$ and is composed of hexagonally close-packed chloride ions, with vanadium atoms occupying 2/3 of the octahedral interstices in alternate layers. Within a layer, each VCl_6 octahedron has three neighboring VCl_6 octahedra with which it shares edges.[1] VCl_3 disproportionates above 600 °C, to VCl_4 and VCl_2 and therefore cannot be sublimed. It is also extremely sensitive to traces of oxygen, which results in the formation of oxochlorides.

Vanadium Tribromide. VBr_3 is formed directly from the reactions of bromine with vanadium or its nitride or carbide at elevated temperatures.[1] More recently, it has been prepared from the reaction between V_2O_5 and CBr_4 and by treatment of VCl_4 with dry HBr.[24] It is purified by sublimation at 350 °C in a bromine atmosphere, which reverses the dissociation to VBr_2 and Br_2. Anhydrous VBr_3 is a grayish-black crystalline powder with a structure analogous to that of VCl_3.[1]

Vanadium Triiodide. VI_3 can be prepared by reaction of vanadium metal with iodine at elevated temperatures. It is a brownish-black, hygroscopic crystalline powder, soluble in most nonpolar solvents, that begins to dissociate into VI_2 and I_2 at 270 °C.[1]

Vanadium Iodo-Chlorides. The reaction of VCl_4 with dry HBr has been reported to give the mixed halides $VClI_2$ and VCl_2I.[24]

3.2.4 Divalent State

The preparations, structures, and properties of V^{II} halides have been reviewed.[1,25]

VF_2 forms deep blue crystalline needles having the rutile type structure with two VF_2 units per unit cell. VCl_2 and VBr_2 can be prepared from the appropriate trihalide by their reduction by dihydrogen or by their disproportionation at an elevated temperature. VI_2 can also be prepared by direct reaction of the elements.

VBr_2 has a layered triangular lattice in the range 1.5–35 °K and is a Heisenberg antiferromagnet.[26] Two forms of VI_2 are produced, depending upon the reaction temperature. The red form has the CdI_2 structure; the black form is closely related but with mixed hexagonal and cubic close-packing of iodide ions.[1] VCl_2 sublimes without decomposition in an inert or HCl atmosphere above 900 °C. Similarly, VBr_2 and VI_2 sublime without loss of halogen in the range 800–900 °C. The dihalides are hygroscopic and dissolve in water to yield blue–purple solutions of $[V(H_2O)_6]^{2+}$. Acidic solutions of the dihalides are strongly reducing.[1]

3.3 Oxohalides

The oxohalides form an important set of compounds, closely related to the halides. Their preparations and properties are well-documented[1,4,27,28] and therefore only a summary is given here.

3.3.1 Pentavalent Oxohalides

The following oxohalides are known for vanadium(V): $[VOX_3]$ (X = F, Cl, Br) and VO_2X (X = F, Cl); preparative routes are available for all.[1,4]

$[VOCl_3]$ is a pale yellow liquid with physical properties similar to VCl_4. $VOBr_3$ slowly decomposes at 25 °C to $VOBr_2$

and Br_2. Both compounds are extremely unstable toward moist air. The gas-phase structures of [$VOCl_3$] and [$VOBr_3$] consist of trigonally distorted tetrahedra as predicted for [VOF_3].[1,4]

3.3.2 *Tetravalent Oxohalides*

All the oxohalides of vanadium(IV), [VOX_2] (X = F, Cl, Br), are known. In general, the complexes are green and monomeric and their chemistry is dominated by the strong vanadium–oxygen bond of the VO^{2+} group. The hydrates [VOF_2]·4H_2O and [VOF_2]·2H_2O are known and several hydrates of [$VOCl_2$] have been reported, of which the best known is [$VOCl_2$]·2.5H_2O, but many of their stoichiometries are uncertain.

3.3.3 *Trivalent Oxohalides*

Crystalline VOCl, prepared by reaction between V_2O_5 and VCl_3, has a layered structure. Each oxygen atom is surrounded by a tetrahedron of vanadium atoms. Each vanadium atom is surrounded by four oxygen and two chlorine atoms in a distorted octahedral arrangement.[1]

3.4 Oxides (*See Oxides: Solid-state Chemistry*)

These have been described in a number of general texts.[1,28] In addition, a number of phases of intermediate composition have been identified, and the lower oxides, in particular, have wide ranges of homogeneity. There is a vast chemistry of polyoxovanadates, which are of interest with regard to their structural and catalytic properties,[29,30] but discussion of their chemistry is outside the scope of this article.

3.4.1 *Pentavalent State*

V_2O_5 is well known and has a structure that essentially comprises distorted trigonal bipyramids of VO_5 sharing edges to form zigzag double chains.[1,31,32] V_2O_5 loses dioxygen reversibly on heating, and this may partly explain its function as a catalyst in a wide variety of both organic and inorganic reactions, an important example being the oxidation of SO_2 to SO_3 in the contact process for the manufacture of sulfuric acid. It is reduced by a number of reagents, such as H_2, C, CO, SO_2, alkali metals, Al, and Ca. The products include the lower oxides, VO_2, V_2O_3, and VO, as well as many other distinct oxide phases. With chlorine it forms oxotrichloride and dioxygen, and with metal oxides it forms vanadates.[1]

V_2O_5 is slightly soluble in water, producing a pale yellow, acidic solution that readily becomes colloidal. In alkalis, it dissolves to form colorless solutions, the nature of the species present depending upon the pH. At high pH, the orthovanadate ion $[VO_4]^{3-}$ is formed, and at intermediate pH a series of hydrolysis–polymerization reactions occur, forming isopolyvanadates.[1,32]

3.4.2 *Tetravalent State*

VO_2 may be prepared by the mild reduction of V_2O_5 with reducing agents such as CO, SO_2, oxalic acid, or hydroxylamine hydrochloride.[1,28,33] At room temperature, it has a distorted rutile structure but above 341 K, an undistorted rutile structure is adopted. Both phases consist of edge-sharing VO_6 octahedra with similar O frameworks.[34] On passing from the low-temperature to the high-temperature form, the V^{4+}-V^{4+} distance changes[34] from 2.7695 Å to 3.0794 Å. VO_2 is amphoteric, dissolving in nonoxidizing acids to give solutions containing the blue oxovanadium(IV) (vanadyl) ion $[VO]^{2+}$, and in alkalis to give the yellow–brown vanadate(IV) (hypovanadate) ion $[V_4O_9]^{2-}$. $[VO_4]^{4-}$ is formed at high pH.[1]

3.4.3 *Tervalent State*

V_2O_3 may be prepared by reduction of V_2O_5 by reducing agents such as C, CO, or H_2. It crystallizes with the corundum structure.[1,28] It is believed to possess only a narrow range of homogeneity. V_2O_3 is antiferromagnetic, having a transition temperature of approximately 160 K. It is readily oxidized in air to VO_2, and may be reduced to the metal by calcium hydride. It reacts with thionyl chloride to give VCl_3. V_2O_3 is basic, dissolving in aqueous acids to give blue or green V^{III} solutions that are strongly reducing.[1]

3.4.4 *Divalent State*

VO is formed as a gray metallic powder by the reduction of higher oxides with a variety of reducing agents such as vanadium or potassium. It has a defect NaCl structure with a wide range of homogeneity, $VO_{1.20}$–$VO_{0.75}$. Above 950 °C, in a vacuum, it decomposes into vanadium metal and V_2O_3. It is an electrical conductor and is paramagnetic between 77 and 300 K. VO is basic and dissolves in mineral acids to give a violet solution of vanadium(II).[1]

3.4.5 *Other Oxides*

In addition to the phases already mentioned, many others in the composition range V_2O_5–VO have been investigated.[1,28,35] Between V_2O_5 and VO_2, there is a succession of phases of general formula V_nO_{2n+1}, of which V_3O_7, V_4O_9, and V_6O_{13} have been characterized. V_6O_{13} is obtained as a blue–black crystalline powder, and is formed by loss of oxygen from one-third of the V_2O_5 [010] planes on heating. Between VO_2 and V_2O_3, there is a series of shear phases, Magneli phases, of general formula V_nO_{2n-1}, based on a rutile structure

with periodic defects. Examples are V_8O_{15}, V_7O_{13}, V_6O_{11}, V_5O_9, and V_4O_7. V_3O_5, which is also known, and V_2O_3 and VO also conform to this general equation, but their structures are not related by chemical shear to those of the Magneli phases. On further reduction of the system, the corundum structure of V_2O_3 is retained down to compositions as low as $VO_{1.35}$, after which VO is formed. This is also nonstoichiometric, with a composition range of $VO_{0.75}$ to $VO_{1.20}$.

3.5 Sulfides

A number of vanadium sulfide phases, ranging from VS_4 to V_3S, have been reported, although few have been well characterized and some may not exist at all. The structures, where known, are often complicated and difficult to describe.[1,28,36]

3.5.1 VS_4

VS_4 may be prepared by the reaction of V_2S_3 with an excess of sulfur at 400 °C. It is a diamagnetic black powder, with a fibrous structure similar to SiS_2, but with S_2^{2-} ions replacing S^{2-} ions. It is a semiconductor. VS_4 is thermally unstable above 500 °C and dissolves readily in alkalis but not in acids.[1,28]

3.5.2 V_2S_5

This compound is obtained by thermal decomposition of ammonium thiovanadate, $(NH_4)_3[VS_4]$. It is readily decomposed to V_2S_3 and free sulfur, and this may be the reason for doubts about its existence.[1,28]

3.5.3 VS_2

Little is known about this sulfide, which is believed to have the CdI_2 structure.[1,28]

3.5.4 V_2S_3

V_2S_3 has a range of homogeneity extending from $VS_{1.17}$ to $VS_{1.53}$. It is obtained as a black paramagnetic solid from the reaction of H_2S on V_2O_3, VO_2, or V_2O_5, or by treating V_2O_5 with carbon disulfide at 700 °C. On heating to 850–950 °C in a vacuum, it dissociates into VS and sulfur. It is oxidized by air and nitric acid, but is insoluble in dilute alkali.[1,28]

3.5.5 VS

This sulfide has a range of homogeneity extending from $VS_{1.00}$ to $VS_{1.16}$. It is obtained as an air-sensitive brownish-black solid by dihydrogen reduction of V_2S_3 at 1000 °C or by reaction between the metal and sulfur in a sealed silica tube at 1000 °C. VS has the NiAs structure and is metallic with essentially temperature-independent paramagnetism.[1,28]

3.5.6 V_3S_4

A high-temperature and a low-temperature form are known. The low-temperature form is hexagonal, isotopic with Nb_3S_4 and transforms above 825 °C to the monoclinic form, which is stable above 950 °C. This form is isostructural with Cr_3S_4.[37,38]

3.5.7 V_5S_4

This sulfide is tetragonal and isostructural with Ti_5Te_4.[1,28]

3.6 Sulfates

The only simple sulfates of vanadium are formed in the oxidation states +3 and +2. Vanadium(III) sulfate can be crystallized as a hydrate from aqueous solution, and is strongly reducing. It gives rise to a series of alums of the type $M^IV(SO_4)_2\cdot12H_2O$, which have been shown to contain the $[V(H_2O_6)]^{3+}$ ion. The ammonium alum, $(NH_4)V(SO_4)_2\cdot12H_2O$, is obtained as air-stable blue–violet crystals by electrolytic reduction of $NH_4[VO_3]$ in sulfuric acid.[1,28]

The violet divalent sulfate $VSO_4\cdot7H_2O$ may be prepared by electrolytic sodium amalgam, or by zinc reduction of a solution of vanadium pentoxide in sulfuric acid, followed by evaporation of the resulting solution in a vacuum over phosphorous pentoxide. It is also strongly reducing, and evolves dihydrogen in water, but not in acid solution. The hexahydrate, $VSO_4\cdot6H_2O$, is obtained by electrolytic reduction of vanadyl(IV) sulfate solution.[21,28]

Both the hepta- and hexahydrate give rise to the reddish-violet Tutton's salts, $M_2[V(H_2O)_6]\cdot(SO_4)_2$ (M = NH_4, K, Rb, or Cs), on treatment of an aqueous solution of the salt with the appropriate alkali metal sulfate. These salts have the schonite, $K_2Mg(SO_4)_2\cdot6H_2O$, structure. They are more stable than the simple sulfate, especially in the presence of excess acid.[1,28]

3.7 Selenides and Tellurides

Several studies have been carried out on the vanadium–selenium and vanadium–tellurium systems,[1] and some of the components of these systems are described below. Vanadium diselenide, $V_{1+x}Se_2$ ($0.02 < x < 0.18$) has a structure of the $Cd(OH)_2$–NiAs type. Several other phases, such as V_5Se_8, V_3Se_4, and V_7Se_8, have ordered superstructures of this type. VSe has the hexagonal NiAs structure. The vanadium-rich

phase V_5Se_4 has a tetragonal structure. The magnetic susceptibility of V_5Se_8 increases significantly with temperature, but VSe_2, V_3Se_4, and the selenides richer in vanadium are metallic, with essentially temperature-independent paramagnetism.[1,39]

Vanadium ditelluride, $V_{1+x}Te_2$ ($0.03 < x < 0.14$), has a monoclinic structure related to that of $Cd(OH)_2$. The nonstoichiometric phases V_5Te_8 and Ve_3Te_4 have superstructures intermediate between the $Cd(OH)_2$ and NiAs types. The vanadium-rich phase, V_5Te_4, is monoclinic. The vanadium tellurides are metallic, with essentially temperature-independent paramagnetism.[1,39]

3.8 Nitrides

Vanadium nitride, VN, with a range of homogeneity from $VN_{1.00}$ to $VN_{0.71}$, may be prepared as a grayish-violet powder by the action of dinitrogen on a mixture of V_2O_3 and carbon at 1250 °C, or by the reaction of vanadium and dinitrogen or ammonia at 900–1300 °C. It is also formed by the thermal decomposition of $(NH_4)_3[VF_6]$ at 600 °C. It has the sodium chloride structure. It reacts with alkalis to give ammonia, and it is also attacked by boiling nitric acid. Another phase, V_2N, with a range of homogeneity from $VN_{0.5}$ to $VN_{0.37}$ is also known.[1]

3.9 Phosphides, Carbides, Silicides, and Borides

The V/P, V/C, V/Si, and V/N systems have been studied over various composition ranges and the main phases correspond to the stoichiometries V_3P, VP, VC, V_3Si, V_5Si_3, VSi_2, V_3B_2, VB, V_3B_4, and VB_2.[1]

3.10 Phosphates

The binary phosphate $V(PO_3)_3$ can be prepared by heating $V_2O_5/H_3PO_4/H_2SO_4$ mixtures at 300 °C. The structure is monoclinic consisting of a mixed network of VO_6 octahedra and PO_4 tetrahedra bonded at the apices into chains.[1,28]

4 COORDINATION CHEMISTRY OF VANADIUM

4.1 Introduction

The coordination chemistry of vanadium is dominated by its variable oxidation numbers, which range over the −I, 0, +I, +II, +III, +IV, and +V states. A very large number of compounds have been prepared, particularly for the higher oxidation states, since the previous edition of this Encyclopedia and reviews have appeared on general coordination chemistry,[40–43] structural advances,[44] aqueous vanadate chemistry,[45] and biologically related topics, including vanadium as a phosphate analogue, haloperoxidases, amavadin, and other biological systems,[46–48] and modeling of vanadium nitrogenase.[46,49]

Much of the recent coordination chemistry of vanadium has been stimulated by interest in the biological significance of the element. Vanadium is important in both reductive[49] and oxidative catalytic transformations[46–48] in biological chemistry (*see* ***Vanadium in Biology***).

Vanadium is known to exist in petroleum and shale deposits as a porphyrin complex.[50] Many catalytic processes that take place in oil production or advanced coal conversion may be critically affected by the presence of trace amounts of vanadium. Also it is known that vanadium, in combination with S compounds, can cause problems in oil hydroprocessing. Investigation of the manner in which V is present in coal, oil, and bitumen has resulted in many studies on porphyrin complexes of V^{IV} and V^{II}.[50,51]

The types of coordination complexes known for vanadium in its various oxidation states are discussed in the following sections.

4.2 Coordination Complexes in Low Oxidation States (<2) (*See also Vanadium: Organometallic Chemistry*)

Complexes containing vanadium in low oxidation states, apart from organometallic compounds, are known with ligands such as bipy, phen, nitric oxide, and tertiary phosphines, which stabilize such oxidation states.[1] Depending on their electronic structure, V^I and V^{-I} complexes may be diamagnetic, which permits study by NMR spectroscopy, and EPR spectroscopy has been used to study paramagnetic V^0 complexes.

4.2.1 Vanadium(-I)

Reduction of $[V(bipy)_3]I_2$ with the metals Mg or Zn yields the complex $[V(bipy)_3]$, which will undergo further reduction by lithium aluminum hydride to $Li[V(bipy)_3]\cdot 4THF$, which formally contains V^{-I}. Similarly, reduction of $[V(phen)_3]$ with dilithium naphthalenide or dilithium benzophenone in THF yields $[V(phen)_3]I_2$. Further reduction with dilithium benzophenone gives the V^{-I} complex $Li[V(phen)_3]\cdot 3.5THF$. The terpyridyl complex $[V(terpy)_2]$ can be obtained as black crystals by reduction of DMF solutions of $[V(terpy)_2]I_2$ with Mg or LiAlH. Such low oxidation state complexes are highly air sensitive and decompose if heated to 100–200 °C in a vacuum. In these systems, the ligands may have an anion radical character.[1]

Tertiary phosphines, together with dinitrogen ligands, stabilize the V(-I) state in complex anions such as *trans*-$[V(N_2)_2(Ph_2PCH_2CH_2PPh_2)_2]^-$, whose X-ray structure is known, and *cis*-$[V(N_2)_2\{(Ph_2P)(CH_2CH_2PPh_2)_3\}]^-$.[52] Mono-dinitrogen compounds as well as complexes with monodentate

phosphines have also been obtained, however, most complexes are unstable in the solid state even under a dinitrogen atmosphere.[52]

Nitrosyl ligands also stabilize V^{-I} complexes because, like dinitrogen, they are good π-acceptors that serve to remove electron density from electron-rich metals. Thus, addition of bpy or phen to an aqueous solution of $[V(CN)_5(NO)]^{3-}$ gives the complexes $[V(NO)_2L_2][CN]$ (L = bipy or phen), and similar products were obtained from mixtures of $H_2VO_4^-$, hydroxylamine hydrochloride and pseudo-halides, such as NCS^- or N^{3-}.[53]

4.2.2 *Vanadium(0)*

EPR spectroscopy has been used to study the $[V(bpy)_3]$ complex and demonstrate that the single unpaired electron is extensively delocalized on the bipyridyl ligands.[54] The V^0 complex $[V(PF_3)_6]$ has been prepared by the oxidation of $[Na(diglyme)_2][V(PF_3)_6]$ with benzenediazonium tetrafluorborate.[55]

4.2.3 *Vanadium(1)*

Some nitrosyl complex compounds have been prepared in which the vanadium center is formally V(I). They carry the triethanolamine (tea) coligand and the vanadium in a structurally characterized example, $[V(NO)(tea)]^-$, is in a distorted, trigonal-bipyramidal environment with the amine and nitrosyl nitrogen donors in the axial positions.[56]

4.3 Vanadium(II) Coordination Complexes

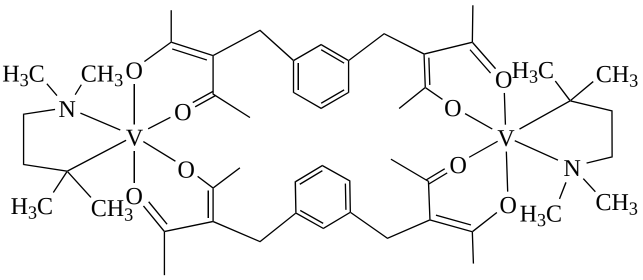
The preparation of complexes of V^{II} was hampered in the past by their easy oxidation.[1,43,57] However, as techniques for the handling of air- and moisture-sensitive compounds have become more routine, the number of synthetic routes to such complexes and the types of complexes formed have increased.

Until recently, the majority of V^{II} coordination complexes contained the hydrated V^{2+} ion, obtained by reduction of acidic solutions of V^V, V^{IV}, or V^{III}. The solutions are strongly reducing, and are oxidized by water with the evolution of dihydrogen. Several crystalline salts containing the $[V(H_2O)_6]^{2+}$ ion are known. The most important of these is the sulfate, $VSO_4 \cdot 6H_2O$, formed by reduction of V_2O_5 solutions in H_2SO_4, and the double sulfates (Tutton's salts), $M_2[V(H_2O)_6](SO_4)_2$ (M = NH_4, K, Rb, or Cs).[1,43,57] The solid-state structures of several vanadium(II) hydrates have been obtained by X-ray structural or neutron diffraction methods.[58]

Most V(II) complexes have predominantly N-, O-, S-, P-, and halide donor ligands. They are presented below in terms of the predominant ligand in the coordination sphere.

4.3.1 *Oxygen Ligands*

Mononuclear octahedral complexes have been obtained for carbonyl-bound acetic acid,[59] and five-coordinate complexes of sterically hindered phenoxides of the type $[V(py)_3(C_6H_3Ph_2\text{-}2,6)_2]$.[60] A more hindered phenol gave a four-coordinate complex, $[V(C_6H_3Pr^i_2\text{-}2,6)_4\{Li(thf)\}_2]$ in which two pairs of *cis*-phenolates were linked by a single $Li(thf)^+$ unit.[61] A binuclear complex of a substituted acetylacetone[62] has the structure shown in (**1**).



(**1**)

4.3.2 *Nitrogen and Phosphorus Ligands*

A general synthetic route to a range of V^{II} complexes has involved well-characterized precursor complexes in this oxidation state.[1,43] Thus, the anion $[V_2(\mu\text{-}Cl_3)(thf)_6]^-$ has been used[43] to give complexes with diamino, pyridyl, and pyrrolidyl ligands and *trans*-$[VCl_2(Me_2NCH_2CH_2NMe_2)_2]$ has been used as a starting material for complexes of organic amidates $[RNC(R^1)NR^-]$ and acetanilide $[PhNC(Me)O^-]$ ligands.[63] Amidinate and amide ligands have been used to prepare dinitrogen complexes such as $[V\{(SiMe_3)NC(Ph)N(SiMe_3)_2\}_2(\mu\text{-}N_2)]$, which reacts reversibly with thf to give $[V\{(SiMe_3)NC(Ph)N(SiMe_3)\}_2(thf)_2]$.[64] Complexes of tertiary phosphine ligands include $[VX_2(R_2PCH_2CH_2PR_2)_2]$ (X = halide or BH_4^-, R = Me or Et)[1,43] and the hydride-bridged complex cation $[\{V(PMe_3)_3\}_2(\mu\text{-}H)_3]^+$.[65]

Vanadium(II) heterocyclic amine complexes of the type $[VX_2L_4]$ and $[VL_6]X_2$ (L = heterocyclic amine, e.g. pyrazole, imidazole, 2-methylimidazole, benzimidazole, isoquinoline; X = anionic ligand) have been known for some time and more recent examples of such complexes include polypyridyl V^{II} complexes of the type $[V(terpy)(bipy)L]^{n+}$. Such complexes are obtained as a result of the disproportionation reaction of $[V^{III}(terpy)Cl_3]$, which yields $[V^{II}(terpy)_2]^{2+}$ and $[V^{IV}O]^{2+}$ in CH_2Cl_2 suspensions.[1]

Low-valent metal porphyrins have been extensively studied, and show some promise in the understanding of the reactions of hemes with dioxygen. Until recently, there have been few examples of low-valent V porphyrins, presumably due to the stability of the oxovanadium(IV) species. The

first V^{II} porphyrins to be isolated have been obtained by reduction of nonoxo V^{IV} complexes of the type $[V^{IV}X_2L]$ (X = Cl, Br; L = porphyrinate(2−), OEP, TPP, TMTP, TPTP) by Zn amalgam to give $[V^{II}Y_2L]$ (Y = thf, $PPhMe_2$). The structures of both complexes $[V^{II}Y_2L]$ showed that the two nonporphyrin ligands assume a trans configuration with the octahedrally coordinated V atom in the plane of the four porphyrin N atoms.[1] An octaethylporphyrinogen V^{II} complex was found to form a μ-N dinuclear V^{III} complex.[66]

4.3.3 Other Ligands

With halide ligands, complex cations of the type $[L_3V(\mu\text{-}Cl)_3VL_3]$ (L = thf or 3-Me-thf) have been extensively studied and give a wide range of halide and other complexes by breaking up the dimer with ligands to give monomeric compounds, or by substitution into the dimer to give complexes such as $[L_3V(\mu\text{-}Cl)_3VL_2(PPh_3)]$.[1,43] Halide complexes of the type *trans*-$[VX_2L_4]$ (X = Cl, Br, I, SCN, N_3, PhS, EtS or BH_4; L = py) have been prepared.[1,43] Oligonuclear complexes have been prepared in addition to the dinuclear cations, these include the series of complexes having a very stable $\{V_3Cl_3\}$ core, *triangulo*-$[V_3(\mu\text{-}Cl)_3(\mu_3\text{-}Cl)L_3]^+$ (L = MeOH, EtOH, etc.),[43] and a tetranuclear species $[V_4(\mu_3\text{-}Cl)_2(\mu\text{-}Cl)_2(\mu\text{-}CF_3CO_2)_2(thf)_6]$.[67]

Vanadium(II) complexes with sulfur-donor ligands are relatively rare. Those reported are prepared from the usual V^{II} precursors noted above. Thus *trans*-$[VCl_2(Me_2NCH_2CH_2NMe_2)_2]$ reacted with 1,2-bis(2-sulfido-phenylsulfanyl)ethane(2-) to give the mixed N,S ligated complex $[V(2\text{-}SC_6H_4SCH_2CH_2SCH_2CH_2C_6H_4S\text{-}2)(Me_2NCH_2CH_2NMe_2)]$. With the tridentate ligand, 1,4,7-trithiocyclononane, (9[ane]S_3), $[V_2(\mu\text{-}Cl)_3(thf)_6]Cl$ gives $[\{V(9[ane]S_3)\}_2(\mu\text{-}Cl)_3]Cl$ and $[VI_2(thf)_4]$ gives the monomer $[VI_2(thf)(9[ane]S_3)]$.[14]

4.4 Vanadium(III) Coordination Complexes

Vanadium(III) complexes are most commonly prepared from V^{III} halides, principally VCl_3, or by electrolytic reduction of V^{IV} or V^V solutions. Most are readily oxidized or hydrolyzed in the presence of air or moisture.

Complexes with monodentate ligands are generally six-coordinate cationic or neutral species having octahedral stereochemistry with trigonal distortion. The electronic spectra and magnetic properties of many six-coordinate V^{III} complexes have been studied and are in accordance with those expected for a d^2 ion in an octahedral field with trigonal distortion.[1]

More recent work has involved the preparation and characterization of vanadium(III) complexes with bidentate and multidentate ligands, especially those with nitrogen- and oxygen-donor atoms, because of their biological significance. Hydride derivatives are of interest in connection with the catalytic properties of vanadium, for example, in alkene dehydrogenation or polymerization. Complexes with sulfur-donor and possibly also nitrogen-donor atoms are relevant to the role played by vanadium in the poisoning of the Co–Mo catalyst used for the hydrodesulfurization of crude oil.[1]

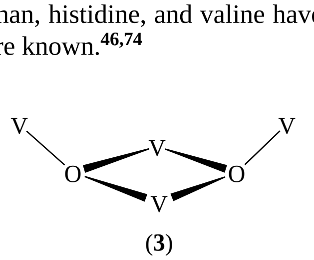
4.4.1 Oxygen Ligands

The chemistry of the blue hexahydrate ion $[V(H_2O)_6]^{3+}$ has been reviewed.[1] Complexes of alkoxides are of interest with regard to biological systems, particularly tunicates,[46] and to polymerization catalysis of alkenes.[68] Alkoxide and phenoxide complexes are often oligomeric and insoluble,[1] unless the O-donor carries bulky substituents, when soluble, mononuclear complexes can be isolated. Five-coordination is then common, for example, in $[VCl(OC_6H_3Pr^i_2\text{-}2,6)_2(thf)_2]$.[69] Binuclear complexes with phenoxides bridging six-coordinate vanadiums are also known, such as $[\{V(OPh)_2(thf)\}_2(\mu\text{-}OPh)_2]$, and a binuclear complex with terminal esters, $[\{VCl_2[CH_3C(O)OC_2H_5]_2\}_2(\mu\text{-}Cl)_2]$, has also been prepared.[70]

With bidentate ligands, both mononuclear and complexes of higher nuclearities may be obtained. The acetylacetonate complex $[V(acac)_3]$ has a monomeric, octahedral structure as do tris(oxalate) complexes and the oxalate anion $[V(oxalate)_2(H_2O)_2]^-$, but catecholate ligands form dinuclear complexes containing a linear oxide-bridged unit, $[\{V(catecholate)_2(L)\}_2(\mu\text{-}O)]$, which are interesting as polymerization procatalysts.[1,68,71] Carboxylate ligands also support oxo-bridged structures, which include complexes having the $\{(\mu\text{-}oxo)\text{-}bis(\mu\text{-}carboxylate)\}$ core, in which the two V^{III} (d^2) ions show antiferromagnetic coupling, and also the trinuclear oxo-bridged cations illustrated in (**2**).[1,72]

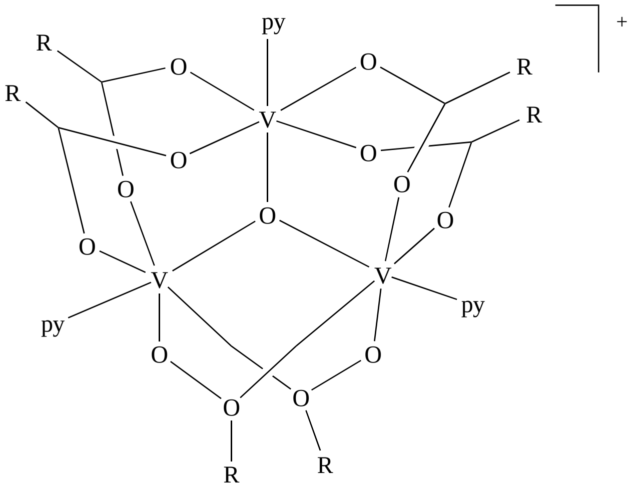
The tetranuclear compounds $[V_4O_2(O_2CEt)_7(bpy)2]$-$[ClO_4]$ (bpy = 2,2-bipyridine), and the related complex $[NEt_4][V_4O_2(O_2CEt)_7(pic)_2]$ (pic = 2-picolinate) have a $[V_4O_2]^{8+}$ 'butterfly' core (**3**) and a $S = 3$ ground state.[73]

Because of their biological relevance, complexes of bidentate amino acids and related ligands have been widely studied[46] (*see* ***Vanadium in Biology***) and are merely mentioned here. Six-coordinated complexes of proline, phenyl analine, tryptophan, histidine, and valine have been prepared and structures are known.[46,74]

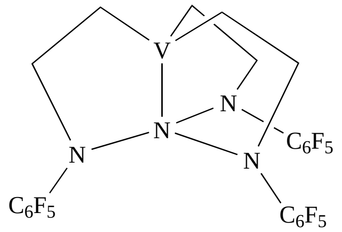


(**3**)

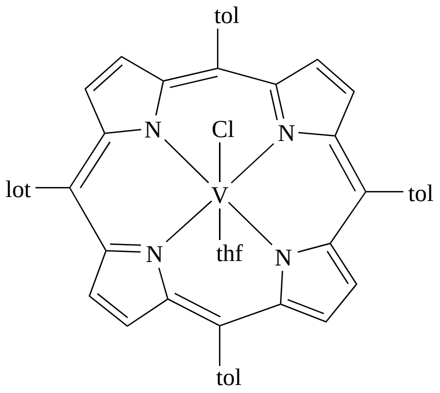
Some V^{III} complexes involving the ONO donor ligand pyridine-2,6-dicarboxylic acid, (DPA), include the seven-coordinated mononuclear complex, $[V(DPA)(PA)(H_2O)_2]$



(**2**)



(**4**)



(**5**), tol = tolyl

(PA = picolinate anion). This complex has a pentagonal bipyramidal structure with the equatorial plane accommodating the ONO and NO donor points, while the two water molecules occupy the axial positions.[75] Seven-coordination is more often seen with polydentate ligands, in particular, tetradentate EDTA and its analogues,[1] for example [V(EDTA)(H_2O)], which is converted to a six-coordinated complex by protonation of an oxygen atom of the EDTA. Nitrilotriacetate (NTA) and related ligands are tridentate O-donors that give six-coordinated complexes of the type [V(NTA)$(H_2O)_3$].[76]

Many complexes have been prepared using Schiff-base-type ligands,[1,46] which can be heptadentate and octadentate and give mononuclear or dinuclear complexes.[1,46,81]

4.4.2 Nitrogen Ligands

A number of acetonitrile, pyridine, and related complexes are known. Examples are $[VX_3(RCN)_3]$ (X = halide; R = Me, Et, or Pr) and $[VCl_3L_3]$ (L = pyridine and γ-picoline).[1] $[VCl_3(MeCN)_3]$ shows *fac-* and *mer*-isomers in solution and $[VCl_3py_3]$ has the *mer*-structure in the solid state, with the pyridines twisted out of the metal–ligand planes.[77]

Polydentate N-donor ligands have been developed with the aim of stabilizing vanadium complexes with low-coordination numbers or with relatively rare ligands, such as hydride or dinitrogen, at vanadium in a higher oxidation state than those previously used (see Sections 4.2 and 4.3) Thus, tris(amide) ligands are used to obtain complexes with hydrides or dinitrogen as bridging ligands in $[\{V[Me_3SiN(CH_2CH_2NSiMe_3)_2]\}_2(\mu\text{-}H)_2]$ and $[\{V[CH_3C(CH_2NPr^i)_3]\}_2(\mu\text{-}N_2)]$,[78] and the tridentate ligand $N\{CH_2CH_2N(C_6F_5)\}_3$ gives the five-coordinated, monopyramidal complex shown in (**4**).[79]

There have been extensive studies of V^{III} complexes of polydentate N- and N,O-donor ligands. These include porphyrins and phthalocyanins.[1,46] X-ray structures have recently been obtained as exemplified in (**5**).[80]

4.4.3 Sulfur Ligands

Compounds in this area have been studied with regard to biological systems and polymerization catalysis; multidentate ligands are generally used. L-cysteine gives[46] the anion [V(L-cysteine)]$^-$ and other mononuclear complexes are: $[VCl_3$(1,4,7-trithiacyclononane)],[14] the trigonal bipyramidal hydrazine complex $[V\{N(CH_2CH_2S)_3\}(N_2H_4)]$,[82] and a series of complexes of the ligand $[O(CH_2CH_2S)_2]^{2-}$, such as $[V\{O(CH_2CH_2S)_2\}(OC_6H_3Pr^i_2\text{-}2,6)$(pyridine)], which are catalyst precursors for olefin polymerization.[83]

Bidentate ligands can be used to generate both homometallic and hetero-metallic species. Thus, ethanethiolate (ent) gives[84] the anions [{V(ent)}$_2$(μ-ent)2]$^-$ and $[\{VCl_3\}_2(\mu\text{-}ent)_3]^{3-}$ and 2-aminoethanethiolate gives a series of linear-type, S-bridged, trinuclear complexes[85] incorporating V^{III} together with Rh^{III} or Ir^{III}. Cubane-type cluster complexes of iron, sulfur, and vanadium, such as the anion $[VFe_3S_4X_3$(dimethylformamide)$_3]^-$ (X = halide), have been developed to mimic the behavior of the active center in vanadium nitrogenase and are discussed elsewhere (*see* ***Vanadium in Biology***).[46]

4.4.4 Halide and Other Ligands

Many examples of $[MX_3L_3]$ complexes with N and P-donor ligands are known and recent X-ray structures generally confirm the proposed geometries for these octahedral compounds.[1] Halide bridges feature in polynuclear complexes of V^{III}, such as the structurally characterized anions $[\{VCl_3\}_2(\mu\text{-}Cl)_3]^{3-}$ and $[V_3OCl_4\{O_2C(C_6H_4SO_2\text{-}2)\}_5]^-$. The terminal and bridging halides of the former complex can be exchanged and the latter compound contains the triangular $[V_3(\mu\text{-}O)_3]^{7+}$ core structure seen in (**2**).[72] Linear oxo-bridged complexes of V^{III} with the $\{V\text{-}O\text{-}V\}^{4+}$ core and such terminal ligands such as PMe_3, BH_4^-, and 1,4,7-triazacylononane have been structurally characterized.[1]

4.5 Vanadium(IV) Coordination Complexes

4.5.1 Introduction

This is the most stable and important oxidation state for vanadium. Aqueous solutions of V^{III} are air oxidized to V^{IV}, and V^V reacts with mild reducing agents to give V^{IV}. The blue oxovanadium(IV) cation $[VO(H_2O)_5]^{2+}$ is prevalent in aqueous solution and in many salts and is used as a starting material for a wide number of complexes. The vanadyl ion $[VO]^{2+}$ dominates the aqueous chemistry of vanadium(IV) and this aspect of vanadium chemistry is effectively summarized in reviews that have already appeared.[1,46,57] The vanadyl ion is still ubiquitous in the more recent chemistry of vanadium(IV), but there has been a considerable expansion in the range of coordination compounds that do not contain the terminal oxo-group. We will discuss vanadyl complexes as a separate group, concentrating on examples from the recent past and outline the chemistry of nonvanadyl complexes according to the predominant donor atom in the coordination sphere of vanadium.

4.5.2 Coordination Complexes of Vanadium(IV) Halides

The earlier coordination chemistry of vanadium(IV) was based upon complexes of VX_4 formed generally by direct interaction with ligands in nonaqueous solvents. The majority of the complexes are of the type $[VX_4L_2]$ (X = halide; L = O-, S-, Se-, N-, P or As-donor ligand), or are anionic complexes such as the hexachlorovanadate(IV), $[VCl_6]^{2-}$, with largely octahedral stereochemistries, showing some tetragonal distortion. The types of complexes formed, along with their methods of preparation, have been reviewed.[1] Simple oxohalide complexes $[VOX_2L_2]$ and oxo-anions such as $[VOF_4]^{2-}$ are also well known and are often used as precursors to the vanadyl complexes discussed in the following section.[1,57]

4.5.3 Complexes of Oxovanadium(IV)

The VO^{2+} (vanadyl) ion is one of the most stable oxo-metal species known, and probably the most stable diatomic ion. Most of these properties stem from the ground-state electronic configuration of the vanadium atom, $[Ar]3d^1$, which shows similarities to the Cu^{2+} d^9 system. The ion also lends itself to study by ESR because of the isotopic purity of the ^{51}V isotope, its high nuclear spin, $I = 7/2$, and the single unpaired outer electron.

Examples of some of the main types of complexes formed by the VO^{2+} ion are shown in Table 1, which is a revised version of that found in Reference 1 in that it includes some recent examples, although most of the original entries are retained for continuity and because the structural pattern is largely unchanged. The complexes formed are classified according to the generalized formula.[1] Monodentate ligands are represented by lower case letters and multidentate ones by LL, LL′, LL′L″ and so on.[1,46,86–90,90]

The VO^{2+} ion bonds most effectively to electronegative donor atoms, that is, F, Cl, O, or N, but complexes having S-donor atoms are known. The vanadyl complexes formed are generally green or blue–green and can be neutral, anionic, or cationic. A commonly used starting reagent for the formation of VO^{2+} complexes is the sulfate, $VOSO_4{\cdot}5H_2O$, prepared by reduction of vanadium(V) in sulfuric acid. Probably, the most extensively studied complex of oxovanadium(IV) is $[VO(acac)_2]$, which is also often used as a starting reagent for VO^{2+} compounds.[1,46] This stable complex has been used as a starting material for the preparation of mixed-ligand complexes by displacement reactions of one or both acac groups,[1,86] and has also been much used in physical studies of the nature of the V=O bond by spectroscopic and crystallographic techniques. The latter investigations indicate that the bond has a partial triple bond character with a predominant axial interaction and an equatorial component involving σ-bonding between the oxygen lone pairs and the V $3d_{xy}$ orbital.[87] This bonding system gives rise to a characteristic strong, sharp IR stretching frequency at around $985 \pm 50\,cm^{-1}$. The position of the V=O stretching frequency is insensitive to molecular changes in the coordination sphere of the V atom.

The vast majority of oxovanadium(IV) complexes have magnetic moments that lie within $0.03\,\mu_B$ of the spin-only value for one electron, that is, $1.73\,\mu_B$. These are magnetically dilute complexes in which the metal ion is not involved in a magnetic exchange with the neighboring metal ions through exchange forces and the orbital contribution to the magnetic moment is quenched. Two complexes that show this behavior are [VO(salicylaldimine)] and VO(phthalocyanine).[1]

The X-ray crystal structures of many oxovanadium(IV) complexes have been determined. In general, the V=O bond is shorter than most other V–O bond lengths, ranging between 1.57 and 1.68 Å, which is in keeping with the above view of the multiple characters of this bond.[1] The most common

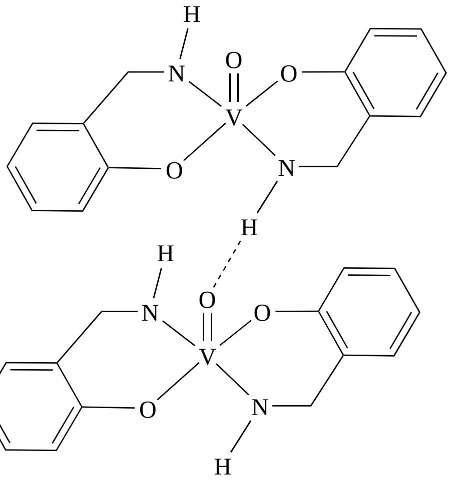
Table 1 Examples of types of VO^{2+} complexes[1,7,14,46,88–94]

General formula[a]	Ligands
$[VOa_{4\,or\,5}]$	a = H_2O, F^-, Cl^-, NCS^-, CN^-, HCO_2^- DMSO, Ph_3PO, pyNO
$[VOa_4b]$	b = H_2O, ROH,
$[VOa_3b_2]$	a = py, DMSO, THF, Ph_3PO, ROH, H_2O
$[VOa_2b_2]$	b = Cl^-, F^-, SO_4^{2-}, Br^-
$[VOa_{2\,or\,3}\cdot LL]$	LL = ox^{2-}, phen, bipy, SO_4^{2-}, diphos, catecholates
	a = F^-, Cl^-, Br^-, NCS^-, H_2O
$[VOa_2LLL]$	a = Cl, LLL = 1,4,7-trithiacyclononane
$[VO(LL)_2]$	LL = $acac^-$, phen, ox^{2-}, MNT, bipy, (HOOCR) (R = H,
$[VO(LL)_2a]$	Me, Et, $ClCH_2$, Cl_2CH, etc.), other β -diketones, maltolates, thiocatecholate, 1-oxy-2-pyridinethiolate
	a = H_2O, X^-, NCS^-, py, Ph_3PO, pyNO, DMSO, N-bases, MeOH
$[VO(LL')_2]$	LL′ = $oxine^-$, unsym. β-diketones, sal^{2-}, benzohydroxamate,
$[VO(LL')_2a]$	quinaldinate, *N*-1- and *N*-3-substituted hydroxytriazenes, big^-, pyc^-
	a = solvent molecule, aromatic amine, heterocyclic base
$[VO(LL')(L''L''')]$	LL′ = X-salen-N(R)(R′), R and R′ alkyl or aryl L″L‴ = X-sal^- (X = H, 5,6-benzo-, 5-halido-, alkoxy-; R, R′ = alkyl or aryl)
$[VO(LL'L)a_{4\,or\,2}]$	LL′L = lut^{2-}, $coll^{2-}$, iminodiacetate
	a = H_2O, aromatic amine or heterocyclic base
$[VO(LL'L)(LL)]$	LL′L, LL′L = lut^{2-}, $coll^{2-}$, iminodiacetate
$[VO(LL'L'')(LL)]$	LL = phen, bipy, $acac^-$
$[VO(LL'L)(LL')]$	LL′ = gly, oxine, $benzohydroxamate^-$, pic^-
$[VO(LL'L'')(LL')]$	
$[VO(LLLL)]$	LLLL = TPP^{2-}, pc^{2-}
$[VO(LL'L'L)]$	LL′L′L and LL′L′L″ = various Schiff bases
$[VO(LL'L'L')]$	$N(CH_2CH_2S)_3^{3-}$
$[VOY]\cdot xH_2O$	Y = EDTA
$(VO)_2(\mu\text{-}Y)\cdot$	Y = tartrate, citrate
$[(VO)_2(LL)_2]$	dba, $danaH_2$, salen-5-Me

[a]The general charge has been omitted from outside the square brackets.

stereochemistry for five-coordinate complexes of VO^{2+} is square pyramidal, as in $[VO(acac)_2]$, although some trigonal bipyramidal structures are known. In complexes such as $[VO(acac)_2]$, the O–V=O angle is greater than 90°; and the V atom lies above the plane formed by the four basal singly bonded oxygen atoms. Similar structural features occur in six-coordinate oxovanadium(IV) complexes, although the sixth ligand is often found to be only weakly coordinated and trans to the V=O bond in such structures.[1]

A great number of Schiff-base complexes of oxovanadium(IV) have been studied by X-ray diffraction. Many of these bases contain O,O,N,N-donor atoms in ligands formed from reaction between substituted salicylaldehyde and aliphatic or aromatic amines,[1,46,88,89,91] but examples with S-donor ligands have also been reported.[92] The distorted square pyramidal geometry found for most of these complexes is analogous to that found with simpler ligands. In some cases, the structure of the Schiff-base complexes is polymeric with the sixth, vacant, position of the square pyramid being occupied by the oxygen atom of the vanadyl group of the adjacent molecule,[1,46,91] or a hydrogen-bonding interaction can occur, as shown in (**6**), where the formation of the binuclear complex makes this system more stable toward reduction to V^{III} than related complexes.[88]

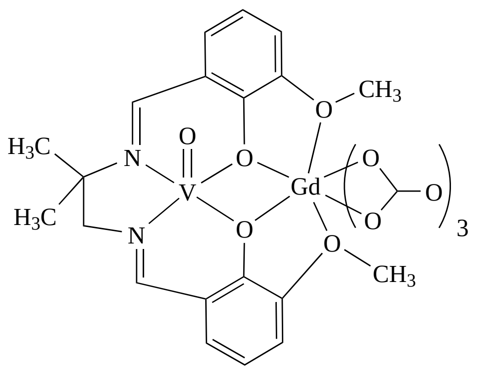


(**6**)

Attempts to model the structure of the V-dependent bromoperoxidase enzyme have resulted in the characterization by X-ray crystallography of a great number of VO^{2+} complexes having N,N,N,N-donor atoms. The imidazole group is thought to mimic the protein environment and complexes such as [VO(SALIMH)(acac)(MeOH)], [VO(SALIMH)SAL], and $[VO(SALIMH)_2(EtOH)]$, have been prepared[1,46] (*see* ***Vanadium in Biology***).

The mixed valence $[V^{IV}\text{–O–}V^{V}]^{3+}$ bridge is a fairly common unit. It is found in complexes such as $Na[V_2O_3(\text{DL-salser})_2]\cdot 5H_2O$, $[V_2O_3(S\text{-peida})_2]^-$, $[V_2O_3(NTA)_2]^{3-}$, $[V_2O_3(pmida)_2]^-$,[1] and $[VO\{salen(5\text{-}Me)_2\}_2][ClO_4]$.[1,88] Multinuclear complexes can also be obtained using Schiff-base ligands carrying pendant donor groups that can bind other metallic centers, such as in the Gd^{3+} adduct shown in (**7**), which shows a ferromagnetic interaction between the metals.[90] Similar complexes have also been obtained with catecholate ligands.[93]

Dinuclear complexes of vanadyl ions have been obtained where two such units are bridged by a tetradentate ligand, such as tartrate, citrate or *N*,*N*-bis(2-hydroxybenzyl)aminoacetate.[95] Dinuclear complexes with bridging alkoxide and carboxylate coligands are also known, structurally characterized examples include $[PPh_4]_2[(VO)_2Cl_4(OR)_2]$ (R = CH_3 or CH_2CH_2Cl) and $[(VO)_2Cl_2\{MeC(CH_2OH)(CH_2O)_2\}_2]$.[96]



(7)

Because of the interest in the nature of vanadium porphyrins occurring in petroleum and coal, there have been many studies on the syntheses of these complexes, their magnetic properties, and ESR spectra and structures.[1,46,51]

4.5.4 Nonoxo Vanadium Complexes

A range of coordination complexes of V^{IV} has been prepared in which the vanadyl group is absent, a number of these compounds being synthesized as part of an effort to understand the nature of biological vanadium sites, such as amavadin,[46] which contains an octadentate, hydroxyiminodipropionate ligand bound to $vanadium^{IV}$ A number of model complexes of this type have been prepared and discussion of this area can be found in the article ***Vanadium in Biology*** Further discussion in this section follows the main ligand donor atom to vanadium.

Nitrogen Ligands. Amide ligands have been used to give four and five-coordinate complexes, such as $[V(NMe_2)_4]$[97] and $[V\{N(CH_2CH_2NR)_3\}X]$ (R = bulky substituent; X = Cl or N_3^-)[98] [see also (**4**)]. Treatment of $[V(NMe_2)_4]$ with aniline gives the V^{IV} imido-complex $[V(NMe_2)_2(NHMe_2)_2({=}NAr)]$, which with an excess of Me_3SiCl gives $[V(NMe_2)_2Cl_2({=}NAr)]$.[97]

Vanadyl porphyrins, VOP, mentioned above [see (**5**)] have been used as precursors for nonoxo vanadium(IV) porphyrins, $[VPX_2]$ (P = OEP, TPP, TMTP, TPTP; X = Cl or Br).[1] EXAFS at the Br K-edge has been used to confirm the trans configuration of X atoms in the complexes. The 'bare' V^{IV} atom renders the compounds extremely reactive and one theory is that they could act as precursors in the synthesis of complexes formed during coal conversion.[1]

N-donor macrocyclic ligands, based on 1,4,7-trithiacyclononane and carrying three pendant arms bearing alkoxides give nonoxo vanadium(IV) complexes.[99]

Sulfur and Selenium Ligands. Complexes containing the $V{=}S^{2+}$ (thiovanadyl) moiety are known. The V=S bond length, 2.061(**1**) Å, is longer than would be expected from comparison with analogous vanadyl complexes. This finding agrees with molecular orbital calculations, which predict a relatively weaker V=S bond.[1] Recently, the thiovanadyl, dithiocarbamate complexes $[VS(S_2CNR_2)_2]$[100] and also the nonthiovanadyl derivatives $[VX_2(S_2CNR_2)_2]$ (X = halide; R = alkyl) have been prepared.[101]

The tridentate, dithiolate ligand $O(CH_2CH_2S)_2$ (odt) gives the six-coordinate compounds $[V(odt)_2]$ and $[V(NCMe)_6][VCl_2(odt)]_2$, whose structures have been determined.[83] The tris-dithiolene complex $[V(SCHCHS)_3]$ has D_{3h} symmetry and the compound has a delocalized electronic structure involving a spread of charge over the dithiolene ligands.[102]

A number of ligands having NSSN- and SNO-donor sets have been developed to bind nonoxo V^{IV}, using Schiff-base-type ligands or the tetradentate disulfide ligand 1,6-bis(*o*-pyridyl)-2,4, dithiahexane (NSSN) which forms the octahedral complex $[VCl_2(NSSN)]$.[103]

4.6 Vanadium(V) Coordination Complexes

4.6.1 Introduction

Many of the complexes of vanadium in their highest oxidation states contain oxygen and fluorine, and most contain at least one terminal oxygen atom. The d^0 electronic configuration means that the complexes are diamagnetic, and their color is the result of charge-transfer transitions. Their diamagnetism has allowed extensive study by ^{51}V NMR spectroscopy.[13] In aqueous solution, vanadium(V) forms a range of oxometalates, whose structures vary with concentration, temperature, and other conditions. Their study is well established and is beyond the scope of this survey, except to note the increasing use of NMR spectroscopy to examine the species that are present in solution.[1,46]

4.6.2 Halide Complexes

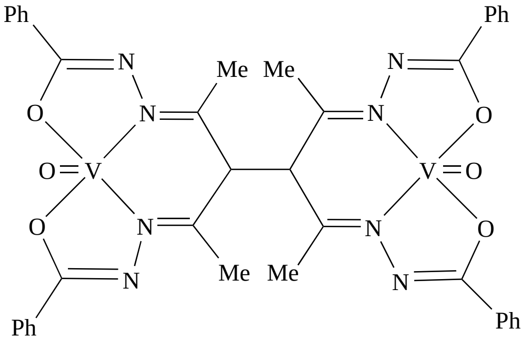
The structure of VF_5 has been studied theoretically.[104] A number of hexafluorovanadates(V) such as $K[VF_6]$ are well known.[1]

4.6.3 Oxo Complexes

Neutral and Cationic Species Containing the VO^{3+} Unit. This unit is found in the oxohalides VOX_3 (X = F, Cl, Br) and the nitrate, $[VO(NO_3)_3]$, that has a distorted pentagonal bipyramidal structure with overall Cs symmetry in the gas phase.[105] The oxochloride, $VOCl_3$, forms a number of addition complexes of the type $[VOCl_3L_n]$ with monodentate (n = 1) or bidentate (n = 2) O-, S-, or N-donor ligands.[1]

$VOCl_3$ also undergoes a number of solvolysis reactions, mainly with alcohols, phenols, and carboxylic acids. Substitution products of the general type $[VOCl_2(OR)]$, $[VOCl(OR)_2]$, and $[VO(OR)_3]$ are obtained. The nature of the product depends on the conditions used, especially the nature of the solvent and the stoichiometry of the reactants.[1] With bulky substituents, mononuclear complexes of this type can be crystallized and structurally characterized, for example $[VO(OC_6H_3Pr^i_2\text{-}2,6)_3]$, has a trigonal pyramidal structure.[69] A related compound is $[VO\{N(CH_2CH_2O)_3\}]$, which has a trigonal pyramidal structure in the solid and in the organic solution, but a different structure in water.[106]

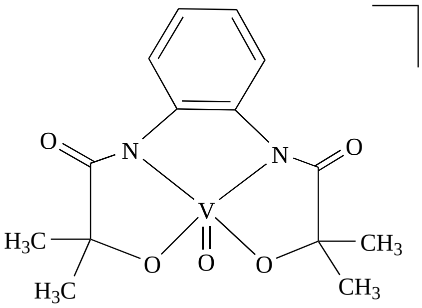
A large group of mononuclear complex cations of the type $[VO(L)]^+$ is known where L is commonly a Schiff-base,[46,107] or a hydroxamate. For example, the series $[VO\{salen(5\text{-}X)\}]^+$ (X = OMe, Me, or Br),[88] and $[VOClL_2]$ (L = benzohydroxamate or N-phenylbenzohydroxamate).[46] They have the essentially square pyramidal geometry of their V^{IV} uncharged analogues (see Section 4.5.3). Dinuclear Schiff-base complexes of the type $[(VOL)_2]$ (L = Schiff base particularly with alkoxysubstituents), have been obtained and have bis(alkoxy) bridging units.[107] Other examples of this type of complex use hydrazone ligands and include, as well as mononuclear complexes, binuclear, ligand-bridged compounds such as shown in (**8**).[108]



(**8**)

Other dinuclear complexes use bridging oxide[109] or fluoride[88] groups. Examples of this type with Schiff bases can be symmetric, as in the cation[88] $[\{VOL\}_2(\mu\text{-F})]^+$ or asymmetric as in $[(VOLL')(\mu\text{-O})(VOLL'')]$[109] (L Schiff-base or similar ligand; L′ and L″ = monodentate ligands).With certain polydentate Schiff-base ligands, dimeric complexes are formed that contain a μ-oxo or μ-OR ligand together with a bridge formed by a pendant phenolate group from the ligand. The V^{IV}–V^V $[V_2O_3]^+$ core in these compounds has the unpaired electron delocalized over the two vanadiums.[109,110]

Anionic Species Containing the VO^{3+} Unit[1]. Complex oxofluorides are well established, as are salts of $[VOCl_4]^-$ and $[VOCl_5]^{2-}$. Anionic complexes with other ligands are rare, but a structurally characterized example is known, as shown in (**9**), and other examples with different ligands have been observed.[92,111]



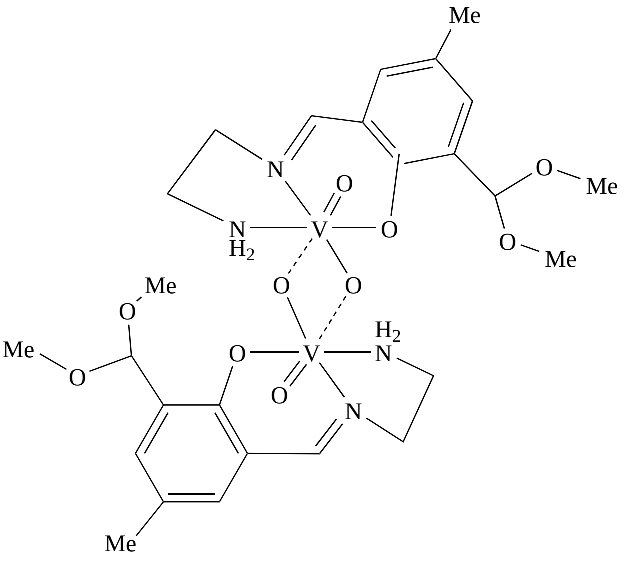
(**9**)

Species Containing the VO_2^+ Unit. Among the first examples of complexes shown to contain the *cis*-dioxo unit were $[VO_2(NO_3)]$, and $[PPh_3Me][VCl_2O_2]$. The oxo-groups were found to be cis to each other and to give rise to the expected two V=O IR bands found in the region of 960 and 970 cm^{-1}.[1] Since that time, a range of mononuclear five-coordinated complexes showing these features has been prepared, most often with Schiff-base coligands, of general formula $[VO_2L]$ (L = Schiff base with NNO- or NO_2-atom ligation).[107,112] Anionic monomeric complexes that have a six-coordinate vanadium such as ammonium dioxo(2-hydroxynaphthaldehyde semicarbazonato)vanadate(V) has been prepared[1] and the species $[VO_2L]^-$ (L = maltolate or triethanolamine) have been observed in solution.[46]

Dimeric complexes of the VO_2^+ group have single oxo-bridges giving a $[O_2V\text{–}O\text{–}VO_2]$ core such as in $[L_2V_2O_4(\mu\text{-}O)]$ (L = 1,4,7-trimethyl-1,4,7-triazacyclononane),[1] or a rare type of dioxo bridge as seen in the compound shown in (**10**).[113] In this compound, the μ-O distances are asymmetric, as indicated, the shorter being about 1.675 Å and the other around 2.27 Å.

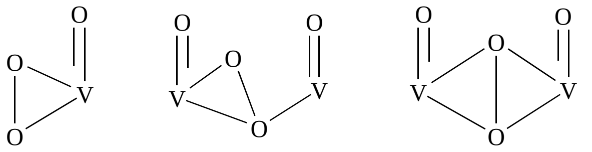
A further type of dinuclear VO_2^+ complex has terminal V=O groups but a pendant alkoxy group from a coligand on each vanadium gives rise to a bis(μ-alkoxy) system, as in $[\{VO_2Ad\}2]^{2-}$ (Ad = adenosine).[46,114]

Perox- Species. Addition of aqueous H_2O_2 to aqueous V^V results in the formation of various peroxo-complexes. In neutral or alkaline solutions, the yellow diperoxoorthovanadate ion, $[VO_2(O_2)_2]^{3-}$, is formed, whereas in acid solutions the red–brown peroxovanadium ion, $[V(O_2)]^{3+}$, is the main species present. Acidic salts such as $KH_2[VO_2(O_2)_2]\cdot H_2O$ and $(NH_4)_2H[VO_2(O_2)_2]\cdot nH_2O$ have been prepared and their IR spectra are characterized by the presence of a strong band at about 850 cm^{-1}, probably associated with the O–O stretching vibration of the peroxo-group, which is coordinated



(**10**)

side-on to the metal (**11a**).[1,46] The peroxo-ligand can act as a terminal, side-on ligand, or in a (μ-peroxy) mode (**11b, 11c**).



(a) (b) (c)

(**11**)

Recent investigations of peroxo-complexes, especially those containing amino and carboxylate ligands, have been stimulated by interest in the vanadium bromoperoxidases and a wide range of peroxo-complexes has been prepared. Several reviews have been devoted to their chemistry and structures[46,115] and only a very brief outline is therefore given here. Types of complexes include those with: one peroxo-ligand $[VO(O_2)(L)]^-$ [L = tridentate, tetradentate or $(bidentate)_2$ ligand], two peroxo-ligands such as $[VO(O_2)_2(L)]^{\bar{n}-}$ [L = monodentate or 1/2(bidentate ligand)], three peroxo-ligands, $[V(O_2)_3(L)]^{2-}$, or four peroxo-ligands, $[V(O_2)_4]^{3-}$. Binuclear complexes are also known with $VO(O_2)$ units bridged by one peroxo-group, or one or two such groups together with bridges formed by other ligands.[46,115]

4.6.4 Nonoxo Complexes

There are few well-characterized examples of this type. Neutral tris(bidentate) V^V complexes of the type $[V(N_3S_2)L(L')]$ (L′ = bipy or phen; L = cat or dtbc) have been synthesized.[1] Complexes of the general type $[V(dtbc)_2L'][SbF_6]$, prepared by oxidation $[V(dtbc)_2L']$ with $Ag[SbF_6]$, have also been investigated.[1]

4.6.5 Nitrogen Ligands

Nitrido- and imido-complexes of V^V have drawn attention because of the interest in nitrogen fixation intermediates and in complexes that might provide catalyst precursors for polymerization of alkynes. Recent examples of such compounds are the six-coordinated cation[116] $[VN(acac)(1,4,7\text{-triazacyclononane})]^+$ and the six-coordinated complexes [V(NR)(L)] [R = alkyl or aryl; L = $N(CH_2CH_2S)_3{}^{3-}$ or $N(CH_2CH_2NR')_3{}^{3-}$].[82,98] The related hydazido(2-) complexes $[V\{N(CH_2CH_2S)_3\}(NNR_2)]$ ($R_2 = CPh_2$ or C_5H_{10})[117] and the doubly nitrido-bridged dimer $[\{V[Me_3SiN(CH_2CH_2NSiMe_3)_2]\}_2(\mu\text{-}N)_2]$[118] have also been structurally characterized.

4.6.6 Sulfur and Selenium Ligands

A number of V^V complexes of the various types described in previous sections have S-donor ligands and a study has been made of vanadium complexes with cysteine and other biologically relevant S-donors[46] (*see* ***Vanadium in Biology***). In this section, we draw attention to the known terminal sulfide and persulfide complexes. The complex anion $[VS_2(S_2)SPh]^{2-}$ (**12**) has both sulfide and persulfide groups and two persulfide groups are found in $[NEt_4][VO(S_2)_2(bpy)]$.[119] The terminal chalcogenide complexes $[V(=Y)\{N(CH_2CH_2NR')_3\}]$ (Y = S or Se, $R' = SiMe_3$) have been prepared by reaction of $[V\{N(CH_2CH_2NR')_3\}]$ with S_8 or gray selenium,[120] and the four-coordinate V=Se complex $[V(Se)\{Se(SiMe_3)_3\}N(SiMe_3)_2]$ has been prepared.[121]

1 INTRODUCTION

Vanadium compounds exist in a variety of formal oxidation states from −3 to +5. Their coordination number varies from 3 to 8. The stereochemistry depends on their oxidation state; V(II): 6-coordinate octahedral, V(III): 3–7-coordinate ($V[CH(SiMe_3)_2]_3$: 3-coordinate planar), V(IV): 4–6 or 8-coordinate ($V(CH_2SiMe_3)_4$: 4-coordinate tetrahedral, $VO(acac)_2$: 5-coordinate tetragonal), V(V): 4–7-coordinate ($VOCl_3$: 4-coordinate tetrahedral). Standard electrode potential in acidic aqueous solution is as follows: $V^{2+} + 2e^- = V - 1.19\,V$, $V^{3+} + e^- = V^{2+} - 0.26\,V$, $VO^{2+} + 2H^+ + e^- = V^{3+} + H_2O + 0.36\,V$, $VO^{2+} + 4H^+ + 5e^- = V + 2H_2O - 0.25\,V$. Generally speaking, vanadium compounds in a high oxidation state serve as oxidants. On the contrary, low-valent vanadium compounds are considered to be reductants. Paramagnetism is another interesting feature of some vanadium compounds.

The first organovanadium compound, which was discovered in 1953, is Cp_2VCl_2. Most organovanadium compounds are highly air and moisture sensitive, but not especially toxic except for the volatile carbonyl compounds. The organovanadium compounds are mostly subjected to interconversion via one-electron redox. Although vanadium compounds including vanadium(II), vanadium(III), vanadium(IV), oxovanadium(IV), and oxovanadium(V) are utilized in organic synthesis as reagents, catalysts, and polymerization catalysts (Ziegler–Natta catalysts, *see Ziegler–Natta Catalysts*), the application of organovanadium compounds to synthetic reactions is rather limited.[1–5] The transformations are characterized by organometallic and/or redox-based reactions. This chapter describes the chemistry of organovanadium compounds mostly from synthetic viewpoints, which are classified depending on the coordination-binding mode.

2 η^6- TO η^8-ARENE AND RELATED COMPLEXES

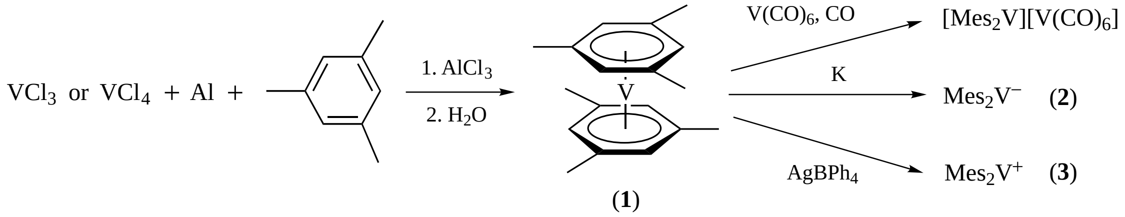
(η^6-Arene)vanadium(0) and related complexes bearing the corresponding aromatic hydrocarbons are one of the important classes of organovanadium compounds. Bis(η^6-arene)vanadiums are synthesized by reductive aromatization of vanadium(III) or vanadium(IV) chloride with arenes in the presence of aluminum and aluminum trichloride, followed by hydrolysis of the generated cationic sandwich complexes.[6,7] Bis(η^6-arene)vanadium(0) is a thermally stable 17-electron neutral sandwich complex. Thus obtained Mes_2V (**1**) undergoes further transformations as shown in Scheme 1; (**1**) is reduced with alkali metal to give the 18-electron complex (**2**).[6] The oxidation with silver tetraphenylborate leads to the vanadium(+1) cation (**3**).[8] A similar transformation is also achieved by treatment with bromo- or iodotriphenylmethane.[9,10] Generally, the six-membered rings are planar with the eclipsed conformation. On the contrary, almost staggered conformation is observed in the case of $[Mes_2V]^-$,[8] in which the distance of V to the ring centroid is around 1.67 Å.

Hexacarbonylvanadium(0), $V(CO)_6$, which is a 17-electron, low-spin d^5, and paramagnetic complex, is reduced to the closed-shell 18-electron species, $V(CO)_6{}^-$, via one-electron reduction (*see* ***Carbonyl Complexes of the Transition Metals***). This redox process is applied to the disproportionation reaction (*see Disproportionation*) in the presence of arene to give $[V(\eta^6\text{-arene})(CO)_4][V(CO)_6]$ (**4**) (Scheme 2).[11]

Another route to bis(η^6-arene)vanadium(0) compounds is the cocondensation of arenes with vaporized vanadium metal (*see* ***Metal Vapor Synthesis of Transition Metal Compounds***).[12,13] On treatment with 1,3-cyclohexadiene and butyllithium, 15-electron vanadocene (**5**) is converted to 16-electron (η^6-benzene)(η^5-cyclopentadienyl)vanadium(I) (**6**) (Scheme 3).[14] Use of potassium naphthalenide affords the corresponding naphthalene complex.

Various bis(η^6-arene)vanadium(0) derivatives are prepared through substitution on the arene ring. Bis(η^6-benzene)vanadium(0) (**7**) undergoes lithiation and coupling with electrophiles to give the substituted bis(η^6-arene)vanadium compounds, like the silyl-bridged derivative (**8**) (Scheme 4).[15]

Triple-decker complexes (**9** and **10**, *see Triple-decker Sandwich*) are also accessible from $CpV(\eta^3\text{-}C_3H_5)_2$ and 1,3-cyclohexadiene, or vanadocene and (naphthalene)$Yb(THF)_3$, respectively.[16] The middle-deck



Scheme 1

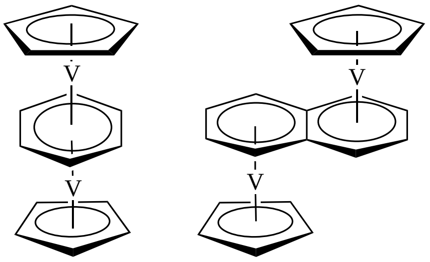
(**4**)

Scheme 2

benzene can be replaced by mesitylene or toluene in the boiling aromatic.[17,18]

As η^7-complex analogs, η^7-Tp or tropylium vanadium complexes (**11**) and (**12**) are obtained from cycloheptatriene by treatment with VCl_4 in the presence of *i*-PrMgBr (Scheme 5) or $CpV(CO)_4$, respectively (Scheme 6).[19–21]



(**9**) (**10**)

[7-7]Bitrovacene, μ-η^7:η^7-$C_{14}H_{12}[(\eta^5\text{-}C_5H_5)V_2]$ (**13**), is synthesized from $CpV(CO)_4$ and dicycloheptatriene. Intervanadium electro- and magneto-communication depends on

the isomer (**14**) possessing the μ-η^5:η^5-fulvalenediyl unit (Scheme 7).[22]

The complexation with the dianion of cyclooctatetraene leads to the formation of the mixed or half-sandwich complexes (*see Half-sandwich Complexes*) as shown in Scheme 8.[23–25] The coordination of the planar η^8-cyclooctatetraene$^{(2-)}$ ligand is observed with $V(cot)_2$. Generally, the distance between vanadium and ring centroid decreases with the increase of the ring size, Cp < C_6H_6 < Tp < cot.

$$CpV(CO)_4 + C_7H_8 \longrightarrow \underset{(\mathbf{12})}{CpVTp} + 1/2\,H_2 + CO$$

Scheme 6

3 η^5-CYCLOPENTADIENYL AND RELATED COMPLEXES

This section describes the organovanadium compounds containing η^5-cyclopentadienyl (Cp) or substituted (Cp′) ligands, which are classified into half-sandwich (*see Half-sandwich Complexes*), sandwich (*see Sandwich Compound*), bent sandwich (*see Bent Metallocenes*), and pseudo-triple decker derivatives. Cyclopentadienyl vanadium compounds are used for the synthesis of various vanadium compounds as mentioned above. Generally, the oxidation state of the cyclopentadienyl vanadium complexes is from −1 to +5.

Bis(η^5-cyclopentadienyl)vanadium (vanadocene, **5**, *see Metallocene Complexes*), which is the key derivative of this series, is characterized by a 15-electron species. Vanadocene is thermally stable under nitrogen but air sensitive. The

Scheme 9

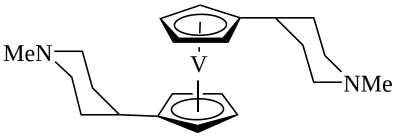
vanadocenes are synthesized from VCl_3 or VCl_2 and alkali metal cyclopentadienide directly or after reduction (Scheme 9).[26–35] For example, the parent vanadocene (**5**) is obtained by reduction of vanadium(III) chloride with zinc and subsequent treatment with the cyclopentadienyl anion. Vanadium(III) chloride is directly converted to a similar complex (**15**) in the presence of sodium or lithium cyclopentadienide even in the absence of a reductant. VCl_4 is also reduced to give vanadocene.[36]

The Cp rings of vanadocenes are usually in the staggered conformation.[37] Electrochemical properties in THF depend on the reversible one-electron reduction to $[Cp_2V]^-$. The oxidation process of Cp_2V involves reversible one-electron oxidation and successive irreversible one-electron oxidation.[38]

Sterically bulky vanadocene $[C_5(i\text{-Pr})_nH_{5-n}]_2V$ is prepared by treatment of VCl_3 or $[V_2Cl_3]_2[Zn_2Cl_6]$ with the corresponding $K[C_5(i\text{-Pr})_nH_{5-n}]$.[39] The dinuclear cyclopentadienyl complex is also accessible. The fulvalenediyl complex (**16**) is obtained from $VCl_2(THF)_2$ and $C_{10}H_6Li_2$ as shown in Scheme 10.[40–42]

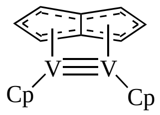
Bis(alkylcyclopentadienyl)vanadium (**17**), which is synthesized as shown in Scheme 11, undergoes chlorination with PCl_3 to give the corresponding blue monochloride (**18**) and green dichloride (**19**).[43]

Heteroatom ring substituted vanadocenes are rare except $(C_5H_4EMe_3)_2V$ (E = Si, Ge, Sn).[44] $(\eta^5\text{-}C_5H_4CH_2CH_2NMe_2)_2V$ is obtained by treatment with $Li(C_5H_4CH_2CH_2NMe_2)$.[45] The amino-functionalized vanadocene derivative (**20**) is also known.[46]

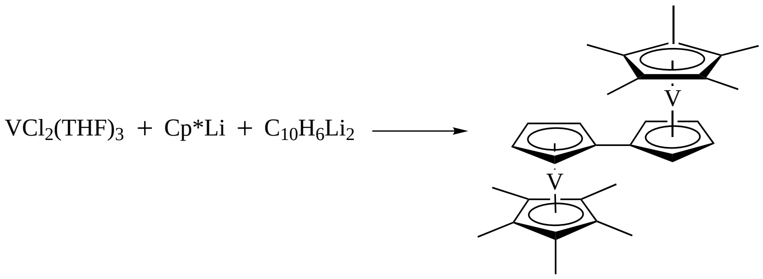


(**20**)

The bimetallic pentalene-bridged complex $[Cp_2V]_2Pn$ (**21**, Pn = C_8H_6) containing a V–V triple bond, in which the vanadium centers adopt a *syn*-coordination, is synthesized from $Li_2Pn{\cdot}xDME$ (DME = 1,2-dimethoxyethane) with 2 equiv of $[CpVCl{\cdot}THF]_n$.[47] The complex shows a high-spin/low-spin (*see High-spin & Low-spin Compounds*) equilibrium in both solution and solid states.

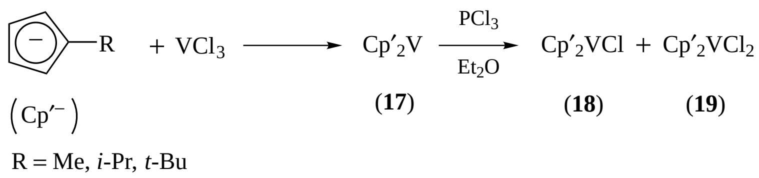


(**21**)



(**16**)

Scheme 10



Scheme 11

Since the vanadium center of vanadocenes is electron-deficient, various vanadium derivatives are formed by the attack with PR_3, CO, or unsaturated π-donating ligands.[48] This reaction provides a useful synthetic method for the synthesis of η^2-alkene complexes as described later. Thus formed $Cp^*_2V(CO)$ (**22**) is converted to the cyano derivative (**23**, *see* ***Cyanide Complexes of the Transition Metals***) on treatment with the isocyanide (Scheme 12). $(\eta^5\text{-}C_5Me_5)_2V$ is incubated with O_2 at −78 °C to yield $[(\mu\text{-}\eta^3\text{-}C_5Me_5O_3)V(O)]_2$ via oxygen insertion into the carbon–vanadium bond.[49]

Various halides (VCl_4, VCl_3, and VBr_2) react with the 6-Me-*nido*-5,6,9-$C_3B_7H_9^-$ to give the paramagnetic air- and moisture-sensitive product, $V(Me\text{-}C_3B_7H_9)_2$, which is considered a tricarbadecaboranyl (*see Carborane*) analog of vanadocene. The complex is not oxidized with Br_2 or Ag^+, indicating that the tricarbadecaboranyl anion stabilizes the metal in a low oxidation state.[50]

1,10-Phenanthroline-5,6-dione reacts with Cp_2V to form the O,O′-coordinated complex (**24**), which is subjected to further complexation with $M'Cl_4$ ($M' = Ti$ or Hf) to give the bimetallic complex (**25**) (Scheme 13).[51] The opposite complexation process is also possible, affording a similar bimetallic complex (**26**) (Scheme 14).

Vanadocene halide is another important analog that is transformed to various vanadocene derivatives. Vanadocene chloride is prepared from vanadium(III) chloride and thallium cyclopentadienide[52] or vanadocene and hydrogen chloride.[53] Vanadocene dihalide is similarly synthesized from vanadium(IV) halide via nucleophilic substitution.[54] Displacement of the chloro group results in functionalization as shown in Scheme 15.

Ring-bridged vanadocene halide and dihalide, (**28**) and (**29**) are obtained from bis(cyclopentadienyl)-substituted dianion (**27**) as shown in Scheme 16.[55] Furthermore,

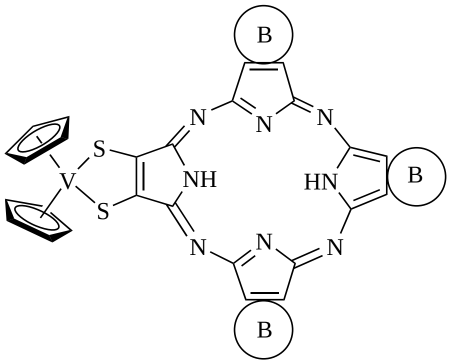
Scheme 17

bis(cyclopenta-2,4-dienyl)dimethylsilanes or -germanes can be used as starting ligands.[56]

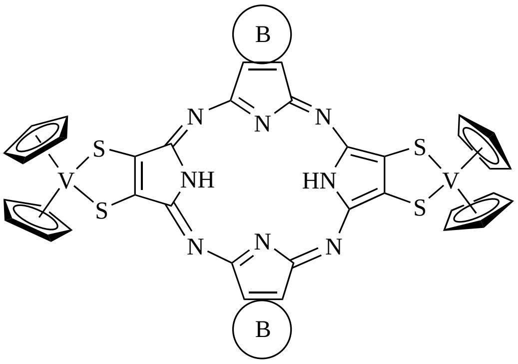
$Cp_2V(OTf)_2$ (**30**), which is derived from vanadocene dichloride, forms the d^1 vanadocene complex (**31**) with 1,10-phenanthroline or 2,2′-bipyridine (Scheme 17).[57] The two nitrogen atoms and centroids of the two cyclopentadienyl rings occupy a distorted tetrahedral geometry around V(IV) center. Relatively low V(IV)–V(III) reduction potential is observed.

A series of soluble vanadocene porphyrazines (**32**) and (**33**) are prepared.[58] The porphyrazine macrocycle mediates magnetic exchange interactions between metal ions bound to the periphery, separated by 14.5 Å.



(**32**)
B = (4-*t*-butylphenyl)$_2$

The 14-electron $[Cp_2V]^+$ cation (**34**) is isolated as an unsolvated species by one-electron oxidation of Cp_2V with $[Cp_2Fe]^+$ (Scheme 18).[59] Cp_2VCl is prepared by treatment of the cation with [PPN]Cl (PPN = bis(triphenylphosphine)nitrogen(+1)). The reaction of vanadium hexacarbonyl with Cp_2V results in the formation of the μ-isocarbonyl (*see Isocarbonyl Complexes*) derivative (**35**) as a transient species, which is converted to $[Cp_2V(CO)_2][V(CO)_6]$ (**36**) on treatment with CO. Use of $Co_2(CO)_8$ instead of $V(CO)_6$ leads to $Cp_2VCo(CO)_4$ (**37**), which slowly decomposes to $[Cp_2V(CO)_2][Co(CO)_4]$ (**38**). Ground-state electron transfer between TCNE and 16-electron $V(C_5R_5)_2Br$ (R = H, Me) is investigated.[60]

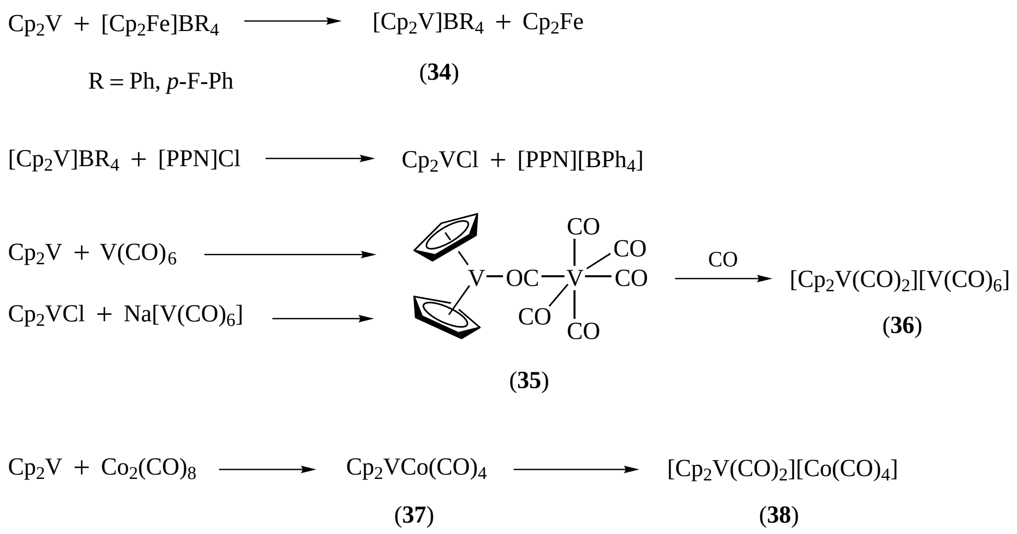


(**33**)
B = 3,6-butyloxybenzene
B = (4-*t*-butylphenyl)$_2$

Methyl substitution on the cyclopentadienyl rings of $Cp'VCl_2$ on the spermicidal activity is investigated.[61] The corresponding oxo compound, $Cp'V(O)Cl_2$, does not show the activity. $V(\eta^5\text{-}C_5H_5)_2((C_2H_5)_2NCS_2)(BF_4)$ is reported to be a potential and stable spermicidal compound.[62] $[Cp_2V(acac)](CF_3SO_3)$ is known as a dual-function anticancer agent with antiangiogenic and antimitotic properties.[63]

$CpV(CO)_4$, which is a typical half-sandwich complex, is prepared by reduction of vanadocene with sodium or potassium under carbon monoxide. Another route to $CpV(CO)_4$ involves the direct reaction of hexacarbonylvanadium(0) with cyclopentadiene. The Cp ring is disordered between staggered and eclipsed conformations.[64] The distance between the centroid and vanadium is 1.9–2.0 Å.

Replacement of the carbonyl ligand affords the corresponding vanadium derivatives.[65–67] The partially phosphine-substituted complex (**39**) is obtained by treatment of phosphine-stabilized VCl_3 with cyclopentadienide, followed by reductive carbonylation (Scheme 19).[68] A variety of cyclopentadienylvanadium halides in the oxidation state 2–5 are synthesized from Cp_2V or $CpV(CO)_4$.[69–75] For example, the reaction of $CpV(CO)_4$ with halogen or oxygen provides the corresponding oxidized complexes as shown in Scheme 20. Use of thiols or chalcogens results in the formation of the corresponding substituted complexes (**40**)[76] and (**41**)[77] (Scheme 21).



Scheme 18

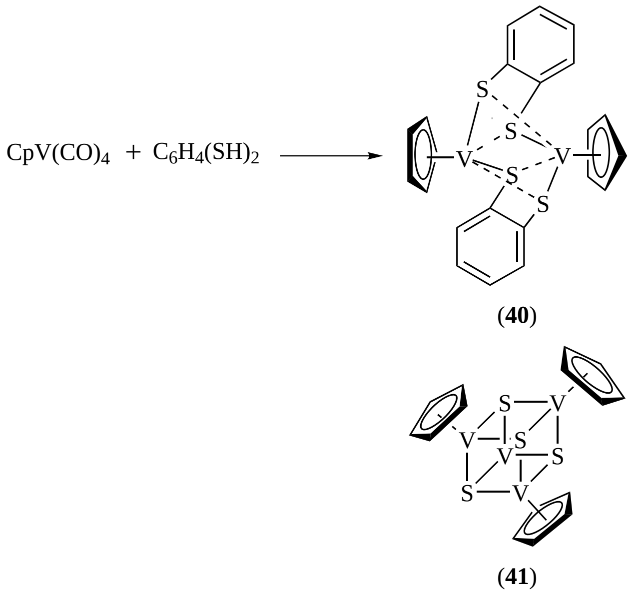
Scheme 20

A fulvene is used for the preparation of the substituted η^5-cyclopentadienylvanadium(I) complexes (**42**) and (**43**) (Scheme 22).[78,79]

Dimerization or cyclotrimerization is performed by reduction of $(C_5Me_4R)VX_3$ (**44**, R = Me, Et) with Na or treatment of VX_3L_3 (L = THF, THT) with $(C_5Me_4R)SnBu_3$ to give the vanadium(III) halides, $(\eta^5\text{-}C_5Me_4R)_2V_2(\mu\text{-}Br)_4$ (**45**, paramagnetic, V–V distance, 2.565 Å) and $(\eta^5\text{-}C_5Me_4R)_3V_3(\mu\text{-}Cl)_6$ (**46**, spin-frustrated antiferromagnetic (*see Antiferromagnetism*), V–V distance, 3.373 Å) (Scheme 23).[80] Unusual difference in V–V distance and magnetochemistry is observed. Halogenation leads to the reformation of (**44**).

Reduction of $[(\eta\text{-}C_5Me_5)VCl(\mu\text{-}N)]_2$ (**47**) with sodium amalgam in toluene, or with lithium nitride or magnesium in tetrahydrofuran, gives diamagnetic $[(\eta^5\text{-}C_5Me_5)V(\mu_3\text{-}N)]_4$ (**48**) (Scheme 24).[81]



Scheme 21

4 η^3-ALLYL AND RELATED COMPLEXES

η^3-Allylvanadium complexes (*see Allyl Complexes*) are synthesized by allylation with Grignard reagents as shown in Scheme 25.[82] Another synthetic route lies in the allylation of a vanadium anionic species with allylic chloride.[83] Codimerization of vanadium-coordinated diphenylacetylene (tolane) and 1,3-butadiene affords the allyl complex (**49**) (Scheme 26).[84]

The η^3-1-azaallyl complex (**51**) is formed by [2 + 2] cycloaddition of (**50**) with alkyne. The metallacycle intermediate is considered to be involved in this transformation (Scheme 27).[85]

Three-electron donor ligands like η^2-acyl ones are also described here. The η^2-CH_2O complex (**52**) is formed by treatment of Cp_2V with paraformaldehyde. Various vanadium compounds are available from (**52**) as shown in Scheme 28.[86]

Use of an acyl chloride permits the transformation from the V(0) compound (**53**) to the η^2-acyl complex (**54**) (Scheme 29).[87–89] The iminoacyl group of (**55**) is also coordinated in the η^2-mode (Scheme 30).[90]

A variety of vanadium carbonyl compounds are obtained from $[V(CO)_6]^-$. Use of 1-chloropenta-2,4-diene under photoirradiation leads to $V(\eta^5\text{-}C_5H_7)(CO)_4$. The η^2-bonded acyl complex is formed similarly by photoinduced substitution with benzoyl chloride.[91] The η^2-C,O coordination mode is

$$2[(\eta\text{-}C_5Me_5)VCl(\mu\text{-}N)]_2 \;+\; 4Na \longrightarrow [(\eta\text{-}C_5Me_5)V(\mu_3\text{-}N)]_4 \;+\; 4NaCl$$

5 η^2-ALKYNE OR ALKENE COMPLEXES

Side-on coordination of an unsaturated ligand, alkyne or alkene, provides the corresponding complexes in the η^2-mode. Vanadium-alkyne complexes like $Cp_2V(RC{\equiv}CR)$ (R = COOMe, CF_3) are formed by treatment of vanadocene with alkynes as shown in Scheme 32.[93–96] (η^2-Alkyne)(η^5-cyclopentadienyl)bis(trimethylphosphine)vanadium(I) (**59**) is obtained by reductive coordination of $CpVCl_2(PMe_3)_2$ (**58**) with alkyne (Scheme 33).[84,97]

Use of $CpV(CO)_4$ under photoirradiation affords $CpV(\eta^2\text{-}C_6F_5C{\equiv}CC_6F_5)(CO)_2$ (Scheme 34).[98] Cyclooligomerization of diphenylacetylene with $Cp_2V_2(CO)_5$ affords the η^4-cyclobutadiene complex (**60**), $V(C_4Ph_4)Cp(CO)_2$ (Scheme 35).[99] The above-mentioned side-on monomeric complex is obtained with the more basic alkyne like dimethylacetylene.

The homobimetallic vanadium d^1-d^1 complex (*see* ***Dinuclear Organometallic Cluster Complexes***), $(Cp_2V)_2$ $(1-2\eta:3-4\eta\text{-RC=C–C=CR})$ is formed by treatment of Cp_2V with $Me_3SiC\equiv C–C\equiv CSiMe_3$ or $Ph_2PC\equiv C–C\equiv CPPh_2$.[100] Antiferromagnetic moments depend on the bridging spacer. The d^2-d^2 homobimetallic complex (**62**) is derived from $Me_3SiC\equiv C–C\equiv C–C\equiv CSiMe_3$ (**61**) as shown in Scheme 36.[101] Cp_2V migration is observed with further complexation of $Cp_2V(3-4\eta\text{-}t\text{-BuC}\equiv C–C_2–C\equiv CC\equiv CBu\text{-}t)$ to give the dimetallic complex $(Cp_2V)_2(1-2\eta:7-8\eta\text{-}t\text{-BuC}\equiv C–C_2–C\equiv CC\equiv CBu\text{-}t)$.[102]

Bis(alkynyl)phosphane (**63**) similarly reacts with Cp_2V to give the vanadacyclopropene phosphane (**64**), which is converted to the alkenyl–alkynyl phosphane (**65**) on treatment with HCl in toluene (Scheme 37).[103]

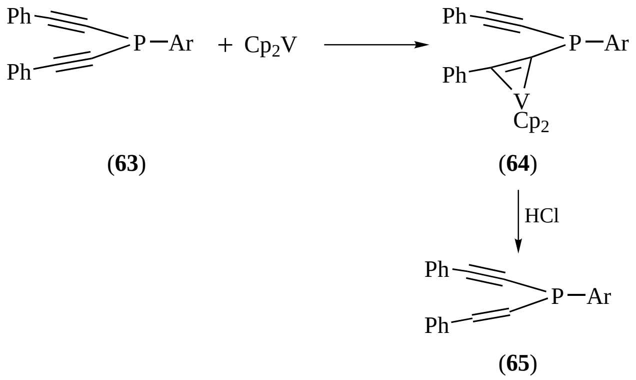
$(C_5H_4R)_2Zr(C\equiv CPh)_2$ (**66**, R = Me, *t*-Bu) is transformed to $Cp_2V(\mu\text{-}\eta^2:\eta^4\text{-butadiyne})ZrCp'_2$ (**67**) in the presence of Cp_2V via the zirconacyclocumulene intermediate as shown in Scheme 38.[104]

The alkyne complex (**68**) reacts with two equivalents of ethene to give the *s-cis*-3,4-(*E*)-diphenyl-1,3-hexadiene complex (**69**) as shown in Scheme 39. Use of 2-butyne leads to the metallacycle (**70**) via bis(alkyne) complex.[84] The bicyclic vanadacyclopentatriene complex (**71**) is formed from 1,7-nonadiyne.

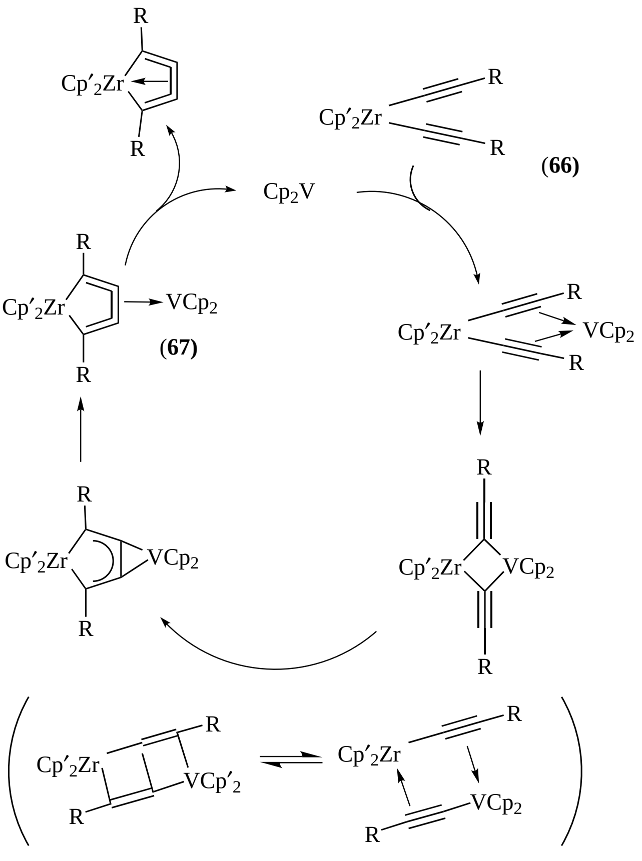
$Cp_2V(\eta^2\text{-alkene})$ is synthesized by treatment of vanadocene with alkene bearing an electron-withdrawing group.[93,105,106] The reaction of vanadocene with dimethyl fumarate or dimethyl maleate leads to the formation of the same complex, bis(η^5-cyclopentadienyl)(η^2-dimethyl fumarate)vanadium (**72**), via isomerization (Scheme 40).

$CpV(\eta^2\text{-ethene})(PMe_3)_2$ (**74**) is obtained as a green paramagnetic complex via the carbon–carbon bond cleavage of the 1,4-divanabutane intermediate, $Cp(PMe_3)_2V(CH_2)_4V(PMe_3)_2Cp$, which is produced by reduction of dichloro(η^5-cyclopentadienyl)bis(trimethylphosphine)vanadium(II) (**73**) with Na/Hg and successive treatment with 1,4-di-Grignard compound (Scheme 41).[84,107] Reaction of (**74**) with carbon monoxide or diphenylacetylene provides the ligand exchange complexes (**75**) and (**76**), respectively. The vanadolactone (**77**) is formed on treatment with carbon dioxide.

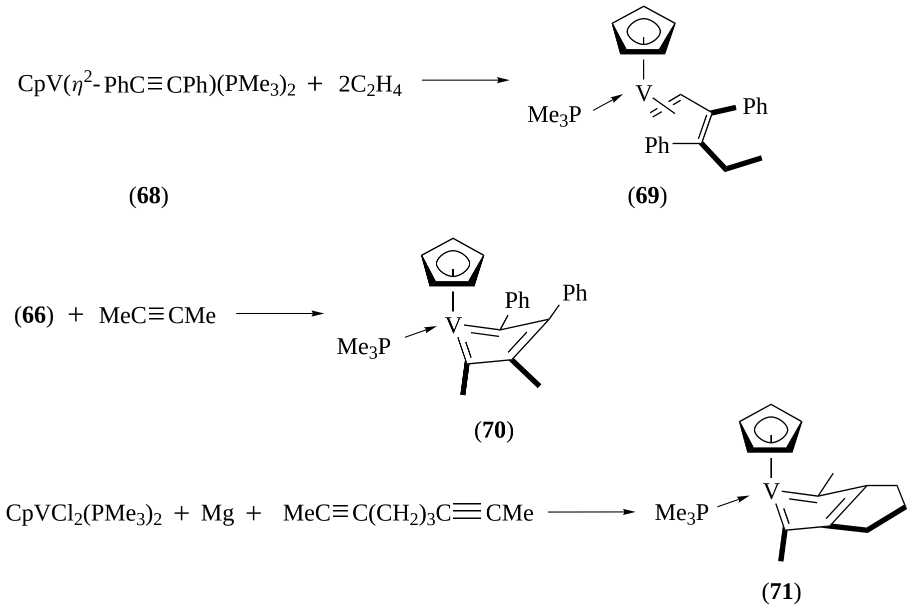
The η^4-vinylketene complex is obtained by photoirradiation of $CpV(CO)_4$ with triphenylcyclopropene via CO insertion.[99]



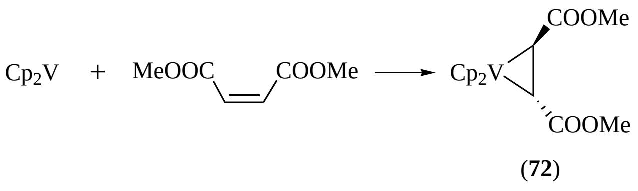
Scheme 37



Scheme 38



Scheme 39



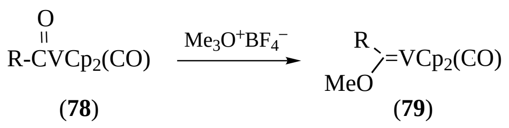
Scheme 40

6 CARBENE COMPLEXES

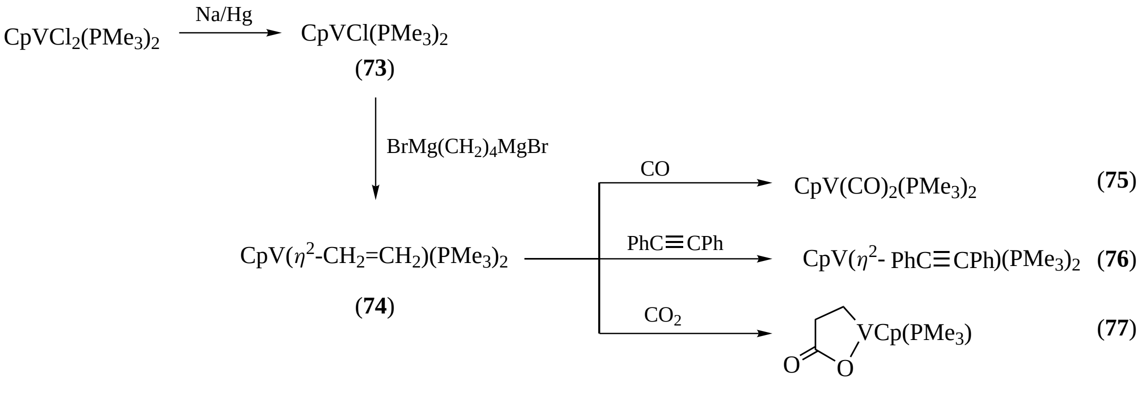
Carbene complexes, in which the carbenes generally bind end-on to the metals through σ donor bond and π bond, are recognized as one of the key organometallics and used especially as catalysts for metathesis polymerization. Although vanadium complexes are of importance in the field of polymer chemistry, only few carbene complexes have been isolated so far.

The acylvanadium complex (**78**) is converted to the Fischer type (*see Fischer-type Carbene Complexes*) vanadium complex (**79**) on treatment with $Me_3{}^+BF_4{}^-$ (Scheme 42).[108]

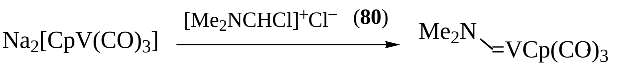
The N-substituted carbene analog is formed from $Na_2[VCp(CO)_3]$ and iminium chloride (**80**) as shown in



Scheme 42



Scheme 41



Scheme 43

Scheme 43.[109] The Fischer-type (*see Fischer-type Carbene Complexes*) vanadium complexes are prepared by treatment of (butadiene)hafnocene (**81**) or (butadiene)zirconocene with $CpV(CO)_4$ (Scheme 44). The equilibrium mixture reacts with cyclopentanone to give the adduct complex (**82**).[110–112]

Thermolysis of (η^5-cyclopentadienyl)bis(neopentyl)(trimethylphosphine)vanadium(I) (**82**) in the presence of 1,2-bis(dimethylphosphino)ethane leads to the formation of the Schrock-type (*see Schrock-type Carbene Complexes*) alkylidene vanadium complex (**83**), which is supported by X-ray crystallographic analysis (Scheme 45).[113,114] The imido vanadium complex (**84**) is converted to the corresponding alkylidene complex (**86**) on treatment with benzylidene(triphenyl)phosphorane (**85**) via substitution of the phosphine ligand (Scheme 46).[115]

Silylation of $Na[V(CO)_2(Me_2PCH_2CH_2PMe_2)_2]$ affords the vanadium carbyne complex (*see Carbyne Complexes*), $V(COSiPh_3)(CO)(Me_2PCH_2CH_2PMe_2)_2$, which is supposed to be a precursor complex for the formation of a η^2-acetylene complex via reductive C–C coupling (*see Reductive C–C Coupling*).[116]

Isocyanide ligands (*see Isocyanide Ligands*) are comparable to carbon monoxide in their σ-donor and π-acceptor ability. Isocyanide complexes (**87**) are formed by ligand exchange of $CpV(CO)_4$ with an isocyanide, which is facilitated by palladium(II) catalyst (Scheme 47).[117] The ligand substitution reaction is also observed with $[V(CO)_6]^-$ to give the corresponding vanadium isocyanide complex (**88**) with the oxidation state −1 (Scheme 48).[118–121] The ligand exchange reaction proceeds via oxidation to give the homoleptic (*see Homoleptic Compound*) vanadium(II) complex (**89**) as shown in Scheme 49.[122,123]

7 σ-BONDED ORGANO- OR HYDRIDOVANADIUM COMPLEXES

The σ-bonded organovanadium compounds are generally unstable, but a wide variety of usage has been developed in organic reaction. The synthetic routes to organovanadium compounds depend on the oxidation state of vanadium. For medium- and high-valent compounds, V–X is replaced by an organic group. Alkyl or aryl vanadium(III) or (IV) compounds (**90**) are synthesized by the reaction of VCl_3 or VCl_4, respectively, with organolithium compounds or Grignard reagents, in which 2,4,6-$Me_3C_6H_2$-, Me_3SiCH_2-, and C_6F_5-substituted derivatives are used (Scheme 50).[124–130] The nitrogen-bridged organovanadium(III) complex (**91**) is obtained when the reaction is carried out under nitrogen (Scheme 51).[131] Thus formed complex (**91**) undergoes oxidation with styrene oxide to the corresponding oxo complex (**92**).

Cyclopentadienyl-substituted vanadium(III) compound (**93**) is also allowed to undergo the substitution reaction to give the σ-alkyl, σ-alkynyl, or σ-aryl complexes (**94**, Scheme 52).[82,132–137] $[NBu_4][V(C_6Cl_5)_4]$, which is prepared from $VCl_3(THF)_3$ and C_6Cl_5Li, is isolated and characterized as a homoleptic, tetrahedral, and paramagnetic d^2 complex.[138]

In the case of low-valent vanadium compounds, metathesis or hydrovanadation is used for the synthesis of organovanadium compounds. Treatment of vanadocene with halomethane results in the formation of the methyl-substituted halovanadocene (**95**) (Scheme 53).[139] The dianion species (**96**) is similarly used for this purpose (Scheme 54).[140]

Coordination numbers of organovanadium compounds are 3 to 6 as exemplified by pseudotetrahedral ($Cp_2V(C{\equiv}CBu\text{-}t)$,[136] $OVMes_3$[126]), square pyramidal (VPh_4),[141] and octahedral ($[(LiOEt_2)_4VPh_6]$).[142] The V(II) and V(III) compounds in a high-spin configuration (*see High-spin & Low-spin Compounds*) exhibit normal Curie–Weiss behavior.[143] Reaction modes vary disproportionation, symproportionation, ligand coupling, and insertion as shown in Scheme 55.

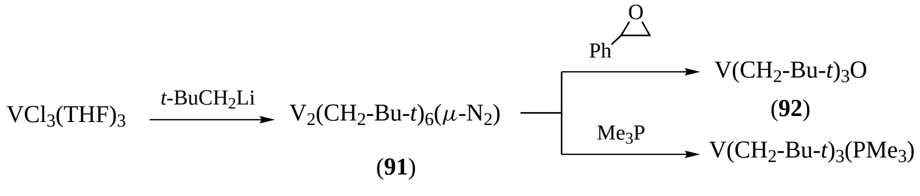
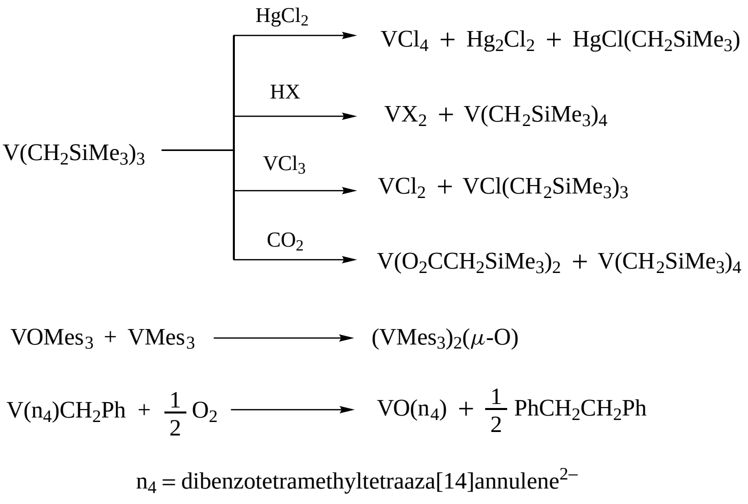
Scheme 54



Scheme 51



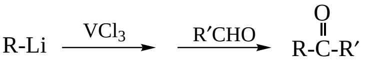
Scheme 55

A variety of synthetic transformations have been developed by using vanadium compounds or intermediates. Cp-substituted vanadiums are used in catalytic polymerization, which involves organovanadium intermediates.[144]

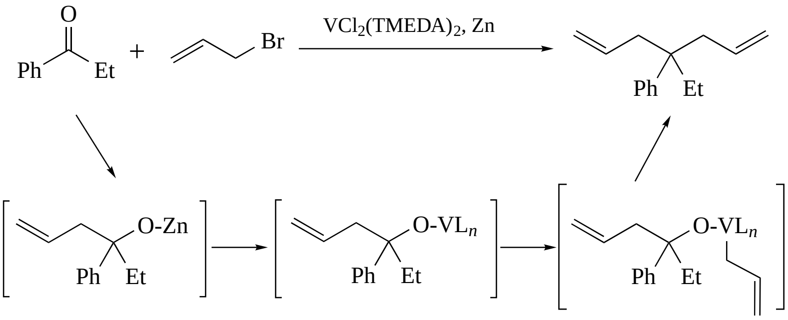
Isomerization of alkenes is catalyzed by bis(η^3-allyl)(η^5-cyclopentadienyl)vanadium(IV).[145] Cyclohexene undergoes catalytic stereoselective aerobic oxidation with $CpV(CO)_4$.[146] Reductive coupling (*see Reductive Coupling*) of aldehydes and aldimines is catalyzed by a Cp-substituted vanadium compound in the presence of a chlorosilane and zinc or aluminum.[147–151] Vanadocene or bis(η^5-cyclopentadienyl)dimethylvanadium(IV) catalyzes the synthesis of 1,2-diphenyldisilane and 1,2,3-triphenyltrisilane from phenylsilane.[152]

Organovanadium compounds exhibit unique reactivity on the basis of the redox characteristics of the vanadium. For example, treatment of VCl_3 in THF with a stoichiometric amount of *n*- or *s*-alkylmagnesium halides affords alkanes, alkenes, and dimers.[153] The organovanadium compounds generated in situ couple chemoselectively with acid chlorides or allyl halides.[154] A related reaction with aldehydes yields coupled ketones via oxidative nucleophilic addition (Scheme 56).[155,156]

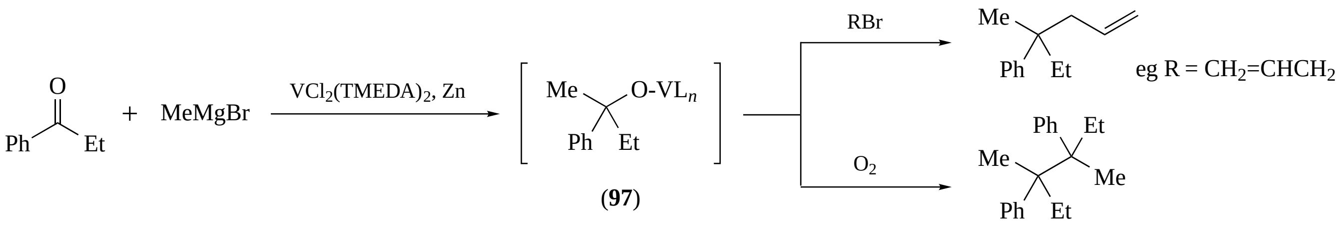
Direct geminal allylation of propiophenone with allyl bromide proceeds in the presence of $VCl_3(THF)_3$/Zn or $VCl_2(TMEDA)_2$/Zn.[157] This deoxygenative transformation is performed by the oxophilicity of low-valent vanadium (Scheme 57). Successive treatment of propiophenone with a Grignard reagent, $VCl_2(TMEDA)_2$, and allylic bromide results in geminal carbon–carbon bond formation at the carbonyl carbon (Scheme 58). Homocoupling, rather than allylation, of the alkoxyvanadium intermediate (**97**) occurs in the presence of a catalytic amount of molecular oxygen.[158] Allylic vanadium and oxovanadium compounds are characterized.[159]



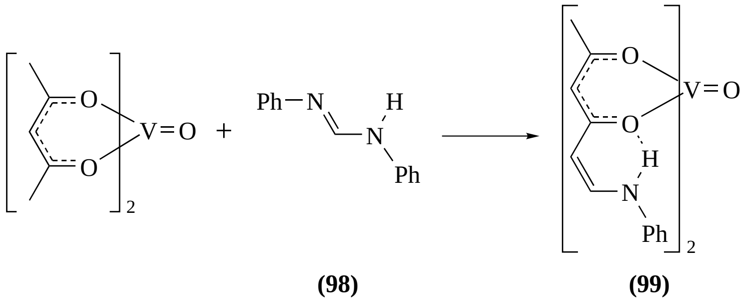
Scheme 56



Scheme 57



Scheme 58



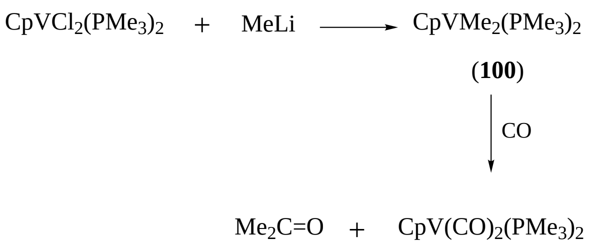
Scheme 59

VO(acac)$_2$ reacts with N,N'-diphenylformamidine (**98**) to give oxobis[6-(phenylamino)hexane-2,4-dionato-O,O′]vanadium(IV) (**99**) via substitution onto methyl group of the acetylacetonate ligand (Scheme 59).[160]

Insertion into a carbon−vanadium bond provides a variety of useful synthetic strategies. For example, the methylvanadium complex (**100**), obtained from CpVCl$_2$(PMe$_3$)$_2$ and MeLi, rapidly inserts carbon monoxide (*see CO Insertion*) to give acetone and CpV(CO)$_2$(PMe$_3$)$_2$ (Scheme 60).[161]

t-Butyl isocyanide likewise inserts into three carbon−vanadium bonds of [V(Mes)$_3$(THF)] to give the tris(η^2-iminoacyl) complex (**101**). When the complex (**101**) is exposed to air, (**101**) is converted to the corresponding amide (**102**), while its exposure to water produces the imine (**103**) through hydrolysis (Scheme 61).[162]

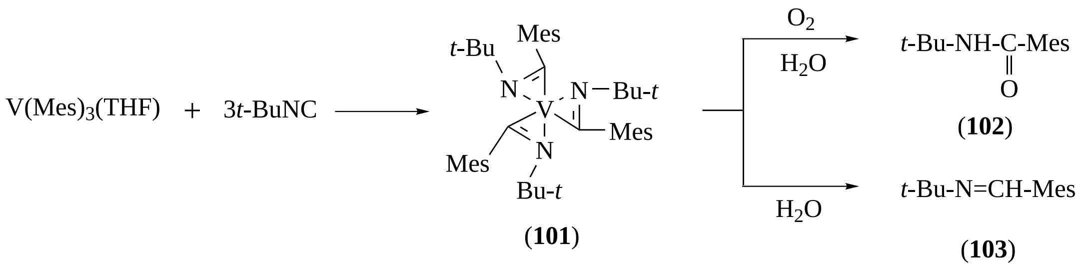
The reaction of VCl$_3$(THF)$_3$ with (Me$_3$Si)$_2$NLi leads to the dimeric complex (**104**) via C–H σ-bond metathesis (*see σ-Bond Metathesis*) of a trimethylsilyl group (Scheme 62).



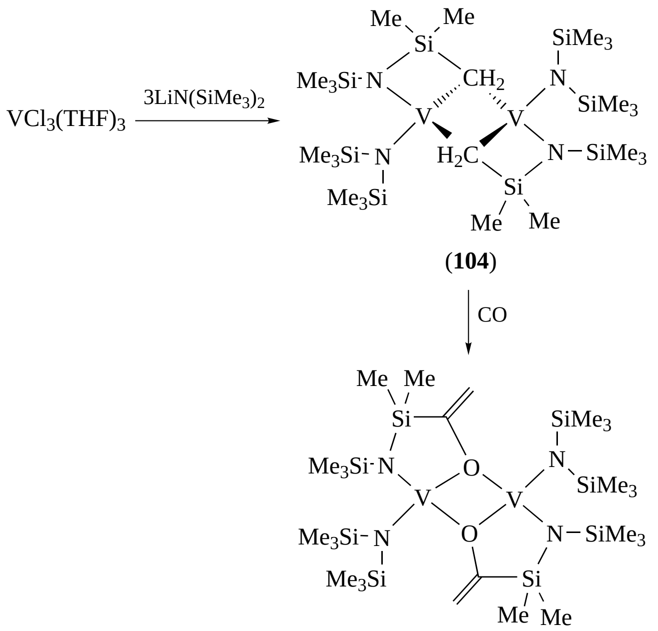
Scheme 60

The dinuclear enolate complex (**105**) is then formed by treatment of (**104**) with carbon monoxide, which inserts into the vanadium−carbon bonds.[163]

Hydrovanadation is an effective route to the organovanadium compounds as shown in Scheme 63.[164–166] Hexacarbonylhydridovanadium, VH(CO)$_6$, is a thermally unstable,



Scheme 61



(105)

Scheme 62

neutral complex with 18-electron configuration. Ligand exchange with the phosphine ligand provides a more stable complex.[167] Treatment of $V(CO)_6^-$ with silica gel leads to a similar hydridovanadium complex (*see Hydrides*).[168–170]

The air-sensitive Cp-substituted hydridovanadium complex is obtained by hydrogenolysis of the corresponding methyl derivative.[53] The corresponding anionic compound is obtained by reduction of $CpV(CO)_4$ with sodium and protonation with water (Scheme 64).[140] Thus obtained $[CpVH(CO)_3]^-$ (**106**) is a useful one-electron reductant to reduce bromo- and iodoalkanes, bromoalkenes, and arylbromides in THF. Furthermore, acid chlorides are reduced to the aldehydes. A similar reduction with (**106**) is performed by using phase-transfer conditions in the presence of tetrabutylammonium hydrogen sulfate. Nitro compounds and organic halides are reduced under these conditions.

Complexation of the oxo group of $VO(CH_2SiMe_3)_n(OSiPh_3)_{3-n}$ ($n = 0-3$) with $Al(CH_2SiMe_3)_3$ facilitates the insertion of ethylene into the carbon–vanadium bond by reducing the degree of π-donation from the oxo ligand. This type of interaction is important in olefin polymerization.[171] The oxovanadium(V)-catalyzed oxidation of benzyltin compounds occurs under oxygen atmosphere to afford the aromatic aldehydes (ketones) and/or carboxylic acids. Oxidative ligand coupling of organoaluminums, organoborons, organozincs, and their -ate complexes is achieved by treatment with oxovanadium(V) compound, leading to the formation of the C,C-coupled adducts.[172] The reaction is considered to proceed via electron-transfer process or transmetalation (*see Transmetalation*) to generate organovanadium species.

The 1,2,4-azaphosphavanada(V)cyclobutane (**108**), which is obtained by cyclization of the imidovanadium(V) compound (**107**) with phosphaalkyne, reacts with alkyne to give

P = tris(3-diethylphophinopropyl)phosphine

Scheme 63

$$CpV(CO)_4 \xrightarrow{\text{Na or Na/Hg}} [Na_2[CpV(CO)_3]^{2-} \xrightarrow[\text{2. } [(Ph_3P)_2N]^+Cl^-]{\text{1. } H_2O} [(Ph_3P)_2N]^+[CpVH(CO)_3]^-$$

the 1*H*-1,2-azaphosphole (**109**) via reductive elimination, (*see Reductive Elimination*), (Scheme 65).[173,174]

8 CONCLUSION

The investigation on the chemistry of organovanadium compounds is rather limited probably because of the difficulty in the characterization and isolation, but their properties and reactivities appear to be of potential as materials, medicine, reagents, and catalysts. Functionalization or design of organic moieties and redox properties will provide a variety of organovanadium compounds, which may open the door of new vanadium chemistry.

bzacH = 1-phenyl-1,3-butanedione; dikeH = β-diketone; dpmH = 2,2,6,6-tetramethylheptanedione (dipivaloylmethane); HIm = imidazole; Hpz = pyrazole; pico = 2-picolylamine.

1 INTRODUCTION

There are a vast number of O-donor ligands, ranging from simple naturally occurring ligands such as water, which have been studied for many decades, to artificial systems such as the crown ethers and calixarenes, which are a relatively recent development. Exhaustive coverage of all these ligands is not possible here, and hence the discussion is divided into categories of the most widely studied systems. The aim of the article is to demonstrate the nature of the complexes formed by the ligands and some of the chemistry involved in obtaining them.

2 WATER, HYDROXIDE, AND OXIDE

2.1 Introduction

A large proportion of inorganic chemistry takes place in aqueous solution, and hence the nature of the species formed when a metal ion is dissolved in water is of great importance, and has been the subject of study for many years. This leads to consideration of water, hydroxide, and oxide as ligands. These are discussed individually below, but it is appropriate to briefly consider the relationship between the three species.

Deprotonation of the parent aqua ions, $[M(OH_2)_x]^{n+}$, gives rise to hydroxo and then oxo complexes, and consequently the nature of the species present in solution is strongly dependant on pH. The acidity of the aqua ions varies enormously with the metal ion, with an approximate correlation with electrostatic considerations. Thus, higher charge density of the metal ion is often associated with greater acidity of the aqua ion. Such trends are not reliable, however, since properties such as high oxidizing power and ‘softness’ (*see* ***Hard & Soft Acids and Bases***) are generally associated with strongly acidic aqua ions. It follows that hydroxo and oxo ligands tend to be associated with highly charged metal ions, while only oxo ligands, which are very difficult to oxidize, are found with the highest oxidation states, in species such as MnO_4^- and CrO_4^{2-}. Exceptions to this can be found in the larger actinide cations, where water molecules are found coordinated to metal ions in oxidation states of 5+ and 6+, although the complexes also include oxo ligands; one example is the complex ion $[UO_2(OH_2)_5]^{2+}$. Various combinations of aqua, hydroxo, and oxo ligands can be found, including species containing all three (most commonly with the vanadyl (*see* ***Vanadium: Inorganic & Coordination Chemistry***), and uranyl (*see* ***Actinides: Inorganic & Coordination Chemistry***) cations).

Finally, it is important to note that, while H_2O is a relatively poor bridging ligand, both hydroxo and oxo ligands readily act as bridges between metal atoms, giving rise to polynuclear species, which are not discussed in detail here (*see* ***Polyoxometalates***).

2.2 Aqua Complexes

Discrete $[M(OH_2)_x]^{n+}$ species are found in the hydrates of many metal salts where the anion is a poor ligand, such as ClO_4^-, PF_6^-, BF_4^-, and so on. In many cases, particularly for the first-row transition metals but also other cations such as Mg^{2+}, Al^{3+}, and In^{3+}, hexaaqua ions are formed with an octahedral arrangement of water O atoms about the metal atom. The larger lanthanide and actinide ions generally form octa- or nonaaqua ions, although octahedral hexaaqua ions have been found in $Ln(ClO_4)_3\cdot 6H_2O$.**[1]** Water is a relatively poor bridging ligand, although a search of the Cambridge Structural Database reveals ~500 examples including main group and transition metal complexes.**[2]**

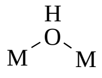
The nature of ions in aqueous solution has been studied using a wide variety of techniques, including X ray and neutron diffraction, and quasielastic neutron scattering, NMR, IR, and UV spectroscopies. The ions are generally considered to have primary and secondary hydration spheres, although there is relatively little quantitative information available concerning the second sphere in solution.**[3]** The rate of exchange of the

H_2O molecules in the hydration spheres with the bulk H_2O solvent varies by many orders of magnitude depending on the metal ion.[3] This, combined with the use of many different experimental techniques, has resulted in discrepancies in the literature, particularly for metal ions with a weakly bound, rapidly exchanging hydration sphere. The Na^+ cation, for example, has had quoted values for the primary solvation number ranging from 2 to 13, although a value close to six is generally accepted.[4]

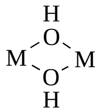
Metals that form relatively stable aqua ions in solution have generally been well characterized. The hydration numbers of the transition metals, for example, have commonly been found to be six, consistent with the results of solid-state studies of crystalline hydrates. Exceptions include Ag^+, which has a hydration number of four, and Cu^{2+}, which has been found to have four short M–O interactions and two longer ones, consistent with a Jahn–Teller distortion (*see Jahn–Teller Effect*) of the complex. The hydration numbers of the lanthanide ions in solution have been the subject of many investigations and some controversy; recent results suggest a decrease from nine to eight across the series from La^{3+} to Lu^{3+}.[4]

2.3 Hydroxo Complexes

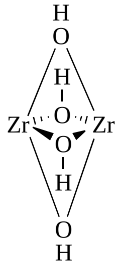
The hydroxide ion assumes bridging coordination modes more often than water. Double μ_2-hydroxide bridges (**2**) are the most common, although single hydroxide bridges (**1**) have been known for some time in complexes such as $[(H_3N)_5Co(\mu\text{-}OH)Co(NH_3)_5]^{5+}$. Both double and single hydroxide bridges may be supported by another bridging ligand. Triple hydroxide bridges are relatively rare and quadruple hydroxide bridges (**3**) have only been observed to date linking zirconium porphyrin moieties.[5] μ_3-Hydroxide (**4**) is also relatively rare, occurring most frequently in cubane type structures (**5**), in species such as $[Cr_4(OH)_4]^{8+}$ and $[Ni_4(OH)_4]^{4+}$.[6]



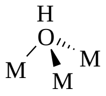
(**1**)



(**2**)

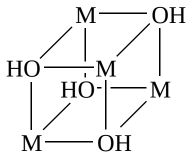


(**3**)

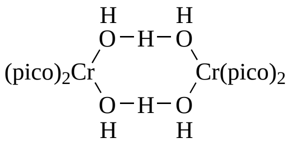


(**4**)

Hydrated hydroxide metal complexes can also form a hydrogen-bonded $H_3O_2^-$ bridging moiety, which has been structurally characterized in single bridged[7] and double bridged species; $[(pico)_2Cr(H_3O_2)_2Cr(pico)_2]$ (**6**),[8] is an example of the latter. These bridges have been formulated as discrete $H_3O_2^-$ and alternatively as H_2O/OH^- bridges;



(**5**)



(**6**)

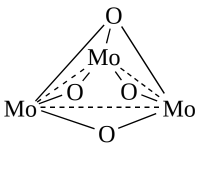
theoretical studies suggest the bridging H atom should be increasingly asymmetrically positioned as the O···O distance increases.[9]

2.4 Oxo Complexes

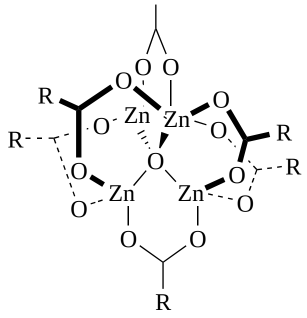
The multiply bonded oxo group, found in transition metal complexes such as UO_2^{2+}, MnO_4^-, and OsO_4, is usually terminal, although very asymmetric μ_2-oxide bridges have been observed, suggesting an M = O → M bridge.

Single, double, and triple μ_2-oxo bridges are known, although single bridges are the most common. The M–O–M angle about a single oxo bridge can vary from 140 to 180°, depending mainly on steric and electronic factors. Double and triple bridges are most commonly found in ***Polyoxometalates***.

μ_3-Oxo bridges are well known and can form planar or pyramidal M_3–O units, usually with equal M–O distances. Molybdenum(IV) in aqueous solutions forms $Mo_3O_4^{4+}$ (**7**), for example, which has three μ_2-oxo bridges and a pyramidal μ_3-oxo bridge.[10] Trimetallic, triangular metal carboxylates contain a triangular μ_3-oxo ligand and are known for a number of transition metals (see Section 6.1). μ_4-Oxide is less common, but is found in a number of carboxylates where the oxo ligand is surrounded by a tetrahedral arrangement of M atoms, which are also linked by the carboxylate ligands (**8**). The $Zn_4O(carboxylate)_6$ unit, for example, has been used as a building block in constructing impressive metal-organic frameworks with highly porous structures.[11] (*See also* ***Oxides: Solid-state Chemistry***).



(**7**)



(**8**)

3 ALKOXIDES AND ARYLOXIDES

Metal alkoxides and aryloxides, of the general formula $M(OR)_x$, can be considered as derived from the alcohol ROH by replacement of the hydroxylic hydrogen atom by the metal.[12] These complexes have been known for many years; $Ti(OEt_4)$ was prepared in 1924 by Bischoff and Adkins,[13] and the synthesis was attempted as early as 1875 by Demarçay[14] although pure product was apparently not obtained. Potential technological applications have resulted in increased activity in this area in recent years (*see* ***Sol–Gel Synthesis of Solids***).[15,16]

3.1 Structure and Bonding

Although usually considered to be a one-electron ligand, alkoxide and aryloxide groups can assume a number of modes of coordination (Figure 1), with the M–O distances decreasing in the order M–OR (μ_3) > (μ_2) > terminal. Shorter terminal M–O distances are found to be associated with larger M–O–C angles; for example, the Zr–O–C angle in $[ZrCl_4(OMe)(MeOH)]$ is 171.4°, compatible with a Zr–O triple bond, with the alkoxide ligand acting as a three-electron donor. Shorter M–O bonds and larger M–O–C angles appear to be associated with increasing electron deficiency of the metal.[17]

Most alkoxides with simple R groups are polymeric or oligomeric to an extent that satisfies the coordination of the metal.[18] Some common types of small oligomeric structures are shown in Figure 2. Although a large body of data has been collected on these systems, it is still difficult to predict which structure will be formed by a certain combination of M and RO. Factors that appear to influence the structure include the size and oxidation state of the metal atom, the steric bulk of the alkyl or aryl group, and the d^n configuration (for the transition elements). The introduction of very bulky alkyl or aryl groups favors the formation of lower oligomers or monomeric species, often with unusually low coordination numbers. A decrease in the extent of oligomerization usually results in an increase in the volatility of the metal alkoxide.

3.2 Synthesis

In some cases, metal alkoxides and aryloxides can be obtained simply by direct reaction of the appropriate alcohol

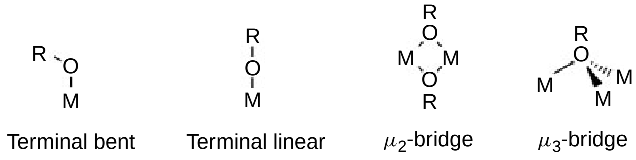


Figure 1 Coordination modes of alkoxide and aryloxide ligands

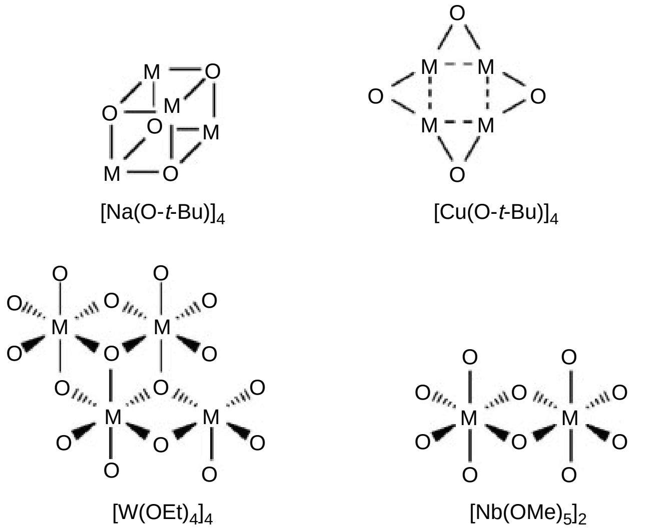

Figure 2 Some structural types for small oligomeric metal alkoxides

or phenol with the bulk metal (equation 1). The method is limited by the low pK_a of alcohols and most phenols to the more electropositive elements. Group 1 metals react readily in this way, while group 2, 3, and the lanthanide metals require the presence of a catalyst, such as iodine or a mercury(II) salt, for the reaction to take place. Electrochemical synthesis using a sacrificial anode of the required metal is applicable to a greater range of metals, but this method has not been widely exploited.

$$M + nROH \longrightarrow M(OR)_n + \frac{n}{2}H_2 \quad (1)$$

A more common approach to the synthesis of metal alkoxides and aryloxides is to make use of a metal halide. This method is particularly effective for the less electropositive elements such as B, Si, and P, where the reaction readily goes to completion (equation 2). Analogous reactions of the halide derivatives of more electropositive elements, such as the transition metals, often give products containing both halide and alkoxide ligands, as shown in equation (3). The acidity of the alcohol also influences the course of the reaction; phenols, for example, are more acidic than alcohols and are more likely to effect complete substitution of the halide ligands (compare equations 3 and 4). The problem of incomplete substitution can be overcome by carrying out the reaction of the metal halide and alcohol in the presence of a base. Anhydrous ammonia is often employed as the proton acceptor, with the precipitation of ammonium chloride forcing the reaction to completion (equation 5). This is probably the most widely used method of synthesizing homoleptic alkoxides and aryloxides.

$$SiCl_4 + 4EtOH \longrightarrow Si(OEt)_4 + 4HCl \quad (2)$$

$$WCl_6 + 3EtOH \longrightarrow WCl_3(OEt)_3 + 3HCl \quad (3)$$

$$\mathrm{WCl_6 + 6PhOH \longrightarrow W(OPh)_6 + 6HCl} \quad (4)$$

$$\mathrm{TiCl_4 + 4ROH + 4RNH_3 \longrightarrow Ti(OR)_4 + 4NH_4Cl} \quad (5)$$

The reaction of metal halides with an alkoxide or aryloxide (most commonly an alkali metal alkoxide), can result in metathetic exchange to give the required complex (equation 6). Such reactions can also result in the formation of heterometallic species (such as $NaZr_2(OR)_4$); this can be a problem when homometallic alkoxides are desired, but it is an important route to heterometallic alkoxides and aryloxides. The nature of the product can be influenced by the alkali metal, the alkoxide ligand, and the relative amounts of the reactants.[19]

$$\mathrm{CuCl_2 + 2LiOR \longrightarrow Cu(OR)_2 + 2LiCl} \quad (6)$$

Metal diamides are useful starting materials in the synthesis of these compounds, particularly for the early transition metals where available routes to the metal alkoxides are limited (equation 7). R in equation (7) is often the bulky $SiMe_3$ group; $N(SiMe_3)_2$ is known to be a good leaving group, and the by-product $HN(SiMe_3)_2$ is reasonably volatile. The use of less bulky dialkylamides such as $M(NMe_2)_n$ can lead to complications such as adduct formation where the dimethylamine formed is coordinated to the metal center. Other convenient starting materials include metal hydrides and alkyls, which react similarly, to give volatile by-products (hydrogen or an alkane) and the metal alkoxide. Finally, alcohol interchange reactions make use of metal alkoxides to produce new alkoxides as shown in equation (8). The order of reactivity of the attacking alcohol tends to be primary > secondary > tertiary. Interchange reactions are particularly useful in the synthesis of phenoxides owing to the higher acidity and lower volatility of phenols relative to alcohols.

$$\mathrm{M(NR_2)_{\mathit{n}} + \mathit{n}R'OH \longrightarrow M(OR')_{\mathit{n}} + \mathit{n}HNR_2} \quad (7)$$

$$\mathrm{M(OR)_{\mathit{n}} + \mathit{n}R'OH \longrightarrow M(OR')_{\mathit{n}} + \mathit{n}ROH} \quad (8)$$

It is important to note that efforts to synthesize metal alkoxides and aryloxides (particularly lanthanide and actinide complexes) have sometimes produced unexpected products, incorporating halide or oxide ligands, for example. As a result, some early literature may contain incorrect formulations.[12,15,17]

3.3 Reactions of Alkoxides and Aryloxides

Protonolysis reactions of alkoxides and aryloxides are common; one example is hydrolysis of the metal alkoxide, giving metal oxide with elimination of the alcohol. Although the aim is often to avoid such a reaction, it is of great interest in the deposition of high-purity metal oxides, which are used in areas such as optoelectronics, high T_c superconductors, and advanced ceramics.[15]

Other protonolysis reactions include reactions with carboxylic acids to give metal carboxylates (see Section 6) and with β-diketones to give the metal β-diketonates (see Section 4), as shown in equations (9) and (10), respectively.

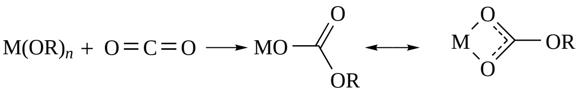
$$\mathrm{M(OR)_{\mathit{n}} + \mathit{n}R'CO_2H \longrightarrow M(O_2CR')_{\mathit{n}} + \mathit{n}ROH} \quad (9)$$

$$\mathrm{M(OR)_{\mathit{n}} + \mathit{n}(dikeH) \longrightarrow M(dike')_{\mathit{n}} + \mathit{n}ROH} \quad (10)$$

Hydrogenolysis can provide a route to metal hydrides; one example is shown in equation (11) (*see* ***Hydride Complexes of the Transition Metals***).

$$\mathrm{(CuO\text{-}\mathit{t}\text{-}Bu)_4 \xrightarrow[PR_3]{H_2} [HCu(PR_3)_2]_2 + \mathit{t}\text{-}BuOH} \quad (11)$$

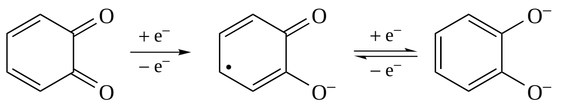
Insertion reactions involving metal alkoxides are also known. For example, carbon dioxide is known to react with some metal alkoxides as shown in equation (12). The formation of a bidentate ligand is a significant thermodynamic driving force for some of these reactions. The isoelectronic aryl and alkyl isocyanates and carbodiimides can react similarly. Insertion reactions involving alkenes and carbon monoxide are known for platinum alkoxides.



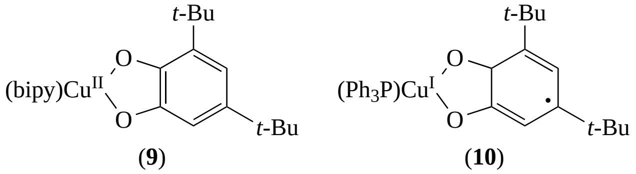
(12)

3.4 Catecholates, *o*-Quinone, and *o*-Semiquinone Ligands

These three ligands are related by the addition or removal of electrons as shown in equation (13). A metal–quinone chelate ring can be considered to have three potential isoelectronic forms, depending on the distribution of formal charge between the metal and ligand. The form that predominates can depend, for example, on the other ligands attached to the metal, as shown for the copper complexes (**9**) and (**10**).[19]



(13)

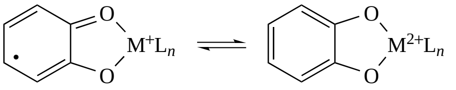


(**9**) (**10**)

Just as the free ligand can be interconverted by redox processes, so can the corresponding metal complexes. For

example, tris(semiquinone)chromium(III) can undergo a stepwise three-electron oxidation to the tris(benzoquinone) complex, or a stepwise three-electron reduction to the tris(catecholato)chromium(III) trianion. Intermediate, mixed-ligand species have also been characterized.[20]

o-Quinone and semiquinone complexes are generally prepared under anhydrous conditions, either directly by combination of the ligand and a metal salt or complex (such as a metal carbonyl complex), or by electrochemical procedures from catecholate complexes. Catecholate complexes are more readily synthesized, and are known for a wide range of metal ions. Characterization of these complexes as quinone, semiquinone, or catecholate, using X-ray diffraction, EPR (*see Electron Paramagnetic Resonance*), NMR, and magnetic methods (*see Magnetochemistry*), is generally straightforward, but complications can arise in systems where there is a small separation between the energies of the metal and quinone electronic levels. This can result in an equilibrium between redox isomers with differing charge distributions as shown in equation (14). The term valence tautomerism has been applied to this phenomenon.[19] Changes in the charge distribution can be induced by changes in temperature, light irradiation or altering the structure of the coligands. These systems have potential applications as sensors and switches.[21]

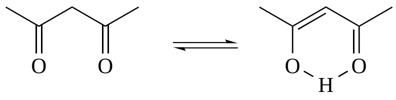


(14)

Much of the interest in these complexes arises from their relevance to biological systems. For example, the binding site for iron in some siderophores is found to include three catecholate groups (*see* ***Iron Transport: Siderophores***). This has led to a great deal of work using catecholate-based systems as sequestering agents for metals of biological and environmental importance.[22,23] Quinone–iron interactions are also important in photosynthesis and respiration processes (*see* ***Photosynthesis***). Finally, it should be noted that *p*-quinones and the related mon*o*- and dianions, by nature of the geometry of the molecule, often form a bridge between metal atoms.

4 *β*-DIKETONES AND RELATED LIGANDS

2,4-Pentanedione (acac) and related *β*-dicarbonyl compounds are an extremely important class of ligands that have been studied widely for many years. In general, *β*-dicarbonyl compounds exist as mixtures of tautomeric keto and enol forms (equation 15). These compounds are usually easily deprotonated to form monoanions, which form the basis for a large class of coordination compounds, encompassing virtually every element. In addition, coordination compounds of the dianions and trianions of *β*-diketones have been observed, as well as complexes of the neutral molecules.[24,25]



(15)

4.1 Structure and Bonding

The *β*-diketones are a versatile class of ligand with many known modes of coordination, some of which are shown in Figure 3. O,O′-chelation (**11**) of the monoanion is by far the most common mode, being found for almost all of the metallic and metalloid elements. Compounds of the stoichiometry $M(dike)_3$ and $M(dike)_2$ are the most common. The former generally have an almost octahedral distribution of the six oxygen atoms when M is a main group or transition metal. These compounds have been used extensively in studies of the mechanism of the racemization of trischelate complexes.

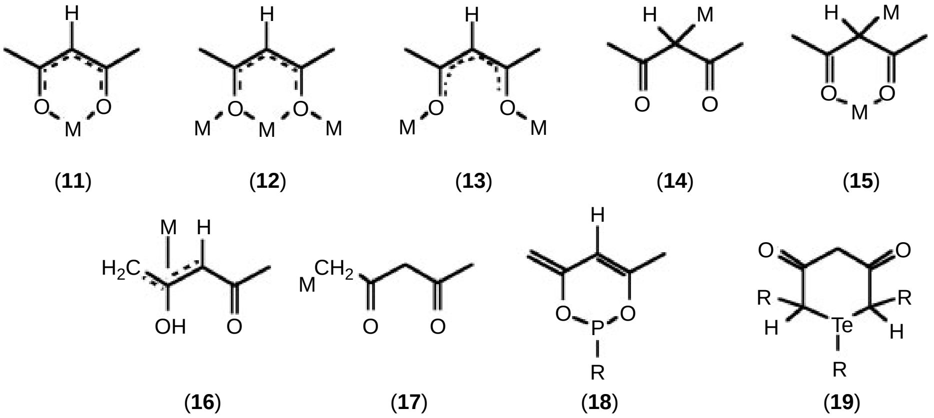


Figure 3 Examples of some of the coordination modes known for *β*-diketonate anions

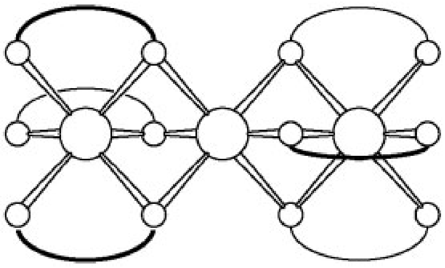
β-Diketone complexes of the lanthanides tend to adopt higher coordination numbers, often crystallizing as hydrates.

Complexes with the composition M(dike)$_2$ usually exist as oligomers, so that the metal atoms are coordinatively saturated. For example, the acetylacetonate complexes of Ni, Zn, and Mn^{II} exist in the solid state as trimers of varying structure, with bridging β-diketonate groups (**20**).[26] The extent of oligomerization varies with the metal cation: Cu^{II} forms a monomer, while Co^{II} forms a tetrameric structure. Substituting the terminal methyl groups with larger substituents favors the formation of the monomer, although these are often solvated to give five- or six-coordinate complexes. O-O′-chelation in combination with bridging (**12**) is thus quite common, whereas the purely bridging mode of coordination (**13**) is rare, but was first observed in lanthanide complexes such as Er$_8$O(OH)$_{12}$(dpm)$_{10}$, which has a complex structure where eight of the dpm ligands are bidentate chelate, and the remaining two are purely bridging.



(**20**) [Mn(acac)$_2$]$_3$

The monoanions of β-dicarbonyl compounds also form organometallic species, usually involving the central carbon atom in the M–C bond (**14**). Such species are known for a number of metals, particularly those of the platinum group. This mode of binding leaves the two carbonyl oxygen atoms free, allowing the formation of bimetallic species (**15**). η^3-Allylic (**16**) and terminal (**17**) carbon bonding have also been observed.

Dianions of β-diketones are also known to form metal complexes, but are much less common than systems containing the monoanion. Such complexes usually involve main group elements or members of the platinum group, and may be coordinated to the O atoms (**18**) or terminal C-atoms (**19**).[25,27]

4.2 Synthesis

Metal β-diketonates are generally synthesized from the neutral β-diketones and the appropriate bulk metal or metal salt are synthesized in solvents such as water, dioxane, ethanol, or neat diketone. The use of the bulk metal is limited to the more electropositive elements such as the group 1 and 2 metals, although the method is more widely applicable with more acidic β-diketones, such as those with perfluoroalkyl substituents. Electrochemical syntheses of some acac complexes have been described, using the appropriate metal anode.

More common is the use of a metal salt, such as halide, hydroxide, oxide, sulfate, carboxylate, and so on. A base can also be added, to convert the β-diketone to the β-ketoenolate anion, which usually has greater solubility in aqueous media.

Metal alkoxides and alkyls are useful starting materials, particularly for the preparation of some unsolvated β-diketones that require anhydrous conditions (see Section 3.3). Addition of β-diketonate ligands to metal alkoxides has also been used to produce heteroleptic metal complexes that are less reactive than the homoleptic metal alkoxides; this simplifies the use of such complexes in chemical vapor deposition applications.[16]

4.3 Reactions of β-diketonates

Metal β-diketonates, particularly acetylacetonates, will undergo electrophilic substitution at the central methine carbon atom in a similar way to aromatic compounds. Known reactions of this sort include bromination, nitration, acylation, and the Mannich reaction.

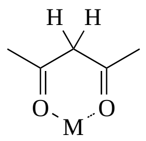
Hydrolysis (the reverse of the preparative reaction) and other exchange reactions of the metal β-diketonates have been studied in some detail in order to probe the mechanisms of inorganic substitution reactions. As mentioned in Section 4.1, there has been intense study of the intramolecular rearrangements of M(dike)$_3$ complexes. Decomposition of metal β-diketonate complexes to give high-purity metals or metal oxides is of technological importance.

Metal β-diketonates are often coordinatively unsaturated (*see Coordinative Saturation & Unsaturation*) and will therefore react with Lewis bases to form complexes. For example, the trimer [Ni(acac)$_2$]$_3$ will react with Lewis bases such as water or pyridine to form monomeric *trans*-[Ni(acac)$_2$L$_2$]. The formation of weak complexes with lanthanide β-diketonates is critical in their use as NMR shift reagents.

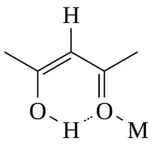
4.4 Complexes of Neutral β-diketones

A number of complexes of neutral β-diketones are known, although such complexes are generally not very stable. They can be synthesized by addition of the β-diketone to a simple metal salt or coordinatively unsaturated metal complex, by controlled hydrolysis of a metal β-diketonate, or by displacement of a weakly bound neutral ligand by the β-diketone.

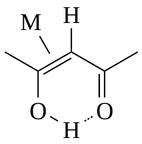
O,O′-chelation (**21**) of acacH has been found in NiBr$_2$(acacH)$_2$ and [Ni(acacH)$_2$(H$_2$O)$_2$](ClO$_4$)$_2$. O-unidentate coordination of the enol form (**22**) has been structurally characterized in MnBr$_2$(acacH)$_2$ and [ReCl(CO)$_3$(bzacH)]$_2$. η^2(C,C′) coordination of the enol (**23**) has been implicated by NMR and IR studies of the platinum complex [PtCl(acac)(acacH)].[28]



(21)



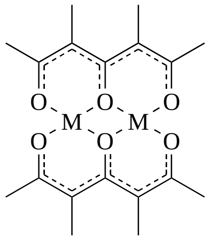
(22)



(23)

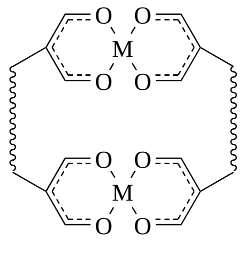
4.5 Polyketonate and Bis-β-diketonate Complexes

1,3,5-Triketones and similar polyketones exhibit keto–enol tautomerism and have been found to coordinate to one or more metal atoms (**24**). Such complexes can bring metal atoms in close proximity, resulting in interesting magnetic properties (*see* ***Magnetism of Transition Metal Ions***).

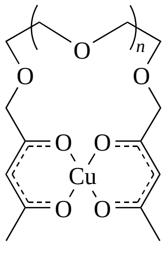


(**24**)

A series of bis-β-diketones, linked by the methine carbon atoms, have been found to form 'cofacial' dicopper(II) species (**25**) which have cavities of varying sizes, depending on the nature of the linking group.[29] The inclusion of various small molecules within the cavity has been investigated. Another interesting system involves bis-β-diketones linked at the terminal carbon atoms by glycol ether linkages of varying lengths, which will transport alkali metal atoms through a membrane only when complexed to a copper(II) cation (**26**).[30]



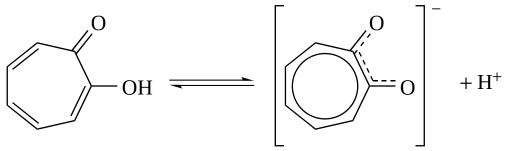
(**25**)



(**26**)

4.6 Tropolonates

Although formally an α-diketone, tropolone gives rise to a monoanion (equation 16) with coordination chemistry similar to that of the β-diketonate anions. The tropolonate ion forms a five-membered chelate ring, which has a smaller Bite Angle (*see Bite Angle*) than β-diketonate anions. This feature, in combination with its rigid planar nature, makes the tropolonate ion suitable for the formation of complexes with high coordination numbers at the central metal ion. For example, the thorium(IV) and uranium(IV) complex anions $M(trop)_5^-$ are 10 coordinate. Another result of the small bite angle of this ligand is that tristropolonato metal complexes are considerably distorted from octahedral geometry.[31]



(16)

5 OXOANIONS

Oxoanions (*see Oxoanion*) include species such as SO_4^{2-}, CrO_4^{2-}, and so on. They consist of a central element, which is often nonmetallic but can also be metallic, to which is bound a number of terminal oxygen atoms.[32] Oxoanions where the central element is carbon, such as CO_3^{2-}, and related substituted species such as carboxylates, RCO_2^-, exhibit somewhat different coordination chemistry to other oxoanions and are discussed in Section 6.

5.1 Structure and Bonding

The terminal oxygen atom in an oxoanion has three lone pairs, and can therefore, in principle, coordinate to up to three metal atoms. The maximum coordination number (i.e. the number of metals to which the oxoanion is bound) for an oxoanion $[XO_n]^{m-}$ is therefore $3n$. In practice, the great majority of mononuclear oxoanions have n in the range 2 to 6, and m in the range 1 to 6, with coordination numbers of four or less.

There are a large number of possible coordination modes for the various oxoanions, in association with varying numbers of metal atoms. It should be noted that a significant problem in defining coordination modes is the length of an M–O bond. It has been suggested that, where the M–O distances differ by less than 0.7 Å, there is a significant interaction between the M atom and both O atoms.[32] Longer bond distances are indicated by dashed lines in the following diagrams. Consideration of the bond lengths within the oxoanion can be useful in describing the bonding, since most X–O bonds in oxoanions have some double bond character and therefore the X–O distances for the coordinated O atoms are expected to increase, while the noncoordinated X–O distances decrease, relative to the free oxoanion. Unfortunately, the changes in the geometry of oxoanions upon coordination are usually small and are difficult to determine accurately.

5.1.1 Coordination Modes of Triangular Oxoanions

The most widely studied of these oxoanions is the nitrate anion, NO_3^-. Some of the known coordination modes of this anion are shown in Figure 4(a). The most common is the symmetrical bidentate mode (**27**). Examples of unidentate (**28**) and asymmetrical bidentate (**29**) coordination modes are also quite plentiful. The most common bridging coordination mode for these and all oxoanions is the symmetrical *syn–syn* mode involving two oxygen atoms of the oxoanion (**30**). The other modes (**31–33**) shown in Figure 4 are relatively rare. The η^1:μ_3 mode with a single oxygen bridging three metal atoms (**32**) has been observed in a tetranuclear manganese complex.[33] The η^3:μ_3 mode (**33**) has been found in $[Cu_3(OH)(pz)_3(Hpz)_2(O_3N)(ONO_2)]\cdot H_2O$[34] and more recently in a bis-β-diketonate complex, where the nitrate anion links octanuclear copper clusters.[31]

5.1.2 Coordination Modes of Bent Oxoanions

Examples of this group of oxoanions include NO_2^-, ClO_2^-, and $H_2PO_2^-$, although most of the available data concern the nitrite anion and hence the discussion will center on complexes of this anion.[35] Some of the known coordination modes are shown in Figure 4(b) (**34–39**). Monodentate coordination predominates, through the terminal O atoms to give nitrito complexes (**34**), and through the central N atom to give nitro complexes (**35**). The most common bridging mode is the N–O mode (**36**), although others are known, combining bidentate O chelate plus monodentate O or N coordination (**37** and **38**, respectively).

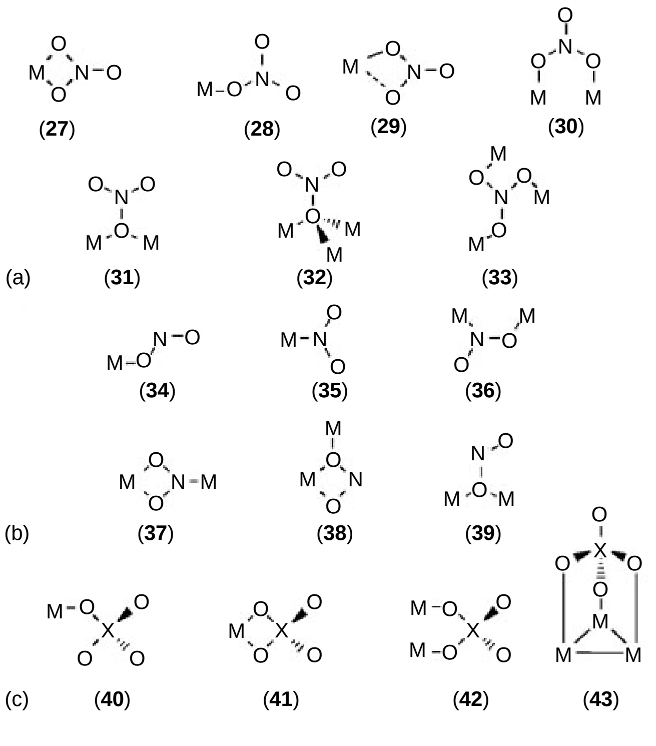


Figure 4 Some coordination modes of the (a) nitrate anion, (b) nitrite anion, and (c) tetrahedral anions

5.1.3 Coordination Modes of Tetrahedral Oxoanions

Examples of oxoanions of this geometry are numerous, and include SO_4^{2-}, SeO_4^{2-}, AsO_4^{3-}, PO_4^{3-}, SiO_4^{4-}, VO_4^{3-}, CrO_4^{2-}, and ReO_4^-. Tetrahedral oxoanions are found to coordinate to up to 12 metal atoms, although simple unidentate (**40**), bidentate chelate (**41**), and bidentate (and higher) bridging (**42**) coordination modes are more common.[32] The tridentate triply-bridging mode (**43**) is an interesting example of coordination to a metal cluster.[36] The number of examples known decreases rapidly for coordination numbers above three.

5.1.4 Coordination Modes of Pyramidal Oxoanions

The most widely studied of these oxoanions is SO_3^-; others include HPO_3^{2-} and IO_3^-. The coordination modes known are similar to those of the tetrahedral oxoanions (Figure 4c), with additional modes involving bonding to the central heteroatom.

5.2 Spectroscopy

The IR spectra of the free oxoanions are well characterized, with the modes of vibration being determined by the number of atoms and the symmetry of the ion. The changes in symmetry and bond order that take place upon coordination can result in significant changes in the IR spectrum, allowing differentiation of the free and complexed species.[28] For example, the IR spectrum of free NO_3^- ion has absorptions at ~1390, 830, and 720 cm^{-1}, whereas coordinated nitrate groups, which have lower symmetry, exhibit six absorptions. While it is usually relatively easy to distinguish between free and complexed oxoanions, it is often much more difficult to determine the mode of coordination (e.g. distinguishing between mono- and bidentate coordination or between bidentate chelate and bridging modes), and hence it is often necessary to obtain crystallographic structure determinations to determine the coordination modes of these anions with certainty. Other spectroscopic techniques that have been employed include EXAFS (*see Extended X-ray Absorption Fine Structure*), ^{17}O NMR, and X-ray powder diffraction.[37]

5.3 Synthesis

Oxoanions usually have weak donor properties relative to water and nitrogen donors, and thus the properties of coordination complexes of these anions are extremely solvent dependent. For example, the ClO_4^- ion is generally considered to be a weakly coordinating anion in aqueous solution, and

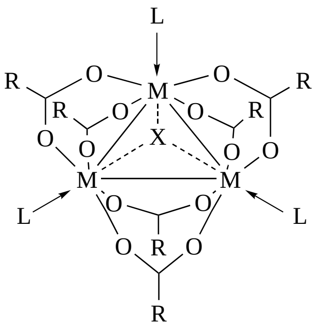
yet in nonaqueous solvents such as $HClO_4$ or Cl_2O_6, ClO_4^- forms complexes with a variety of metals clearly involving anion coordination to the metal ions. Stronger ligands, such as the NO_3^- anion, are known to form complexes even in aqueous solution. The octahedral periodate and tellurate anions readily form stable complexes in aqueous solutions.[38] Hence, synthesis of oxoanion complexes is generally straightforward, provided water or other strong ligands are excluded.

6 CARBOXYLATE AND RELATED SPECIES

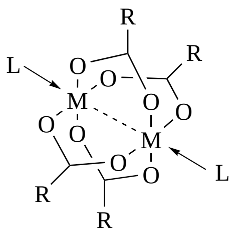
6.1 Monocarboxylates

Monocarboxylates are an attractive class of ligand for the coordination chemist; they bind to metal atoms in a variety of ways giving, in many instances, complexes with interesting properties, and they are readily available.[37] Figure 5(a) shows some of the known modes of coordination (**44–51**). Unidentate (**44**) and symmetrical chelate coordination (**45**) modes are well established, with the unidentate mode being more commonly observed. The presence of unidentate carboxylate can be established by IR spectroscopy, by virtue of the inequivalence of the two C–O bonds in the coordinated anion,[28] although care must be exercised since the environment of the free carboxylate O atom, and even sample preparation, can influence the IR spectrum.

The most common bridging mode of coordination is *syn–syn* (**47**). The nature of the metal–metal interactions in such systems has been the subject of much study, with interaction varying from the relatively weak in dimeric Cu^{II} complexes, to strongly M–M bonded species such as $Mo_2(O_2CR)_4$, which contains a formal quadruple bond. The two systems that have been most studied are the bimetallic (**52**) and trimetallic (**53**) complexes, often referred to as 'paddle-wheel' and 'triangular' complexes respectively.[39] These structural motifs have been widely utilized in the construction of coordination polymers and metal-organic frameworks.[11,40]



(**52**)



(**53**)

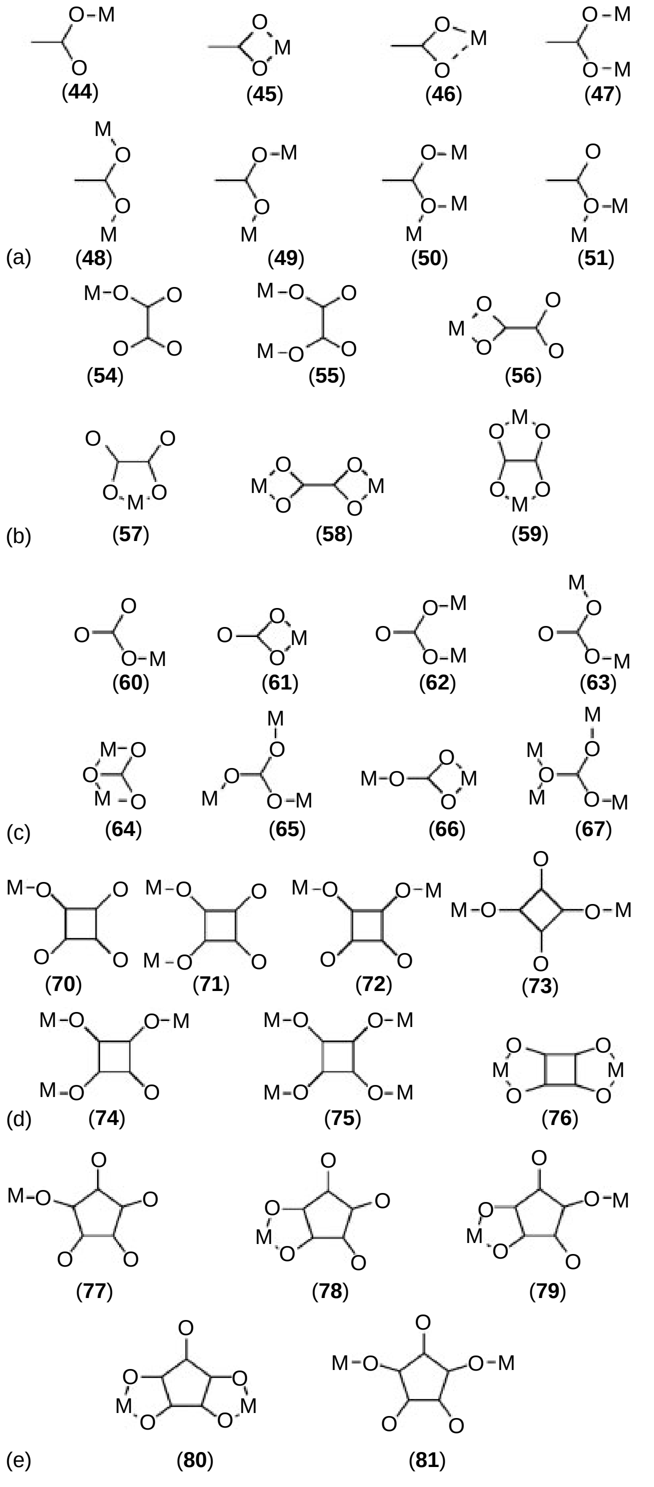


Figure 5 Some coordination modes of (a) monocarboxylate anions, (b) dicarboxylate anions, (c) the carbonate anion, (d) the dianion of squaric acid, and (e) the dianion of croconic acid

Distinguishing the various bridging modes of the carboxylates has been carried out using IR and NMR

spectroscopies and magnetic measurements, although support from X-ray structure determinations has been vital in obtaining definitive information on these complexes.

Carboxylate complexes are often synthesized by refluxing the acid with the metal salts (such as carbonate, sulfate, oxide, etc.), or by reaction of the sodium or silver salt of the acid with the metal halide. Insertion of CO_2 into σ-bonded organotransition metal species has also been used to generate carboxylate complexes, as has exchange reactions with metal alkoxides (see Section 3.3).

6.2 Dicarboxylates

The coordination chemistry of the dicarboxylates is somewhat different to that of the monocarboxylates, since the close proximity of the carboxylate groups allows coordination involving one O atom of each. The simplest and most intensively studied of these compounds is oxalic acid (ethanedioic acid), complexes of which are found in nature (e.g. in the mineral humboltine). Some coordination modes for this acid are shown in Figure 5(b). Unlike monocarboxylates, chelate coordination is favored over the unidentate mode (**54**). Of the two modes of chelate coordination, the formation of the larger chelate ring (**57**) is generally formed in preference to the four-membered chelate ring (**56**), with the latter becoming more common in higher members of the dicarboxylate series, where the two carboxylate groups are further apart.

There are many possible bridging modes (**55**,**58**,**59**) for the dicarboxylic acids with the bis-bidentate bridging mode (**59**) being the most common. The bridging mode (**58**) is very rare for the shorter dicarboxylates,[35] but is widely observed with the longer more rigid dicarboxylates used in some metal-organic frameworks.[11,40] X-ray diffraction is the most reliable method of determining the coordination mode of the dicarboxylates, although chemical methods have been useful; for example, protonation reactions can reveal the presence of uncoordinated carboxylate groups, since these are easily protonated unlike the coordinated groups. Metal interactions in dicarboxylate complexes, particularly oxalate complexes, have been of interest, with copper complexes being the most studied. The magnetic properties of oxalate-bridged Cu^{II} dimers $[LCu(ox)CuL']^{2+}$ has been found to be highly variable, and strongly influenced by the nature of the terminal ligands L and L′.[41] Dicarboxylate complexes are usually synthesized by reaction of an aqueous solution of the alkali metal salt of the dicarboxylate with a metal halide, or by reduction of a metal salt by the dicarboxylic acid. For example, oxalic acid readily reduces iron oxides to form the iron(II) complex.

6.3 Carbonates

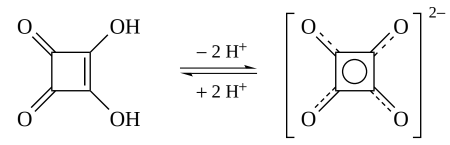
The carbonate ion is a component of many naturally occurring minerals and is important in biological systems and thus it has been widely studied. The coordination chemistry of this anion is well developed and the common unidentate (**60**) and bidentate chelate (**61**) coordination modes have been observed, as well as a wide variety of quite complex bridging modes (**62–67**). Vibrational spectroscopy is quite useful in distinguishing free carbonate from the nonbridging coordination modes, since coordination results in a change in the symmetry of the ion.[28] The bridging modes can usually only be determined via structure determination studies.

Carbonate complexes are usually synthesized from carbonate or bicarbonate anions in alkaline aqueous solution. The reaction of metal hydroxides with carbon dioxide is another route to carbonate complexes. Other methods include the oxidation of metal carbonyl complexes (equation 17), and the oxidation of metal salts in the presence of carbon dioxide.

$$[CpMo(CO)_3]^- \xrightarrow{O_2} CpMo(CO)_2(\eta^2\text{-}O_2CO) \qquad (17)$$

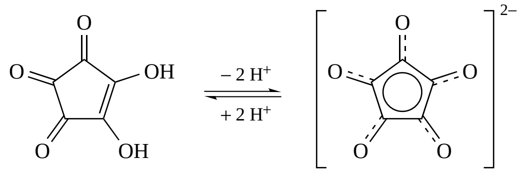
6.4 Cyclic Oxocarbon Acids

Of the known cyclic oxocarbon acids, the systems based on squaric (**68**) and croconic (**69**) acids have been most widely studied.[42] The loss of two protons from these acids gives rise to aromatic dianions as shown in equations (18) and (19), and these can coordinate to metal anions in a variety of ways. Unidentate coordination (**70**,**77**) is known for both systems but is not common. Simple bidentate chelate coordination (**78**) is also relatively uncommon but is observed in a number of croconate complexes. The squarate anion adopts this mode only with larger cations, such as the group 2 and lanthanide metals, and then only in association with additional bridging interactions. Bridging coordination modes dominate the chemistry of these anions, some of which are shown here (**71–76**), (**79–81**). The various modes of coordination can usually be distinguished by IR spectroscopy, and the use of ^{13}C NMR spectroscopy has also been investigated.



(18)

(**68**) Squaric acid



(19)

(**69**) Croconic acid

The magnetic properties of complexes of these anions have been studied, particularly copper(II) complexes, and have been compared with the results obtained with analogous oxalato complexes;[41] the squarato and croconato bridges are

able to transmit magnetic effects between metal atoms, but are not as efficient as the oxalato bridge.[42]

Squarato and croconato metal complexes are usually synthesized by mixing an aqueous solution of the dipotassium salt of the acid with a metal ion, although nonaqueous solvents have also been employed.

6.5 Carbamates

Carbamate ($R_2NCO_2^-$) complexes are similar electronically and structurally to monocarboxylate complexes, although they are not as accessible synthetically and are generally less stable.[43] Unidentate, chelate, and bridging coordination modes have been observed, although the number of bridging modes found to date is less than that known for carboxylates. *Syn–syn* bridging is the most common, and bimetallic 'paddlewheel' type structures (**53**) are known.

Carbamate complexes are synthesized by carbonation of metal dialkylamides (equation 20), or by reaction of the appropriate amine, carbon dioxide, and a metal halide (equation 21). In both cases, it has been suggested that the reaction involves combination of the amine and carbon dioxide to form the carbamate anion, followed by anion exchange.[43]

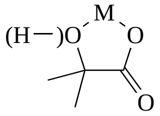
$$M(NMe_2)_n + nCO_2 \longrightarrow M(O_2CNMe_2)_n \qquad (20)$$

$$MCl_n + 2n\ NHR_2 + nCO_2 \longrightarrow M(O_2CNR_2)_n + nNH_2R_2Cl \qquad (21)$$

6.6 Hydroxycarboxylic Acids

Many hydroxycarboxylic acids are naturally occurring, and their coordination chemistry is of importance in biological processes.[44] These complexes also have uses in many other areas such as analytical chemistry, electroplating processes, and pharmacology. The most widely studied aliphatic hydroxy acids are the lower members of the 2-hydroxyalkanoic acids, while studies of aromatic hydroxy acids have often centered on salicylic acid. A number of these acids contain one or more chiral carbon centers, and hence complexes of these acids have been useful in studying chiroptical properties such as the Cotton Effect (*see Cotton Effect*).

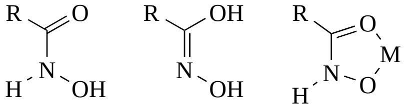
A common feature of the coordination chemistry is the formation of a five-membered chelate ring involving one O atom of the carboxylate group, and the O atom of the hydroxyl group, which may or may not retain the hydroxylic H atom (**82**). The O atoms may also bridge to other metal atoms.



(**82**)

6.7 Hydroxamates

Hydroxamic acid[45] exists in two tautomeric forms (**83**) and (**84**). Spectroscopic evidence suggests that metal complexes are generally best described by the structure (**85**), as a hydroxamide group rather than a hydroxyoxime. Hydroxamic acids are of importance in analytical chemistry, having been widely used as metal precipitants and as colorimetric reagents. Another interesting aspect is the presence of hydroxamate binding groups in siderophores (*see* ***Iron Transport: Siderophores***).[23]



(**83**) (**84**) (**85**)

7 MACROCYCLIC O-DONOR LIGANDS

7.1 Introduction

Unlike most of the O-donor ligands discussed in this article, the study of synthetic macrocycles (*see* ***Macrocyclic Ligands***) such as Crown Ethers (*see Crown Ethers*), Cryptands & Cryptates (*see Cryptands & Cryptates*), and the calixarenes (*see Calixarenes*) is a relatively recent development. The beginnings of this area are perhaps best marked by the paper by C. J. Pedersen published in 1967, describing the synthesis of a number of crown ethers, and most importantly, the ability of these macrocycles to form stable complexes with simple inorganic cations.[46] The development of the macropolycyclic cryptands, by J. M. Lehn, followed soon after.[47] The pioneering work of C. D. Gutsche in the mid-1970s initiated study of the macrocycles now known as calixarenes.[48] The rapid expansion of this field forces us to limit the discussion here to some representative aspects of metal complexes of these O-donor macrocycles.

7.2 Crown Ethers and Cryptands

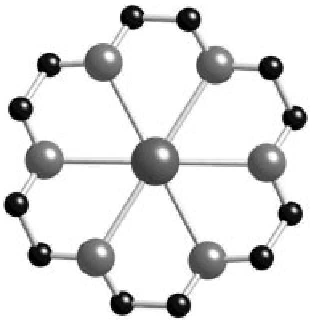
7.2.1 *Complexation*

The crown ethers form stable complexes with many cations, both inorganic and organic, as well as neutral species.[49] As would be expected, the Macrocyclic Effect (*see Macrocycle*) provides a significant contribution to this stability. For example, the stability constant of the K^+ complex of 18-crown-6 in anhydrous methanol is $10^{6.1}$, whereas the complex of the open chain analog has a stability constant of $10^{2.3}$. The tricyclic cryptands are even more preorganized, and generally form more stable complexes than the corresponding crown

ethers (this is sometimes called the 'cryptate effect').[49] The preorganization concept is taken to its logical conclusion in the class of receptors termed *spherands*, which are fully preorganized for the target guest producing extremely stable complexes.[50]

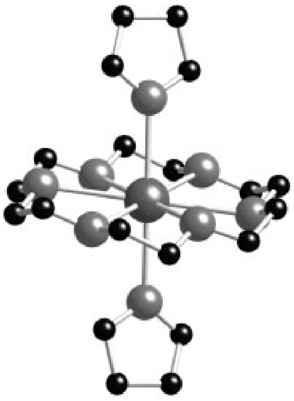
The crown ethers and cryptands generally form more stable complexes with 'hard' metal ions, such as the group 1, 2, and lanthanide ions. The introduction of softer heteroatoms into the macrocycle can change the selectivity dramatically. There is much interest in 'tuning' macrocycles in this way to favor complexation of certain metal atoms, but O-donor macrocycles will dominate the discussion here.

There has been a great deal of work on group 1 metal ion complexes of crown ethers and cryptands, producing many estimates of stability constants and other thermodynamic data. The importance of factors such as relative sizes of the cation and the macrocycle cavity has been widely discussed (the 'hole-size' effect). This concept is of most use in relatively rigid systems such as the cryptands, where the receptor molecule cannot easily distort to accommodate cations of the 'wrong' size. Thus, [2.2.2]cryptand has a cavity size close to the ionic radius of K^+, and it complexes this cation selectively over the smaller Na^+ and larger Cs^+. In more flexible systems, other factors such as ligand conformations, chelate ring size and solvation enthalpy become relatively more important, so that a simple match of cation and macrocycle hole size is generally not sufficient to predict selectivity.[51] Changing solvents, for example, can reverse the trends in stability constants in some systems. The thermodynamics and kinetics of cation/macrocycle interaction is an important area of study, and a great deal of the available data has been compiled by R. Izatt and coworkers, along with useful discussion of the factors influencing the stability of the complexes.[52,53]



(**86**)

[K^+(18-crown-6)][54]



(**87**)

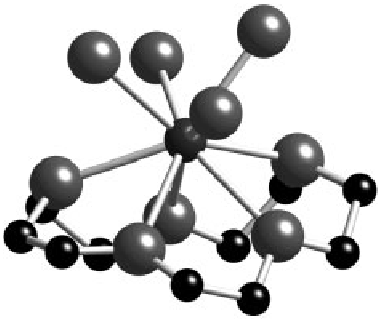
[K^+(18-crown-6)(thf)^2][54]

7.2.2 Structural Aspects

The solid-state structures of crown ether complexes can be broadly categorized on the basis of relative sizes of the cation radius and the macrocycle cavity. The simplest case is where there is a close fit between the cation and macrocycle; a beautiful example of this is the potassium complex of 18-crown-6 (**86**). The K^+ ion is bound to all six O atoms of the crown, and sits in the plane of the macrocycle. The structural chemistry of this seemingly complementary pairing is far from simple, however, and a range of different structural types has been found for these complexes.[51] For example, additional ligands are often found coordinated to the potassium cation in 18-crown-6 complexes, as shown for (**87**) where two thf molecules are bound to the potassium cation, above and below the plane of the macrocycle. Remarkably, structures (**86**) and (**87**) are found in a single crystal structure,[54] illustrating that subtle changes can induce different crown ether complex structures.

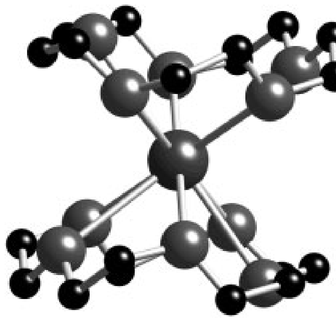
If the cation is large relative to the cavity size of the macrocycle, the cation can still interact with the crown ether, by 'perching' out of the average plane of the crown. There are a number of structural types that can occur in such complexes. One case is the formation of a complex with the metal ion situated above the crown, and the coordination sphere saturated by other ligands; an example of this is the [Sm(15-crown-5)$(H_2O)_4$]$^{3+}$ cation (**88**).[55] Alternatively, a 1:2 complex may be formed, with the metal ion sandwiched between two crown ethers. The K^+ complex of 15-crown-5 (**89**) exhibits such a structure, with the ten-coordinate K^+ ion bound to all the O-donor atoms of the two crowns.[56] A sandwich-type structure is also possible in 1:1 crown ether complexes, as shown for the CsSCN complex of 18-crown-6 (**90**).[57] In this case, the SCN^- ligands act as bridges to give the Cs^+ ion a coordination number of eight. A triple layer 'club sandwich' structure with a 2:3 metal to crown ratio has also been observed in a Cs^+ complex of 18-crown-6.[58]

Examples where the metal cation is small compared to the size of the macrocycle fall into two categories. The most common result is a constriction of the crown ether cavity, so that the macrocycle shrinks to match the cation radius. An example is the Na^+ complex of 18-crown-6 (**91**);[59] the conformation of the crown is quite distorted compared to that observed in (**86**), with five of the O-donor atoms lying in a plane about the metal ion, and the sixth folded out of the plane.



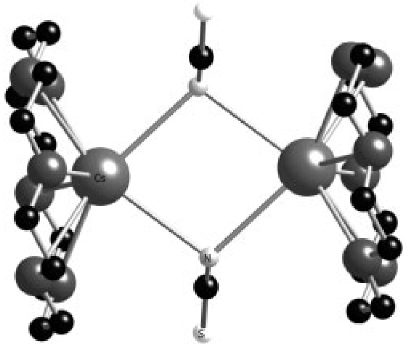
(**88**)

$[Sm(H_2O)_4(15\text{-crown-}5)]^{3+}$[55]



(**89**)

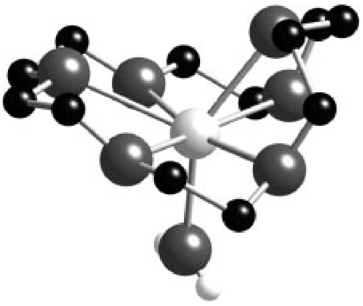
$[K(15\text{-crown-}5)_2]^{+}$[56]



(**90**)

$[Cs(SCN)(18\text{-crown-}6)]_2$[57]

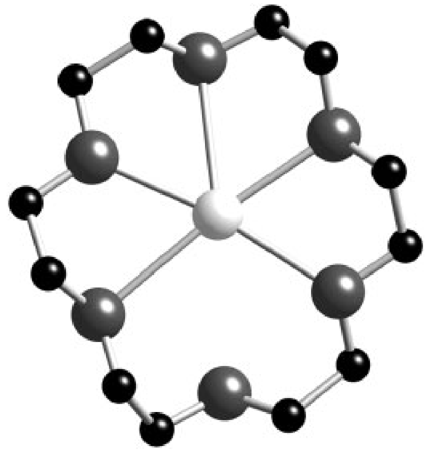
Distortion such as this may result in the exclusion of one or more of the crown O atoms from the coordination sphere of the metal. This situation is found in another Na^+ complex of 18-crown-6 (**92**), again showing that subtle structural differences can occur for the same cation-crown combination.[60] Extremely large and flexible crown ethers can completely encapsulate metal ions, as is found in the K^+ complex of a 30-crown-10 ligand, and the Na^+ complex of a 24-crown-8 derivative, for example.[51] This 'wrapping' of the cation bears structural



(**91**)

$[Na(18\text{-crown-}6)OH_2)]^{+}$[59]

resemblance to the complexes formed by natural ionophores such as valinomycin.

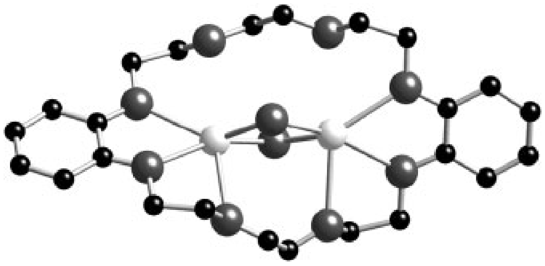


(**92**)

$[Na(18\text{-crown-}6)]^{+}$[60]

The second structural type that can be formed where the cation is small relative to the macrocycle is a bimetallic complex where the crown contains two metal ions. One example is the disodium complex of dibenzo[24]crown-8 (**93**), where each sodium ion is bound to three O atoms of the crown.[61] Such complexes are relatively rare, and usually limited to singly charged cations, presumably for electrostatic reasons.

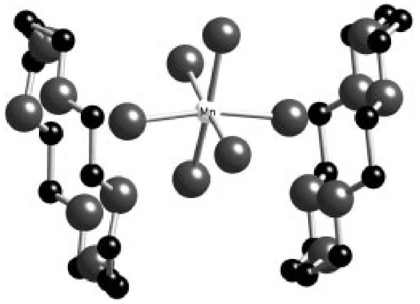
The complexes discussed so far all involve direct interaction between the metal ion and the crown ether. Another important class of crown ether derivatives is that involving second sphere coordination.[62] These compounds involve interaction between the ligands in the primary coordination sphere (such as H_2O in $M(H_2O)_6{}^{n+}$ cations), and the second sphere ligand, the crown ether, often by means of hydrogen bonds. Such a structure is found in the $[Mn(OH_2)_6](ClO_4)_2$ adduct of 18-crown-6 (**94**).[63] It is not surprising that transition metal/crown ether chemistry often involves adducts, since



(**93**)

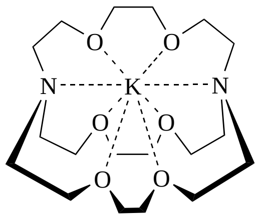
$[Na_2(benzo\text{-}24\text{-}crown\text{-}8)(2\text{-}nitrophenolato)_2]$ –
only O-atoms of bridging phenolates shown for clarity[61]

ligands such as H_2O and NH_3 tend to bond to transition metal ions more strongly than the crown ethers. Aqua and ammine complexes dominate this area, although interaction between acidic methyl group C–H bonds and crown ethers has been observed. It is interesting to note the formation of complexes where the crown ether is simultaneously involved in both the primary and secondary coordination spheres. This is often observed where the cation is small relative to the crown ether. An example is the lithium complex of 18-crown-6 (**95**), where water molecules coordinated to the lithium cation also form hydrogen bonds with the crown ether O atoms.[64]



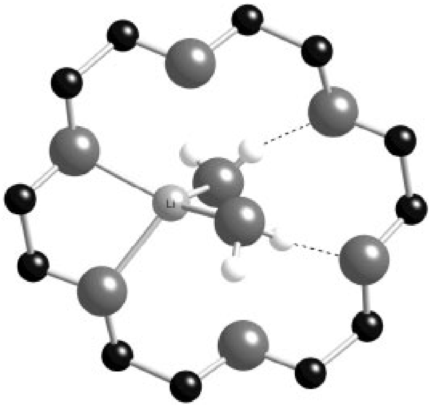
(**94**)

$Mn(H_2O)_6^{2+}\cdot 2(18\text{-}crown\text{-}6)$[63]



(**96**)

Crystal structure determinations of various cryptates have shown that the metal atom is usually held within the



(**95**)

$[Li(18\text{-}crown\text{-}6)(OH_2)_2]^+$[64]

three-dimensional cavity, as shown for the K^+ complex of [2.2.2]-cryptate (**96**). The cavity can expand to accommodate larger cations, and this is often accompanied by coordination of solvent or anionic ligands; for example, the $[Eu(ClO_4)([2.2.2]\text{-}cryptand)]^{2+}$ cation is 10 coordinate with bidentate coordination of the ClO_4^- anion.[65] As mentioned above, the cryptands are less flexible than the crown ether, and this is reflected in the less variable structures of the metal complexes.

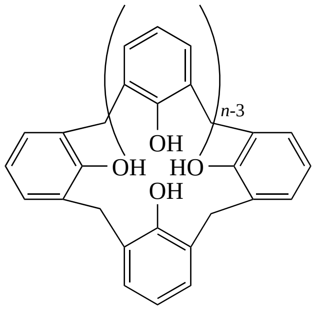
7.3 Calixarenes

7.3.1 Introduction

An interesting group of aryloxides are the macrocyclic polyphenols known as calix[*n*]arenes (**97**), where *n* indicates the number of aryl units comprising the macrocycle.[48,66] More recently, the term calixarene has been extended to include macrocycles comprising of other aromatic units (such as resorcinols, napthols, pyrroles, furan, etc.);[66] here, the discussion will be limited to the calixarenes produced from the base catalyzed condensation of para-substituted phenols and formaldehyde. The most common ring sizes are $n = 4$, 6, or 8, although ring sizes up to $n = 20$ have been isolated.[66] The phenolic calixarenes act as effective ligands, particularly for hard metal cations. The parent macrocycles can also be functionalized in a wide variety of ways to give macrocycles with desired properties. A brief overview of the phenolic calixarenes, and then derivatized calixarenes, as ligands is given below.

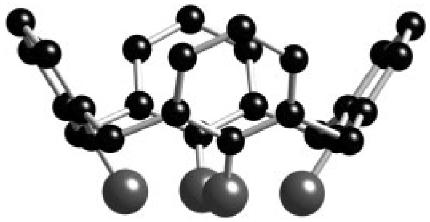
7.3.2 Phenoxide Calixarene Complexes

The cyclic tetramer is the smallest readily available calixarene; it can assume a number of conformations, but is most commonly found in the conelike conformation (**98**)



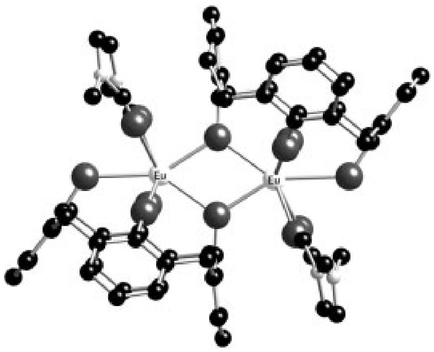
(**97**)

that gave rise to the name calixarene (from the Greek *calix* meaning ‘vase’). Metal cations typically interact with the phenol O-donor atoms at the lower rim of the calixarene forming mono or binuclear complexes;[48] the 2:2 europium complex of *p-t*-butylcalix[4]arene (**99**) is a typical example.[67] Conversely, the cation Cs^+ has been shown to occupy the cavity defined by the aromatic rings (**100**).[68]



(**98**)

Cone conformer of calix[4]arene

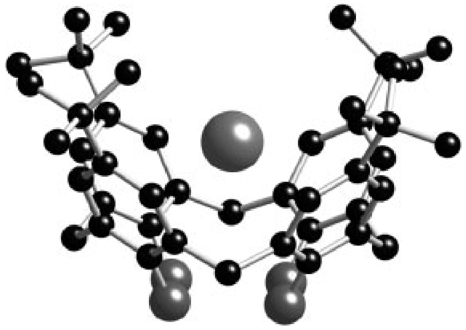


(**99**)

Europium complex of *p-t*-butylcalix[4]arene [$Eu_2(dmf)_4$(t-butylcalix[4]arene-3H)$_2$] (butyl groups omitted for clarity)[66]

The quasi-planar array of oxygen atoms at the lower rim of the calix[4]arene has inspired studies of calix[4]arene-metal complexes as models for metal-oxo surfaces of heterogeneous catalysts.[69]

Structurally characterized complexes of larger calixarenes are less common than those of calix[4]arenes, but the number is rapidly increasing.[70] Calix[6]arenes have been found to act as a ditopic ligand for a number of alkali metals and transition elements, although a Eu^{III} complex of *p-t*-butylcalix[6]arene was found to have a 1:2 metal:calixarene ratio, where one calixarene was bound to the metal atom by only one phenolic O atom, and the other was free in the crystal lattice.[71]



(**100**)

Cesium complex of *p-t*-butylcalix[4]arene[67]

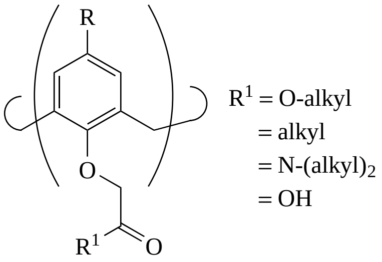
Calix[8]arenes are also found to act as a ditopic receptor in most cases.[66,70] The calixarenes assume various ‘pinched’ conformations in these complexes, resembling two calix[4]arene cone units linked together. Two 1:1 complexes, of Ca^{II} and Eu^{III}, have been characterized where a roughly planar circular conformation is observed, with only two of the phenolic O atoms interacting with the metal atom.[70] It is interesting to note that the free *p-t*-butylcalix[8]arene has been found to crystallize as a pyridine solvate with a planar, circular conformation in one case, and a pinched conformation in a subsequent report.[48]

7.3.3 Derivatized Calixarene Complexes

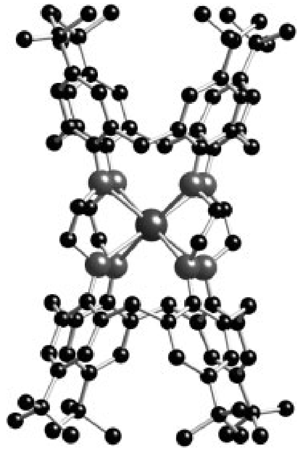
Both the lower (phenolic) rim and the upper rim of the calixarene can be functionalized. A huge range of calixarene derivatives have been synthesized in this way, and only a few can be mentioned here. In addition, the linking methylene groups can be modified to give another group of useful ligands.[48]

Alkylation of the lower rim substitution with carbonyl-containing groups (**101**) has produced probably the most widely studied of the calixarene-based ionophores.[72] These derivatives have been studied predominantly as ionophores for hard metal cations, and can form complexes of comparable stability to those of the cryptands in some cases. Such calixarenes have found applications as ionophores in ion selective electrodes.[73]

Lower rim substitution can also be used to link calixarene molecules. An elegant example was produced by linking two calix[4]arenes with four ethylene bridges to produce what was termed as a calix[4]tube (**102**).[74] The synthesis was templated by the potassium ion, and the product was found to bind this cation selectively.

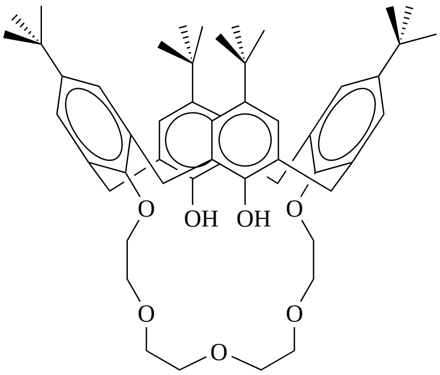


(**101**)



(**102**)

''Calix[4]tube'' potassium complex[73]



(**103**)

Upper rim substitution is typically more synthetically challenging than the lower rim, but can confer very useful properties on the macrocycle. For example, water soluble *p*-sulfonatocalixarenes have been synthesized and found to be highly water soluble, unlike the hydrophobic *p-t*-butyl derivatives.[75] The sulfonated calixarenes form a variety of metal complexes where the metal is usually bound to the sulfonato groups of the calixarene.

Finally, both upper and lower rim substitution have been used to produce a class of macrocycles referred to as *calixarene-crown ethers*, or *calixcrowns*. One simple example is shown here (**103**). These receptors combine characteristics of the crown ethers and calixarenes, and have been intensively studied for metal ion extraction, in particular, for the removal of cesium from nuclear waste.[76]

8 MISCELLANEOUS η^1O-DONOR LIGANDS[77]

8.1 Dialkyl Sulfoxides

The most widely studied is dimethyl sulfoxide (DMSO), with the number of studies increasing sharply in the mid-1960s, when DMSO became commercially available. DMSO can form O-bonded and S-bonded complexes, with hard metal ions generally forming O-bonded complexes and softer metal ions S-bonded complexes as expected.[78] Complexes such as $[RhCl_3(OSMe_2)(SMe_2O)_2]$, containing both O- and S-bonded DMSO, have been described, however.

DMSO complexes can often be prepared simply by dissolving the appropriate metal salt in DMSO, and then precipitating the complex by adding a less polar solvent such as benzene. The hydrated metal salt can often be used in this process, although in the preparation of other dialkyl sulfoxide solvates it has been found that removal of water is necessary.

8.2 Carboxylic Acid Amides

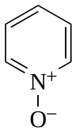
The carboxylic acid amides most commonly studied as ligands are formamide, acetamide, and the *N*-substituted derivatives, particularly *N*,*N*-dimethylformamide (DMF). These compounds are often used as solvents and have high dielectric constants, particularly when they contain an N–H bond, and such uses helped to stimulate interest in the amides as ligands. There are two possible donor atoms, N or O, but all complexes of the simple amide ligands, characterized by X-ray structure determination at least, have M–O bonds. The amides are usually terminal ligands but can bridge between metal atoms in some instances.

The carbonate acid amides are not generally as strongly bound as the dialkyl sulfoxides and water competes for coordination sites, giving products containing coordinated amide and water. Anhydrous reagents, or dehydration procedures using triethyl orthoformate or 2,2′-dimethoxypropane, are generally required in the preparation of such complexes. In addition, complexes containing the amide and an anionic ligand are often obtained when the anion has some coordinating ability (e.g. Cl^-, NO_3^-), to give molecular rather than ionic species.

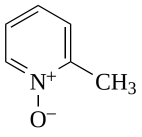
8.3 Amine *N*-oxides

The majority of studies involve aromatic N–O ligands, some common examples being pyridine *N*-oxide and methyl substituted derivatives (**104–106**). They are versatile ligands,

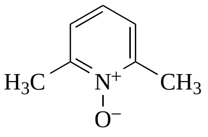
forming complexes with almost every element. The *N*-oxide ligands can often be displaced by water, and hence the complexes are generally prepared under anhydrous conditions.



(**104**) pyNO



(**105**) 2-MepyNO



(**106**) 2,6-diMepyNO

The first-row transition metals generally form octahedral complexes $[M(pyNO)_6]^{n+}$ with pyridine *N*-oxide in the absence of other competing coordinating agents. An interesting example is $[Cu(pyNO)_6](ClO_4)_2$, which has a regular octahedron of O atoms about the Cu atoms, rather than the expected Jahn–Teller distortion. Ligands with substituents ortho to the nitrogen atom can tend to form complexes with lower coordination numbers, such as four-coordinate Co^{II} in $[Co(2,6\text{-diMepyNO})_4](ClO_4)_2$.

8.4 Phosphine Oxides and Arsine Oxides

These ligands have the general formulae OPX_3 where X = alkyl or aryl (R), OR, NR_2 or halide, and $OAsR_3$. The most widely studied of these is $OPPh_3$. Complexes are prepared by direct reactions of the ligand and a metal salt in an organic solvent. The ligands form M–O bonds, and can form bridges between metal atoms. In almost all cases, no more than four of the bulky triphenylphosphine oxide ligands are found coordinated to a metal center, with the remainder of the coordination sphere comprising of smaller ligands.

IR spectroscopy has been useful in detecting interactions between these ligands and metal ions, by virtue of the lowering of the P–O and As–O stretching frequencies upon complexation. ^{31}P NMR has also been investigated but is of limited use, since most systems exhibit fast ligand exchange on the NMR timescale.

Glossary

Atlas: ch. Baerlocher, W. M. Meier and D. H. Olson, 'Atlas of Zeolite Structure Types', Elsevier, 2001
Basalt: fine-grained rock of volcanic origin
Biogenic: produced from living organisms
Borolanite: coarse-grained volcanic rock with high feldspar and felspathoid content
Boronation: reaction of borane (BH_3) with OH groups
Carboniogenic: production of carbon cations from hydrocarbons
Clathrate: a three-dimensional assemblage of molecular units, held together by weak van der Waals type forces, forming cavities of molecular dimensions in which can be located 'guest' molecules
Cracking: splitting of the long hydrocarbon chains in crude oil to small molecular units
Crown ether: complex synthetic organic molecule containing ether 'rings'
Crystal system: classification of crystals by the symmetry of their external or internal geometries
Cubic close packing: arrangement of atoms in a crystal in their closest possible way having cubic symmetry
Diagenesis: process that affects a sediment while it is at, or near, the Earth's surface (caused by temperature and pressure)
Dyke: a vertical sheet of igneous rock extruded into an existing rock
Fault plane: layers in a crystal structure at which defect(s) arrangements in the normal stacking of the layer can occur
Feldspar: alkali aluminosilicate rocks with dense framework structures
Felspathic: containing feldspar minerals
Felspathoid: natural aluminosilicate minerals with framework structures containing water and salt molecules in their cavities
Gas–solid chromatography: analytical separation of gases on a solid, porous, substrate
Granodiorite: coarse-grained acid rock of volcanic origin
Guest: molecule trapped inside a clathrate
Hexagonal close packing: as for cubic close packing but with adoption of hexagonal symmetry
Hydrolysis: splitting of water molecules to give H^+ and OH^- species
Ignimbrite: tuffs welded by their high-temperature deposition caused by the emission of an incandescent cloud of gas and ash from a volcano (a 'nuée ardente')
Intergrowth: simultaneous crystallization of two minerals
Intumescence: visible loss of water with heating
Isotypic: having the same structure
Magma: molten fluid formed within the Earth's crust or mantle containing molten silicates, water, and gases; magma that is extruded on to the surface of the Earth is called lava
Metamorphism: change created in rocks by heat, pressure, and chemically active fluids within the Earth's crust
Meteoric (water): water that percolates rocks from above (e.g. from rivers, rain, snow, etc.)
Microporous: solid material containing pores of less than about 20 Å in diameter
Molecular sieve: a structure that can separate molecules on the basis of size
Mepheline: a sodium felspathoid
Pegmatite: coarse-grained mineral vein with well formed crystals
Plagioclase: sodium/calcium aluminosilicate mineral of the feldspar group
Pyroclastic: ejected by volcanic eruption
Radiolarians: a protozoon having a silica skeleton
Sedimentary: processes whereby rocks (minerals) are formed from materials derived from other rocks by weathering, erosion, and transportation
Silanation: reaction of silane (SiH_4) with OH groups
Sorption: uptake of liquid or gas by a microporous material
Space-filling: spatial arrangement of polyhedra such that each polyhedron shares all its faces with other polyhedra
Stacking fault: misalignment of layer(s) arising from a fault plane
Stoichiometry: the relative numbers of atomic constituents making up a chemical compound
Truncated octahedron: a polyhedron composed of eight hexagonal and six square faces
Tuff: ash and dust blown out of a volcano during eruption and subsequently consolidated
Unit cell: the smallest repeating structural unit in a solid structure at the atomic scale
Zeolites: natural and synthetic hydrated aluminosilicates with open framework structures enclosing cavities and channels in which reside mobile cations and water molecules

Zeotypes: zeolite-like framework structures with atoms other than Si, Al in the tetrahedral positions in the framework

Abbreviations

$AlPO_4$ = Aluminophosphate; BP = British Petroleum; BET = Brunauer, Emmett, and Teller; DABCO = 1,4-diazabicyclo[2,2,2]octane; FCAPO = Framework constituent aluminophosphate; FCC = Fluidized bed cracking catalyst; LPG = Liquid petroleum gas; MAS NMR = Magic angle spinning nuclear magnetic resonance; MeAPO = Metal aluminophosphate; MeAPSO = Metal silicoaluminophosphate; PSA = Pressure swing application; REY = Rare earth exchanged synthetic zeolite Y; SAPO = Silicoaluminophosphate; SBU = Secondary building unit; T = tetrahedrally coordinated atom; TEA = Triethanolamine; TMA = Tetramethylammonium; TPA = Tetrapropylammonium; UOP = Union Oil Products, USA; USY = Ultrastable synthetic zeolite Y; VEB = VEB Leuna Werke, Bitterfeld, Germany; XAPO = Aluminophosphate containing Fe, Ti, as T atoms; ZSM = Zeolite Socony Mobil.

1 INTRODUCTION

In 1756, Cronstedt,[1] a Swedish mineralogist, discovered a new mineral that visibly lost water when heated. Because of this easily observed intumescence, he coined the word 'zeolite' from two Greek words 'zein' and 'lithos', meaning 'boiling stone', to name the new species. Cronstedt's mineral was later named stilbite.

This facile loss of water was shown to be reversible by Damour[2] (1840) and, in 1858, Eichorn[3] showed that the zeolite chabazite contained alkali and alkaline earth metals, which were capable of being reversibly replaced, that is, the zeolite exhibited cation-exchange properties. Analysis of zeolite minerals showed them to be aluminosilicates and their easy loss of water and cation exchange was evidence for the open nature of their structures, often likened to a sponge. The description 'zeolitic water' has been widely used to describe loosely held water in any solid.

The need for commercial water softeners prompted attempts to synthesize zeolites. These were not successful, although St Claire Deville[4] (1862) claimed to be able to make levyne. The early attempts at zeolite synthesis have been extensively reviewed by Morely and Ingersoll[5] (1937). Lack of available, definitive, characterization methods makes it difficult to confirm their work.

Progress to 1925 was largely through mineralogical identification of new zeolite species but in this year Weigel and Steinhoff[6] reported that chabazite sorbed water, methanol and ethanol, and methanoic (formic) acid but excluded acetone, ether, and benzene. The significance of this observation was realized by McBain,[7] who described it as a 'molecular sieving' effect (1932). In 1930, Taylor[8] solved the structure of analcime and Pauling[9] published a series of seminal papers based upon single-crystal X-ray studies, which showed how silicates and aluminosilicates were constructed from tetrahedral building blocks, that is, the $[SiO_4]^{4-}$ and $[AlO_4]^{5-}$ units of structure. His work included the zeolite natrolite and the felspathoids sodalite and cancrinite, which are now known to have structures closely related to the zeolite minerals. Figure 1 shows the Si/Al coordination tetrahedra and their linking to create the chain-like element of structure identified in natrolite. The importance of Pauling's work was that it illustrated the way in which the tetrahedral units linked by sharing all corners to produce the three-dimensional framework structures associated with the zeolite and felspathoid minerals. It is this regular and reproducible molecular architecture that confers on the zeolites their uniquely useful properties.

This was evident to R. M. Barrer[10] who from the mid-1930s to 1996 provided the scientific base upon which the current widespread industrial use of zeolites has been founded. His pioneering work on zeolite synthesis, ion exchange, gas sorption, and structures, from both theoretical and practical standpoints, has spawned the continuing growth of zeolite science and technology encouraged by the discovery of their catalytic properties in the early 1960s. The world's zeolite literature continues to grow at a rate of close to 100 publications per week. This is almost entirely devoted to synthetic materials of zeolite structure type, and has caused a reassessment of the strict mineralogical concept of zeolites as aluminosilicates containing mobile cations and water molecules that promote the properties of cation exchange and reversible water uptake.

This will be considered in detail later in this article but it is convenient first to consider the assemblages of (Si,Al)

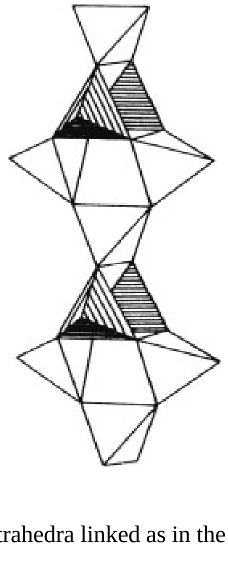

Figure 1 Si,AlO_4 tetrahedra linked as in the zeolite natrolite

tetrahedra, which can be recognized as forming part of zeolitic frameworks.

2 ZEOLITE STRUCTURES

2.1 Introduction to Zeolite Structures

The picture of a zeolite structure can now be refined as closer to a honeycomb of channels and cavities created by rigidly (at room temperature) linked tetrahedra. The three-dimensional structures are constructed from pores of molecular dimensions, that is, zeolites are microporous solids. The *Atlas of Zeolite Structure Types* 5th Edition edited by Baerlocher, Meier, and Olson.[11] defines the framework density in terms of the number of tetrahedrally coordinated atoms (T) per unit of 1000 Å^3, and sets 20–21 T per 1000 Å^3 as the lower limit of micro-porosity. The current upper limit is about 11 T per 1000 Å^3 in a synthetic framework structure known as cloverite. The *Atlas* will be used as a major source throughout this section. The *Atlas* lists all known zeolite-type frameworks and encompasses materials not previously included in the restricted definition of zeolites as being only continuous aluminosilicate structures. This extension will be expanded on later but it is important to appreciate that the major bases for definition are the recognition of micro-porosity, as mentioned above, and the identification of structural subunits constraining the pores and cavities within the frameworks. These are called secondary building units (SBUs) and can be simple arrangements of tetrahedra to construct obvious arrangements such as four-, six-, or eight-membered rings or more complex structures (Figure 2). They contain up to 16 tetrahedral (T) atoms and are identified as being the only SBU linking to produce an entire and unique zeolite framework. The more simple SBUs are often described as oxygen rings or windows (clearly linkage of, say, six tetrahedra by two of their corners to create an hexagonal ring will also produce a ring of six oxygens).

Table 1 lists their shorthand notation often found in zeolite texts.

Table 1 Simple zeolite SBUs and their shorthand notation

Number of linked tetrahedra	SBU created	Shorthand description[a]
4	4 oxygen ring	S4R
5	5 oxygen ring	S5R
6	6 oxygen ring	S6R
8	8 oxygen ring	S8R
8	4–4 oxygen rings	D4R
